Acronyms

Foreword by the Secretary General

Preface by the Joint Coordinators of the Group of Experts of the Regular Process

Part I Summary

Part II The context of the assessment

Chapter 1: Introduction – Planet, oceans and life

Chapter 2: Mandate, information sources and method of work

Part III Assessment of major ecosystem services from the marine environment (other than provisioning services)

Chapter 3: Scientific understanding of ecosystem services

Chapter 4: The ocean's role in the hydrological cycle

Chapter 5: Sea-Air Interaction

Chapter 6: Primary production, cycling of nutrients, surface layer and plankton

Chapter 7: Calcium carbonate production and contribution to coastal sediments

Chapter 8: Aesthetic, cultural, religious and spiritual ecosystem services derived from the marine environment

Chapter 9: Conclusions on major ecosystem services other than provisioning services

Part IV Assessment of the cross-cutting issues: food security and food safety

Chapter 10: The oceans and seas as sources of food

Chapter 11: Capture fisheries

Chapter 12: Aquaculture

Chapter 13: Fish stock propagation

Chapter 14: Seaweeds

Chapter 15: Social and economic aspects of sea-based food and fisheries

Chapter 16: Synthesis of Part IV: Food security and safety

Part V Assessment of other human activities and the marine environment

Chapter 17: Shipping

Chapter 18: Ports

Chapter 19: Submarine cables and pipelines
Chapter 20: Coastal, riverine and atmospheric inputs from land
Chapter 21: Offshore hydrocarbon industries
Chapter 22: Other marine-based energy industries
Chapter 23: Offshore mining industries
Chapter 24: Solid waste disposal
Chapter 25: Marine debris
Chapter 26: Land-sea physical interaction
Chapter 27: Tourism and recreation
Chapter 28: Desalinization
Chapter 29: Use of marine genetic resources
Chapter 30: Marine scientific research
Chapter 31: Conclusions on other human activities
Chapter 32: Capacity-building in relation to human activities affecting the marine environment

Part VI Assessment of marine biological diversity and habitats

Chapter 33: Introduction

Section A — Overview of marine biological diversity

Chapter 34: Global patterns in marine biodiversity

Chapter 35: Extent of assessment of marine biological diversity

Chapter 36: Overall status of major groups of species and habitats

Chapter 36A: North Atlantic Ocean

Chapter 36B: South Atlantic Ocean

Chapter 36C: North Pacific Ocean

Chapter 36D: South Pacific Ocean

Chapter 36E: Indian Ocean

Chapter 36F: Open ocean deep sea

Chapter 36G: Arctic Ocean

Chapter 36H: Southern Ocean

Section B — Marine ecosystems, species and habitats scientifically identified as threatened, declining or otherwise in need of special attention or protection

I. Marine species

Chapter 37: Marine Mammals

Chapter 38: Seabirds

Chapter 39: Marine Reptiles

Chapter 40: Sharks and other elasmobranchs

Chapter 41: Tunas and billfishes

II. Marine ecosystems and habitats

Chapter 42: Cold-water corals

Chapter 43: Tropical and sub-tropical coral reefs

Chapter 44: Estuaries and deltas

Chapter 45: Hydrothermal vents and cold seeps

Chapter 46: High-latitude ice and the biodiversity dependent on it

Chapter 47: Kelp forests and seagrass meadows

Chapter 48: Mangroves

Chapter 49: Salt Marshes

Chapter 50: Sargasso Sea

Chapter 51: Biological communities on seamounts and other submarine features potentially threatened by disturbance

Section C — Environmental, economic and/or social aspects of the conservation of marine species and habitats and capacity-building needs

Chapter 52: Synthesis of Part VI: Marine biological diversity and habitats

Chapter 53: Capacity-building needs in relation to the status of species and habitats

Part VII Overall assessment

Chapter 54: Overall assessment of human impact on the oceans

Chapter 55: Overall value of the oceans to humans

Foreword by the Secretary-General of the United Nations

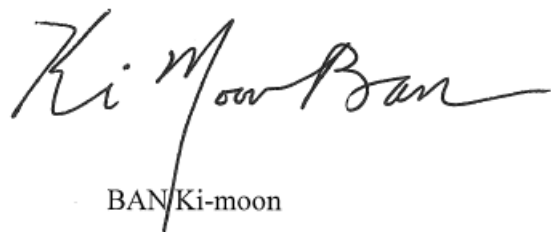

The First Global Integrated Marine Assessment, also known as the “World Ocean Assessment I”, is the outcome of the first cycle of the Regular Process for Global Reporting and Assessment of the State of the Marine Environment, including Socioeconomic Aspects.

Hundreds of scientists from many countries, representing various disciplines and steered by a 22-member Group of Experts, examined the state of knowledge of the world’s oceans and the ways in which humans benefit from and affect them. Their findings indicate that the oceans’ carrying capacity is near or at its limit. It is clear that urgent action on a global scale is needed to protect the world’s oceans from the many pressures they face.

The first World Ocean Assessment provides an important scientific basis for the consideration of ocean issues by Governments, intergovernmental processes, and all policy-makers and others involved in ocean affairs. The Assessment reinforces the science-policy interface and establishes the basis for future assessments. Together with future assessments and related initiatives, it will help in the implementation of the recently adopted 2030 Agenda for Sustainable Development, particularly its ocean-related goals.

I thank the Group of Experts and all others whose dedication produced this Assessment, including the Co-Chairs, the Bureau of the Ad Hoc Working Group of the Whole of the Regular Process and its secretariat. I would also like to acknowledge the significant scientific, technical and financial assistance to the Regular Process provided by the European Union, the United Nations Environment Programme, the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization and other relevant intergovernmental organizations.

I look forward to working with all partners to ensure that the world’s oceans, which are so essential for human well-being and prosperity, are healthy, productive and resilient for today’s and future generations.

BAN Ki-moon

Preface

As we seek to pursue sustainable development, we all need an understanding of the ways – environmental, social and economic – in which we humans interact with the world around us. Globally, the drive towards sustainable development cannot ignore the seven-tenths of the planet covered by the ocean. Such thoughts led to the recommendation of the 2002 Johannesburg World Summit on Sustainable Development, that there should be a regular process for the global reporting and assessment of the state of the marine environment, including socioeconomic aspects. We need to understand the overall benefits of the ocean to us humans, and the overall impacts of humans on the ocean.

In September 2015, the United Nations adopted the Sustainable Development Goals, including SDG 14 (“Conserve and sustainably use oceans, seas and marine resources for sustainable development”). It is therefore timely that the work put in hand by the Johannesburg Summit has now produced *The First Global Integrated Marine Assessment – World Ocean Assessment I* under the auspices of the United Nations General Assembly. The General Assembly considered and endorsed not only its Outline, but also the terms of reference and working methods of the Group of Experts and the guidance to contributors. The approach to the assessment has therefore been carefully considered at the global level.

Implementing the approach has been a major task, relying essentially on voluntary efforts from hundreds of experts in many fields. We and our colleagues in the Group of Experts of the Regular Process have been privileged to organize, contribute to, and produce the final version of, this Assessment. Crucial support has been provided by the secretariat of the Regular Process in the United Nations Secretariat, the Division for Ocean Affairs and the Law of the Sea of the Office of Legal Affairs, by several international organizations and by a number of United Nations Member States, as detailed in Chapter 2 (Mandate, information sources and method of work). The full draft assessment was reviewed by United Nations Member States. Under the terms of reference and working methods, the Group of Experts is collectively responsible for the final text.

The Regular Process was tasked with providing a first Assessment that could serve as a baseline for future cycles of the process. The vast scale of the ocean and the complexities of its many facets are revealed again and again throughout this first Assessment. Likewise, the challenges that must be faced are presented. We have also sought to identify the main gaps in knowledge and in capacity-building that hinder the responses to these challenges. These elements are all summarized in Part I of the Assessment – Summary – under ten themes: climate change, over-exploitation of marine living resources, the significance of food security and food safety, patterns of biodiversity and the changes in them, the pressures from increased uses of ocean space, the threats from increased pollution, the effects of cumulative impacts, the inequalities in the distribution of benefits from the ocean, the importance of coherent management of human impacts on the ocean, and the problems of delay in implementing known solutions.

The General Assembly decided that the Assessment should not undertake policy analysis. We have therefore not ranked these themes in order of importance. Similarly, recommendations for action were not sought. It therefore remains for national governments and the competent international authorities to decide what action to take in the light of the Assessment.

LORNA INNISS

ALAN SIMCOCK

Joint Coordinators of the Group of Experts of the Regular Process

Summary of the First Global Integrated Marine Assessment

I. Introduction¹

Let us consider how dependent on the ocean we are. The ocean is vast: it covers seven tenths of the planet, is on average about 4,000 metres deep and contains 1.3 billion cubic kilometres of water (97 per cent of all the water on the surface of the Earth). There are, however, 7 billion people on Earth. This means that each one of us has just one fifth of a cubic kilometre of ocean as our portion to provide us with all the services that we get from the ocean. That small, one fifth of a cubic kilometre portion generates half of the annual production of the oxygen that each of us breathes, and all of the sea fish and other seafood that each of us eats. It is the ultimate source of all the freshwater that each of us will drink in our lifetimes.

The ocean is a highway for ships that carry the goods that we produce and consume. The seabed and the strata beneath it hold minerals and oil and gas deposits that we increasingly need to use. Submarine cables across the ocean floor carry 90 per cent of the electronic traffic of communications, financial transactions and information exchange. Our energy supply will increasingly rely on sea-based wind turbines and wave and tidal power from the ocean. Large numbers of us take our holidays by the sea. The seabed is a rich repository for archaeology.

That one fifth of a cubic kilometre also suffers from the sewage, garbage, spilled oil and industrial waste which we collectively allow to go into the ocean every day. Demands on the ocean continue to rise together with the world's population. By the year 2050, it is estimated that there will be 10 billion people on Earth. Our portion, or our children's portion, of the ocean will then have shrunk to one eighth of a cubic kilometre. That reduced portion will still have to provide each of us with oxygen, food and water, while still suffering from the pollution and waste that we allow to enter the ocean.

The ocean is also home to a rich diversity of animals, plants, seaweeds and microbes, from the largest animal on the planet (the blue whale) to plankton and bacteria that can only be seen with powerful microscopes. We use some of those directly, and many more contribute indirectly to the benefits that we derive from the ocean. Even those organisms without any apparent connection with humans are part of the biodiversity whose value we have belatedly recognized. However, our relationship with the ocean and its creatures works both ways. We intentionally exploit many components of that rich biodiversity and increase the mortality of other components, even though we are not deliberately harvesting them. Carelessly (for example, through the input of waste material) or because of an initial lack of knowledge (for example, through the ocean acidification from increased emissions of carbon dioxide), we are altering the environment in which those organisms live. All those actions are affecting their ability to thrive and, sometimes, even to survive.

The impacts of humanity on the ocean are parts of our inheritance and future. They have helped to shape our present and will shape not only the future of the ocean and its biodiversity as an integral physical and biological system, but also the ability of the ocean to provide the services that we use now, that we will increasingly need to use in the future and that are vital to each of us and to human well-being overall.

Managing our uses of the ocean is therefore vital. The successful management of any activity, however, requires an adequate understanding of the activity and of the context in which it takes place. Such an understanding is needed even more when management

¹ In the present summary, the chapters referred to in footnotes are chapters of parts II to VII of the first global integrated marine assessment. When placed at the end of a paragraph, such footnotes apply to all preceding paragraphs up to the previous such footnote.

tasks are split among many players: unless each knows how the part they play fits into the overall pattern, there are risks of confusion, contradictory actions and failure to act. Managing the human uses of the ocean has inevitably to be divided among many players. In the course of their activities, individuals and commercial enterprises that use the ocean on a constant basis take decisions that affect the human impacts on the ocean.²

The United Nations Convention on the Law of the Sea³ establishes the legal framework within which all activities in the oceans and seas must be carried out. National Governments and regional and global intergovernmental organizations all have their parts to play in regulating those activities. However, each of those many players tends to have a limited view of the ocean that is focused on their own sectoral interests. Without a sound framework in which to work, they may well fail to take into account the ways in which their decisions and actions interact with those of others. Such failures can add to the complexity of the manifold problems that exist.

It is therefore not surprising that, in 2002, the World Summit on Sustainable Development recommended that there be a regular process for global reporting and assessment of the state of the marine environment, including socioeconomic aspects, or that the General Assembly accepted that recommendation. In its resolution 64/71, the Assembly adopted the recommendation that the Regular Process for Global Reporting and Assessment of the State of the Marine Environment, including Socioeconomic Aspects should review the state of the marine environment, including socioeconomic aspects, on a continual and systematic basis by providing regular assessments at the global and supraregional levels and an integrated view of environmental, economic and social aspects.

Those regular reviews of the state of the ocean, the way in which the many dynamics of the ocean interact and the ways in which humans are using it should enable the many people and institutions involved in human uses to position their decisions more effectively in the overall context of the ocean. The First Global Integrated Marine Assessment, also known as the first World Ocean Assessment, is the first outcome of the Regular Process. It is divided into seven parts, which are described in detail below. The present part (part I, the summary) provides: (a) a summary of the organization of the Process and the Assessment; (b) a short description of the 10 main themes that have been identified; (c) a more detailed description of each of those themes, based on the content of parts II to VII; and (d) indications of the most serious gaps in our knowledge of the ocean and related human activities, as well as in the capacities to engage in some activities and to assess them all, drawing on the content of parts III to VII.⁴

II. Background to the Assessment: the ocean around us

The starting point is the four main ocean basins of our planet: the Arctic Ocean, the Atlantic Ocean, the Indian Ocean and the Pacific Ocean.⁵ Even though they have different names, they form one single interconnected ocean system. The basins have been created over geological times by the movement of the tectonic plates across the Earth's mantle. The tectonic plates have differing forms at their edges, giving broad or narrow continental shelves and varying profiles to the continental slopes leading down to the continental rises and the abyssal plains. Geomorphic activity in the abyssal plains between the continents gives rise to abyssal ridges, volcanic islands, seamounts, guyots (plateau-like seamounts), rift-valley segments and trenches. Erosion and sedimentation (either submarine or riverine, when the sea level was lower during the ice ages) have

² See chaps. 1 and 3.

³ United Nations, *Treaty Series*, vol. 1833, No. 31363.

⁴ See chaps. 1 and 2.

⁵ The Southern Ocean is formed by the southernmost parts of the Atlantic, Indian and Pacific Ocean basins. The first World Ocean Assessment does not consider enclosed seas, such as the Caspian Sea or the Dead Sea.

created submarine canyons, glacial troughs, sills, fans and escarpments. Around the ocean basins, there are marginal seas, more or less separated from the main ocean basins by islands, archipelagos or peninsulas, or bounded by submarine ridges and formed by various processes.⁶

The water of the ocean mixes and circulates within those geological structures. Although the proportion of the different chemical components dissolved in seawater is essentially constant over time, that water is not uniform: there are very important physical and chemical variations within the seawater. Salinity varies according to the relative balance between inputs of freshwater and evaporation. Differences in salinity and temperature of water masses can cause seawater to be stratified into separate layers. Such stratification can lead to variations in the distribution of both oxygen and nutrients, with an obvious variety of consequences in both cases for the biotas sensitive to those factors. A further variation is in the penetration of light, which controls where the photosynthesis on which nearly all ocean life depends can take place. Below a few tens of metres at the coastal level or a few hundred meters in the clearer open ocean, the ocean becomes dark and there is no photosynthesis.⁷

Superimposed on all this is a change in the acidity of the ocean. The ocean absorbs annually about 26 per cent of the anthropogenic carbon dioxide emitted into the atmosphere. That gas reacts with the seawater to form carbonic acid, which is making the ocean more acid.

The ocean is strongly coupled with the atmosphere, mutually transferring substances (mostly gases), heat and momentum at its surface, forming a single coupled system. That system is influenced by the seasonal changes caused by the Earth's tilted rotation with respect to the sun. Variations in sea-surface temperature among different parts of the ocean are important in creating winds, areas of high and low air pressure and storms (including the highly damaging hurricanes, typhoons and cyclones). In their turn, winds help to shape the surface currents of the ocean, which transport heat from the tropics towards the poles. The ocean surface water arriving in the cold polar regions partly freezes, rendering the remainder more saline and thus heavier. That more saline water sinks to the bottom and flows towards the equator, starting a return flow to the tropics: the meridional overturning circulation, also called the thermohaline circulation. A further overall forcing factor is the movements generated by the tidal system, predominantly driven by the gravitational effect of the moon and sun.⁸

The movements of seawater help to control the distribution of nutrients in the ocean. The ocean enjoys both a steady (and, in some places, excessive) input from land of inorganic nutrients needed for plant growth (especially nitrogen, phosphorus and their compounds, but also lesser amounts of other vital nutrients) and a continuous recycling of all the nutrients already in the ocean through biogeochemical processes, including bacterial action. Areas of upwelling, where nutrient-rich water is brought to the surface, are particularly important, because they result in a high level of primary production from photosynthesis by phytoplankton in the zone of light penetration, combining carbon from atmospheric carbon dioxide with the other nutrients, and releasing oxygen back into the atmosphere. Whether in the water column or when it sinks to the seabed, that primary production constitutes the basis on which the oceanic food web is built, through each successive layer up to the top predators (large fish, marine mammals, marine reptiles, seabirds and, through capture fisheries, humans).⁹

The distribution of living marine resources around the world is the outcome of that complex interplay of geological forms, ocean currents, nutrient fluxes, weather, seasons and sunlight. Not surprisingly, the resulting distribution of living resources reflects that complexity. Because some ocean areas have high levels of primary production, the density of living marine resources in those areas and the contiguous areas to which

⁶ See chap. 1.

⁷ See chaps. 1 and 4.

⁸ See chaps. 1 and 5.

⁹ See chaps. 1 and 6.

currents carry that production is also high. Some of those areas of dense living marine resources are also areas of high biological diversity. The general level of biological diversity in the ocean is also high. For example, just under half of the world's animal phyla are found only in the ocean, compared to one single phylum found only on land.

Human uses of the ocean are shaped not only by the complex patterns of the physical characteristics of the ocean, of its currents and of the distribution of marine life, but also by the terrestrial conditions that have influenced the locations of human settlements, by economic pressures and by the social rules that have developed to control human activities — including national legislation, the law of the sea, international agreements on particular human uses of the sea and broader international agreements that apply to both land and sea.¹⁰

III. Carrying out the Assessment

A. Organization

To carry out the complex task of assessing the environmental, social and economic aspects of the ocean, the General Assembly has established arrangements capable of bringing to bear the many different skills needed. After the holding of two international workshops to consider modalities for the Regular Process, the Assembly started the first phase in 2006, the Assessment of Assessments. This examined more than 1,200 ocean assessments — some regional, others global, some as thematically restricted as the status and trend of a single fish stock or pollutant in a specific area, others as broad as integrated assessments of entire marine ecosystems. The Assessment of Assessments resulted in conclusions on good practice in that field and in recommendations on how the task of carrying out fully integrated assessments might be approached.

The General Assembly set up an Ad Hoc Working Group of the Whole, which examined those conclusions and recommendations and put proposals to the Assembly. In 2009, the Assembly approved the framework for the Regular Process developed in that way. The framework consists of: (a) the overall objective for the Regular Process; (b) a description of the scope of the Regular Process; (c) a set of principles to guide its establishment and operation; and (d) best practices on key design features for the Regular Process, as identified in the Assessment of Assessments. The framework also provided that capacity-building, the sharing of data and information and the transfer of technology would be crucial elements.

Between 2009 and 2011, the General Assembly set up, on the recommendation of the Ad Hoc Working Group of the Whole, the main institutional arrangements for the Regular Process, namely:

(a) The Ad Hoc Working Group of the Whole of the General Assembly on the Regular Process for Global Reporting and Assessment of the State of the Marine Environment, including Socioeconomic Aspects, which has overseen and guided the Process, meeting at least once a year. In 2011, the Working Group established a Bureau to put its decisions into practice during intersessional periods;

(b) The Group of Experts of the Regular Process, which has the task of carrying out assessments within the framework of the Regular Process at the request of the Assembly and under the supervision of the Working Group. The Group of Experts is collectively responsible for its work on the Assessment. It consists of 22 members, for a maximum possible membership of 25, who are appointed through the regional groups within the Assembly. The work of the Group members has been either voluntary or supported by their parent institutions;

(c) The Pool of Experts, which provides a pool of skilled support to assist with the wide range of issues that an assessment of the ocean, integrated across ecosystem

¹⁰ See chaps. 33 and 34.

components, sectors and environmental, social and economic aspects, has to cover. The members of the Pool have been nominated by States through the chairs of the regional groups within the Assembly and are allocated tasks by the Bureau on the recommendations of the Group of Experts. The work of the Pool members has been either voluntary or supported by their parent institutions;

(d) The secretariat of the Regular Process, which has been provided by the Division for Ocean Affairs and the Law of the Sea of the United Nations. No additional staff were recruited specifically for this work, as it was to be carried out within the overall resource level of the Division;

(e) Technical and scientific support for the Regular Process, which has been available, as a result of invitations from the Assembly, from the Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization (UNESCO), the United Nations Environment Programme (UNEP), the International Maritime Organization, the Food and Agriculture Organization of the United Nations (FAO), and the International Atomic Energy Agency;

(f) Workshops, which have been held as forums where experts could make an input to the planning and development of the Assessment. Eight workshops have been held around the world to consider the scope and methods of the Assessment, the information available in the region where each was held and capacity-building needs in that region;

(g) A website (www.worldoceanassessment.org), which has been established to make information about the Assessment available and to provide a means of communication among members of the Group of Experts and of the Pool of Experts.

In its resolution 68/70 adopted on 9 December 2013, the General Assembly took note of the guidance to contributors adopted by the Bureau of the Ad Hoc Working Group of the Whole ([A/68/82](#) and Corr.1, annex II). In that guidance, it is stated that contributors are expected to act in their personal capacity as independent experts, and not as representatives of any Government or any other authority or organization. They should neither seek nor accept instructions from outside the Regular Process regarding their work on the preparation of the Assessment, although they are free to consult widely with other experts and with government officials, in order to ensure that their contributions are credible, legitimate and relevant.

The Group of Experts proposed a draft outline for the first global integrated assessment of the marine environment. After detailed dialogue, revision and consideration by the Working Group, the outline was submitted in the report on the work of the Ad Hoc Working Group of the Whole ([A/67/87](#), annex II) and adopted by the General Assembly on 11 December 2012 in its resolution 67/78. On 29 December 2014, the Assembly took note in its resolution 69/245 of the updated outline contained in annex II to [A/69/77](#). The chapters have been prepared by writing teams of one or more members. Conveners from the Group of Experts or the Pool of Experts have led those teams. One or more lead members from the Group of Experts has overseen the preparation of (or, in some cases, prepared) each draft chapter. In some cases, the draft chapters have been reviewed by one or more commentators and, in all cases, by the Group of Experts as a whole. Synthesis chapters (drawing together the main points from each part) and the present summary have been prepared by members of the Group of Experts.

Notwithstanding the generous support of the hosts of the workshops and other support described in chapter 2, the production of the first World Ocean Assessment has been constrained by lack of resources. Apart from the costs of the workshops met by host States, support for the website from Australia and Norway and support by Australia, Belgium, Canada, China, the Republic of Korea, the United Kingdom of Great Britain and Northern Ireland and the United States of America for the travel costs of the members of the Group of Experts from those countries, outgoings have been met from a voluntary trust fund set up by the Secretary-General of the United Nations. Donations to that trust fund from Belgium, China, Côte d'Ivoire, Iceland, Ireland, Jamaica, New

Zealand, Norway, Portugal, and the Republic of Korea have amounted to \$315,000. Generous support to the Regular Process has also been provided, financially and technically, by the European Union, the Intergovernmental Oceanographic Commission and UNEP.¹¹

B. Structure of the Assessment

The Assessment is divided into the seven parts described below.

Part I: summary

The summary describes how the Assessment has been carried out, the overall assessment of the scale of human impact on the ocean, the overall value of the ocean to humans and the main pressures on the marine environment and human economic and social well-being. As guides for future action, it also sets out the gaps (general or partial) in knowledge and in capacity-building.

Part II: context of the Assessment

Chapter 1 is a broad, introductory survey of the role played by the ocean in the life of the planet, the ways in which the ocean functions, and humans' relationships to the ocean. Chapter 2 explains in more detail the rationale for the Assessment and how it has been produced.

Part III: assessment of major ecosystem services from the marine environment (other than provisioning services)

Ecosystem services are those processes, products and features of natural ecosystems that support human well-being. Some (fish, hydrocarbons or minerals) are part of the market economy. Others are not marketed. Part III looks at the non-marketed ecosystem services that the ocean provides to the planet. It considers, first, the scientific understanding of those ecosystem services and then the Earth's hydrological cycle, interactions between air and sea, primary production and ocean-based carbonate production. Finally, it looks at aesthetic, cultural, religious and spiritual ecosystem services (including some cultural objects that are in trade). Where relevant, it draws heavily on the work of the Intergovernmental Panel on Climate Change, with the aim of using the work of the Panel, not of duplicating or challenging it.

Part IV: assessment of the cross-cutting issues of food security and food safety

Part IV, which covers the one cross-cutting theme selected for examination, examines all aspects of the vital function of the ocean in providing food for humans. It draws substantially on information collected by FAO. The economic significance of employment in fisheries and aquaculture and the relationship those industries have with coastal communities are addressed, including gaps in capacity-building for developing countries.

Part V: assessment of other human activities and the marine environment

All other human activities that can impact on the ocean (other than those relating to food production) are covered in part V of the Assessment. To the extent that the available information allows, each chapter describes the location and scale of the activity, the economic benefits, employment and social role, environmental consequences (where appropriate), links to other activities and gaps in knowledge and capacity-building.

Part VI: assessment of marine biological diversity and habitats

¹¹ See chap. 2.

Part VI: (a) gives an overview of marine biological diversity and what is known about it; (b) reviews the status and trends of, and pressures on, marine ecosystems, species and habitats that have been scientifically identified as threatened, declining or otherwise in need of special attention or protection; (c) examines the significant environmental, economic and social aspects of the conservation of marine species and habitats; and (d) identifies gaps in capacity to identify marine species and habitats that are recognized as threatened, declining or otherwise in need of special attention or protection, and to assess the environmental, social and economic aspects of the conservation of marine species and habitats.

Part VII: overall assessment

Finally, part VII considers the overall way in which the various human impacts cumulatively affect the ocean, and the overall benefits that humans draw from the ocean.¹²

IV. Ten main themes

Ten main themes emerge from the detailed examination set out in parts III to VI of the first World Ocean Assessment. The order in which they are presented does not reflect any assessment of the order of importance for action. The present Assessment has been prepared on the basis of the outline, in which it is stated that the First Global Integrated Marine Assessment will not include any analysis of policies. In the light of the dialogue in the Working Group, that limitation has been understood to include the prioritization of actions or the making of recommendations (A/69/77, annex II).

Theme A

Climate change and related changes in the atmosphere have serious implications for the ocean, including rises in sea level, higher levels of acidity in the ocean, the reduced mixing of ocean water and increasing deoxygenation. There are many uncertainties here, but the consensus is that increases in global temperature, in the amount of carbon dioxide in the atmosphere and in the radiation from the sun that reaches the ocean have already had an impact on some aspects of the ocean and will produce further significant incremental changes over time. The basic mechanisms of change are understood but the ability to predict the detail of changes is limited. In many cases, the direction of change is known, but uncertainty remains about the timing and rate of change, as well as its magnitude and spatial pattern.¹³

Theme B

The exploitation of living marine resources has exceeded sustainable levels in many regions. In some jurisdictions, various combinations of management measures, positive incentives and changes to governance have allowed those historical trends to be reversed, but they persist in others. Where fisheries have imposed levels of mortality on fish stocks and wildlife populations above sustainable levels for some considerable time, those stocks have become depleted. Overexploitation has also brought about changes to ecosystems (for example, overfishing of herbivorous fish in parts of the Caribbean has led to the smothering of corals by algae). Overexploitation can also make fish stocks less productive by reducing the numbers of spawning fish, with adverse effects often amplified by the removal of the larger, older fish, which produce disproportionately more eggs of higher quality than younger, smaller individuals. At the same time, reproductive success is also being reduced by pollution, loss of habitat and other forms of disturbance, including climate change. All those factors result, more generally, in

¹² See chap. 1.

¹³ See also paras. 44-72 below.

declining biological resources with important implications for food security and biodiversity.¹⁴

Theme C

With regard to the cross-cutting issue of food security and food safety (part IV), fish products are the major source of animal protein for a significant fraction of the world's population, particularly in countries where hunger is widespread. Globally, the current mix of the global capture fisheries is near the ocean's productive capacity, with catches on the order of 80 million tons. Ending overfishing (including illegal, unreported and unregulated fishing) and rebuilding depleted resources could result in a potential increase of as much as 20 per cent in yield, but this would require addressing the transitional costs (especially the social and economic costs) of rebuilding depleted stocks. In some areas, pollution and dead zones are also depressing the production of food from the sea. Small-scale fisheries are often also a critical source of livelihoods, as well as of food, for many poor residents in coastal areas. Rebuilding the resources on which they depend and moving to sustainable exploitation will potentially have important benefits for food security. The contribution of aquaculture to food security is growing rapidly and has greater potential for growth than capture fisheries, but it brings with it new or increased pressures on marine ecosystems.¹⁵

Theme D

There are clear patterns in biodiversity around the world. The pressures on marine biodiversity are increasing, particularly near large population centres and in areas, such as the open ocean, that have so far suffered only limited impacts. Crucial areas for biodiversity, the so-called biodiversity hotspots, often overlap with the areas critical for the provision of ecosystem services by the ocean. In some of those hotspots, the ecosystem services create the conditions for high biodiversity, while in others, both the rich biodiversity and the ecosystem services result independently from the local physical and oceanographic conditions. In both cases, many of those hotspots have become magnets for human uses, in order to take advantage of the economic and social benefits that they offer. This creates enhanced potential for conflicting pressures.¹⁶

Theme E

Increased use of ocean space, especially in coastal areas, create conflicting demands for dedicated marine space. This arises both from the expansion of long-standing uses of the ocean (such as fishing and shipping) and from newly developing uses (such as hydrocarbon extraction, mining and the generation of renewable energy conducted offshore). In most cases, those various activities are increasing without any clear overarching management system or a thorough evaluation of their cumulative impacts on the ocean environment, thus increasing the potential for conflicting and cumulative pressures.¹⁷

Theme F

The current, and growing, levels of population and industrial and agricultural production result in increasing inputs of harmful material and excess nutrients into the ocean. Growing concentrations of population can impose, and in many areas are imposing, levels of sewage discharge that are beyond the local carrying capacity and which cause harm to human health. Even if discharges of industrial effluents and emissions were restrained to the lowest levels in proportion to production that are currently practicable, continuing growth in production would result in increased inputs to the ocean. The growing use of plastics that degrade very slowly result in increased quantities reaching the ocean and have many adverse effects, including the creation of

¹⁴ See also paras. 73-87 below.

¹⁵ See also paras. 88-96 below.

¹⁶ See also paras. 97-108 below.

¹⁷ See also paras. 109-122 below.

large quantities of marine debris in the ocean, and negative impacts on marine life and on the aesthetic aspects of many ocean areas, and thus consequent socioeconomic effects.¹⁸

Theme G

Adverse impacts on marine ecosystems come from the cumulative impacts of a number of human activities. Ecosystems, and their biodiversity, that might be resilient to one form or intensity of impact can be much more severely affected by a combination of impacts: the total impact of several pressures on the same ecosystem often being much larger than the sum of the individual impacts. Where biodiversity has been altered, the resilience of ecosystems to other impacts, including climate change, is often reduced. Thus the cumulative impacts of activities that, in the past, seemed to be sustainable are resulting in major changes to some ecosystems and in a reduction in the ecosystem services that they provide.¹⁹

Theme H

The distribution around the world of the benefits drawn from the ocean is still very uneven. In some fields, this unevenness is due to the natural distribution of resources in areas under the jurisdiction of the various States (for example, hydrocarbons, minerals and some fish stocks). The distribution of some benefits is becoming less skewed: for example, the consumption of fish per capita in some developing countries is growing; the balance between cargoes loaded and unloaded in the ports of developing countries is moving closer to those in developed countries in tonnage terms. In many fields, however, including some forms of tourism and the general trade in fish, an imbalance remains between the developed and developing parts of the world. Significant differences in capacities to manage sewage, pollution and habitats also create inequities. Gaps in capacity-building hamper less developed countries in taking advantage of what the ocean can offer them, as well as reduce their capability to address the factors that degrade the ocean.²⁰

Theme I

The sustainable use of the ocean cannot be achieved unless the management of all sectors of human activities affecting the ocean is coherent. Human impacts on the sea are no longer minor in relation to the overall scale of the ocean. A coherent overall approach is needed. This requires taking into account the effects on ecosystems of each of the many pressures, what is being done in other sectors and the way that they interact. As the brief summary above of the many processes at work in the ocean demonstrates, the ocean is a complex set of systems that are all interconnected. In all sectors, albeit unevenly, there has been a progressive, continuing development of management: from no regulation to the regulation of specific impacts, to the regulation of sector-wide impacts and finally to regulation taking account of aspects of all relevant sectors.

Such a coherent approach to management requires a wider range of knowledge about the ocean. Many of the gaps in the knowledge that such an integrated approach requires are identified in the present Assessment. There are also widespread gaps in the skills needed to assess the ocean with respect to some aspects (for example, the integration of environmental, social and economic aspects). In many cases, there are gaps in the resources needed for the successful application of such knowledge and skills. Gaps in capacity-building are identified briefly at the end of the present summary, and in more detail in parts III to VI.²¹

¹⁸ See also paras. 123-151 below.

¹⁹ See also paras. 152-166 below.

²⁰ See also paras. 167-186 below.

²¹ See also paras. 187-196 below.

Theme J

There is the delay in implementing known solutions to problems that have already been identified as threatening to degrade the ocean further. In many fields, it has been shown that there are practicable, known measures to address many of the pressures described above. Such pressures are continuously degrading the ocean, thereby causing social and economic problems. Delays in implementing such measures, even if they are only partial and will leave more to be done, mean that we are unnecessarily incurring those environmental, social and economic costs.²²

Conclusion

The 10 themes are described in more detail in section V below. As explained above, the order in which the themes are presented does not represent any judgement on their priority. Elements in those themes overlap, and the same issue may be relevant to more than one theme. The identification of knowledge gaps and capacity-building gaps follows in the final two sections of the summary.

V. Further details on the 10 main themes

A. Impacts of climate change and related changes in the atmosphere

Changes

Major features of the ocean are changing significantly as a result of climate change and related changes in the atmosphere. The work of the Intergovernmental Panel on Climate Change has been used, where climate is concerned, as the basis of the present assessment, as required in the outline (A/69/77, annex II).

Sea-surface temperature

The Intergovernmental Panel on Climate Change has reaffirmed in its fifth report its conclusion that global sea-surface temperatures have increased since the late nineteenth century. Upper-ocean temperature (and hence its heat content) varies over multiple time scales, including seasonal, inter-annual (for example, those associated with the El Niño-Southern Oscillation), decadal and centennial periods. Depth-averaged ocean-temperature trends from 1971 to 2010 are positive (that is, they show warming) over most of the globe. The warming is more prominent in the northern hemisphere, especially in the North Atlantic. Zonally averaged upper-ocean temperature trends show warming at nearly all latitudes and depths. However, the greater volume of the ocean in the southern hemisphere increases the contribution of its warming to the global heat content.

The ocean's large mass and high heat capacity enable it to store huge amounts of energy, more than 1,000 times than that found in the atmosphere for an equivalent increase in temperature. The earth is absorbing more heat than it is emitting back into space, and nearly all that excess heat is entering the ocean and being stored there. The ocean has absorbed about 93 per cent of the combined extra heat stored by warmed air, sea, land, and melted ice between 1971 and 2010. During the past three decades, approximately 70 per cent of the world's coastline has experienced significant increases in sea-surface temperature. This has been accompanied by an increase in the yearly number of extremely hot days along 38 per cent of the world's coastline. Warming has also been occurring at a significantly earlier date in the year along approximately 36 per cent of the world's temperate coastal areas (between 30° and 60° latitude in both hemispheres). That warming is resulting in an increasingly poleward distribution of many marine species.²³

²² See also paras. 197-202 below.

²³ See chap. 5.

Sea-level rise

It is very likely that extreme sea-level maxima have already increased globally since the 1970s, mainly as a result of global mean sea-level rise. That rise is due in part to anthropogenic warming, causing ocean thermal expansion and the melting of glaciers and of the polar continental ice sheets. Globally averaged sea level has thus risen by 3.2 mm a year for the past two decades, of which about a third is derived from thermal expansion. Some of the remainder is due to fluxes of freshwater from the continents, which have increased as a result of the melting of continental glaciers and ice sheets.

Finally, regional and local sea-level changes are also influenced by natural factors, such as regional variability in winds and ocean currents, vertical movements of the land, isostatic adjustment of the levels of land in response to changes in physical pressures on it and coastal erosion, combined with human perturbations by change in land use and coastal development. As a result, sea levels will rise more than the global mean in some regions, and will actually fall in others. A 4°C warming by 2100 (which is predicted in the high-end emissions scenario in the report of the Intergovernmental Panel on Climate Change) would lead, by the end of that period, to a median sea-level rise of nearly 1 metre above the 1980 to 1999 levels.²⁴

Ocean acidification

Rising concentrations of carbon dioxide in the atmosphere are resulting in increased uptake of that gas by the ocean. There is no doubt that the ocean is absorbing more and more of it: about 26 per cent of the increasing emissions of anthropogenic carbon dioxide is absorbed by the ocean, where it reacts with seawater to form carbonic acid. The resulting acidification of the ocean is occurring at different rates around the seas, but is generally decreasing the levels of calcium carbonate dissolved in seawater, thus lowering the availability of carbonate ions, which are needed for the formation by marine species of shells and skeletons. In some areas, this could affect species that are important for capture fisheries.²⁵

Salinity

Alongside broad-scale ocean warming, shifts in ocean salinity (salt content) have also occurred. The variations in the salinity of the ocean around the world result from differences in the balance between freshwater inflows (from rivers and glacier and ice-cap melt), rainfall and evaporation, all of which are affected by climate change. The shifts in salinity, which are calculated from a sparse historical observing system, suggest that at the surface, high-salinity subtropical ocean regions and the entire Atlantic basin have become more saline, while low-salinity regions, such as the western Pacific Warm Pool, and high-latitude regions have become even less saline. Since variations in salinity are one of the drivers of ocean currents, those changes can have an effect on the circulation of seawater and on stratification, as well as having a direct effect on the lives of plants and animals by changing their environment.²⁶

Stratification

Differences in salinity and temperature among different bodies of seawater result in stratification, in which the seawater forms layers, with limited exchanges between them. Increases in the degree of stratification have been noted around the world, particularly in the North Pacific and, more generally, north of 40°S. Increased stratification brings with it a decrease in vertical mixing in the ocean water column. This decreased mixing, in turn, reduces oxygen content and the extent to which the ocean is able to absorb heat and carbon dioxide, because less water from the lower layers is brought up to the surface, where such absorption takes place. Reductions in vertical

²⁴ See chap. 4.

²⁵ See chaps. 5-7.

²⁶ See chaps. 4 and 5.

mixing also impact the amount of nutrients brought up from lower levels into the zone that sunlight penetrates, with consequent reductions in ecosystem productivity.²⁷

Ocean circulation

The intensified study of the ocean as part of the study of climate change has led to a much clearer understanding of the mechanisms of ocean circulation and its annual and decadal variations. As a result of changes in the heating of different parts of the ocean, patterns of variation in heat distribution across the ocean (such as the El Niño-Southern Oscillation) are also changing. Those changes in patterns result in significant changes in weather patterns on land. Water masses are also moving differently in areas over continental shelves, with consequent effects on the distribution of species. There is evidence that the global circulation through the open ocean may also be changing, which might lead, over time, to reductions in the transfer of heat from the equatorial regions to the poles and into the ocean depths.

Storms and other extreme weather events

Increasing seawater temperatures provide more energy for storms that develop at sea. The scientific consensus is that this will lead to fewer but more intense tropical cyclones globally. Evidence exists that the observed expansion of the tropics since approximately 1979 is accompanied by a pronounced poleward migration of the latitude at which the maximum intensities of storms occur. This will certainly affect coastal areas that have not been exposed previously to the dangers caused by tropical cyclones.²⁸

Ultraviolet radiation and the ozone layer

The ultraviolet (UV) radiation emitted by the sun in the UV-B range (280-315 nanometres wavelength) has a wide range of potentially harmful effects, including the inhibition of primary production by phytoplankton and cyanobacteria, changes in the structure and function of plankton communities and alterations of the nitrogen cycle. The ozone layer in the Earth's stratosphere blocks most UV-B from reaching the ocean's surface. Consequently, stratospheric ozone depletion since the 1970s has been a concern. International action (under the Montreal Protocol on Substances that Deplete the Ozone Layer)²⁹ to address that depletion has been taken, and the situation appears to have stabilized, although with some variation from year to year. Given those developments and the variations in the water depths to which UV-B penetrates, a consensus on the magnitude of the ozone-depletion effect on net primary production and nutrient cycling has yet to be reached. There is, however, a potential effect of ultraviolet on nanoparticles.³⁰

Implications for human well-being and biodiversity

Changes in seasonal life cycles in the ocean

It has been predicted under some climate change scenarios that up to 60 per cent of the current biomass in the ocean could be affected, either positively or negatively, resulting in disruptions to many existing ecosystem services. For example, modelling studies of species with strong temperature preferences, such as skipjack and bluefin tuna, predict major changes in range and/or decreases in productivity.³¹

The effects are found in all regions. For example, in the North-West Atlantic, the combination of changes in feeding patterns triggered by overfishing and changes in climate formed the primary pressures thought to have brought about shifts in species composition amounting to a full regime change, from one dominated by cod to one

²⁷ See chaps. 1 and 4-6.

²⁸ See chap. 5.

²⁹ United Nations, *Treaty Series*, vol. 1522, No. 26369.

³⁰ See theme F above and chap. 6.

³¹ See chaps. 42 and 52.

dominated by crustacea. Even in the open ocean, climate warming will increase ocean stratification in some broad areas, reduce primary production and/or result in a shift in productivity to smaller species (from diatoms of 2-200 microns to picoplankton of 0.2-2 microns) of phytoplankton. This has the effect of changing the efficiency of the transfer of energy to other parts of the food web, causing biotic changes over major regions of the open ocean, such as the equatorial Pacific.³²

Loss of sea ice in high latitudes and associated ecosystems

The high-latitude ice-covered ecosystems host globally significant arrays of biodiversity, and the size and nature of those ecosystems make them critically important to the biological, chemical and physical balance of the biosphere. Biodiversity in those systems has developed remarkable adaptations to survive both extreme cold and highly variable climatic conditions.

High-latitude seas are relatively low in biological productivity, and ice algal communities, unique to those latitudes, play a particularly important role in system dynamics. Ice algae are estimated to contribute more than 50 per cent of the primary production in the permanently ice-covered central Arctic. As sea-ice cover declines, this productivity may decline and open water species may increase. The high-latitude ecosystems are undergoing change at a rate more rapid than in other places on earth. In the past 100 years, average Arctic temperatures have increased at almost twice the average global rate. Reduced sea ice, especially a shift towards less multi-year sea ice, will affect a wide range of species in those waters. For example, owing to low reproductive rates and long lifetimes, some iconic species (including the polar bear) will be challenged to adapt to the current fast warming of the Arctic and may be extirpated from portions of their range within the next 100 years.³³

Plankton

Phytoplankton and marine bacteria carry out most of the primary production on which food webs depend. The climate-driven increases in the temperature of the upper ocean that had been predicted are now causing shifts in phytoplankton communities. This may have profound effects on net primary production and nutrient cycles over the next 100 years. In general, when smaller plankton account for most net primary production, as is typically the case in oligotrophic open-ocean waters (that is, areas where levels of nutrients are low), net primary production is lower and the microbial food web dominates energy flows and nutrient cycles. Under such conditions, the carrying capacity for currently harvestable fish stocks is lower and exports of organic carbon, nitrogen and phosphorus to the deep sea may be smaller.

On the other hand, as the upper ocean warms, the geographic range of nitrogen-fixing plankton (diazotrophs) will expand. This could enhance the fixation of nitrogen by as much as 35-65 per cent by 2100. This would lead to an increase in net primary production, and therefore an increase in carbon uptake, and some species of a higher trophic level may become more productive.

The balance between those two changes is unclear. A shift towards less primary production would have serious implications for human food security and the support of marine biodiversity.³⁴

Fish stock distribution

As seawater temperatures increase, the distribution of many fish stocks and the fisheries that depend upon them is shifting. While the broad pattern is one of stocks moving poleward and deeper in order to stay within waters that meet their temperature preference, the picture is by no means uniform, nor are those shifts happening in

³² See chaps. 6 and 36A.

³³ See chaps. 36G, 36H and 37.

³⁴ See chap. 6.

concert for the various species. Increasing water temperatures will also increase metabolic rates and, in some cases, the range and productivity of some stocks. The result is changes in ecosystems occurring at various rates ranging from near zero to very rapid. Research on those effects is scattered, with diverse results, but as ocean climate continues to change, those considerations are of increasing concern for food production. Greater uncertainty for fisheries results in social, economic and food security impacts, complicating sustainable management.³⁵

Seaweeds and seagrasses

Cold-water seaweeds, in particular kelps, have reproductive regimes that are temperature-sensitive. Increase in seawater temperature affects their reproduction and survival, which will consequently affect their population distribution and harvest. Kelp die-offs have already been reported along the coasts of Europe, and changes in species distribution have been noted in Northern Europe, Southern Africa and Southern Australia, with warm-water-tolerant species replacing those that are intolerant of warmer water. The diminished kelp harvest reduces what is available for human food and the supply of substances derived from kelp that are used in industry and pharmaceutical and food preparation.

Communities with kelp-based livelihoods and economies will be affected. For seagrasses, increased seawater temperatures have been implicated in the occurrence of a wasting disease that decimated seagrass meadows in the north-eastern and north-western parts of the United States. Changes in species distribution and the loss of kelp forest and seagrass beds have resulted in changes in the ways that those two ecosystems provide food, habitats and nursery areas for fish and shellfish, with repercussions on fishing yields and livelihoods.³⁶

Shellfish productivity

Because of the acidification of the ocean, impacts on the production by shellfish of their calcium carbonate shells has already been observed periodically at aquaculture facilities, hindering production. As acidification intensifies, this problem will become more widespread, and occur in wild, as well as in cultured, stocks. However, like all other ocean properties, acidification is not evenly distributed, so that the effects will not be uniform across areas and there will be substantial variation over small spatial scales. In addition, temperature, salinity and other changes will also change shellfish distributions and productivity, positively or negatively in different areas. As with fishing, the course of those changes is highly uncertain and may be disruptive to existing shellfish fisheries and aquaculture.³⁷

Low-lying coasts

Sea-level rise, due to ocean warming and the melting of land ice, poses a significant threat to coastal systems and low-lying areas around the world, through inundations, the erosion of coastlines and the contamination of freshwater reserves and food crops. To a large extent, such effects are inevitable, as they are the consequences of conditions already in place, but they could have devastating effects if mitigation options are not pursued. Entire communities on low-lying islands (including States such as Kiribati, Maldives and Tuvalu) have nowhere to retreat to within their islands and have therefore no alternative but to abandon their homes entirely, at a cost they are often ill-placed to bear. Coastal regions, particularly some low-lying river deltas, have very high population densities. Over 150 million people are estimated to live on land that is no more than 1 metre above today's high-tide levels, and 250 million at elevations within five metres of that level. Because of their high population densities, coastal cities are particularly

³⁵ See chaps. 36A-H and 52.

³⁶ See chaps. 14 and 47.

³⁷ See chaps. 5, 11 and 52.

vulnerable to sea-level rise in concert with other effects of climate change, such as changes in storm patterns.³⁸

Coral reefs

Corals are subject to “bleaching” when the seawater temperature is too high: they lose the symbiotic algae that give coral its colour and part of its nutrients. Coral bleaching was a relatively unknown phenomenon until the early 1980s, when a series of local bleaching events occurred, principally in the eastern tropical Pacific and Wider Caribbean regions. Severe, prolonged or repeated bleaching can lead to the death of coral colonies. An increase of only 1°C to 2°C above the normal local seasonal maximum can induce bleaching. Although most coral species are susceptible to bleaching, their thermal tolerance varies. Many heat-stressed or bleached corals subsequently die from coral diseases.

Rising temperatures have accelerated bleaching and mass mortality during the past 25 years. The bleaching events in 1998 and 2005 caused high coral mortality at many reefs, with little sign of recovery. Global analysis shows that this widespread threat has significantly damaged most coral reefs around the world. Where recovery has taken place, it has been strongest on reefs that were highly protected from human pressures. However, a comparison of the recent and accelerating thermal stress events with the slow recovery rate of most reefs suggests that temperature increase is outpacing recovery.

Losses of coral reefs can have negative effects on fish production and fisheries, coastal protection, ecotourism and other community uses of coral reefs. Current scientific data and modelling predict that most of the world’s tropical and subtropical coral reefs, particularly those in shallow waters, will suffer from annual bleaching by 2050, and will eventually become functionally extinct as sources of goods and services. This will have not only profound effects on small island developing States and subsistence fishermen in low-latitude coastal areas, but also locally significant effects even in major economies, such as that of the United States.³⁹

Submarine cables

Submarine cables have always been at risk of breaks from submarine landslides, mainly at the edge of the continental shelf. As the pattern of cyclones, hurricanes and typhoons changes, submarine areas that have so far been stable may become less so and thus produce submarine landslides and consequent cable breaks. With the increasing dependence of world trade on the Internet, such breaks (in addition to breaks from other causes, such as ship anchors and bottom trawling) could delay or interrupt communications vital to that trade.⁴⁰

Eutrophication problems

Where there are narrow continental shelves, some wind conditions can bring nutrient-rich, oxygen-poor water up into coastal waters, and produce hypoxic (low-oxygen) or even anoxic conditions (the implications of which are described under theme F). Changes in ocean circulation appear to be enhancing those effects. Examples of this can be found on the western coasts of the American continent immediately north and south of the equator, the western coast of sub-Saharan Africa and the western coast of the Indian subcontinent.⁴¹

Opening of Arctic shipping routes

Although the number of ships transiting Arctic waters is currently low, it has been escalating for the past decade, and the retreat of the polar sea ice as a result of

³⁸ See chap. 4.

³⁹ See chaps. 34, 36D and 43.

⁴⁰ See chap. 19.

⁴¹ See chaps. 6 and 20.

planetary warming means that there are increasing possibilities for shipping traffic between the Atlantic and Pacific Oceans around the north of the American and Eurasian continents during the northern summer. The movement of species between the Pacific and the Atlantic demonstrates the scale of the potential impact. Those routes are shorter and may be more economic, but shipping brings with it increased risks of marine pollution both from acute disasters and chronic pollution and the potential introduction of invasive non-native species. The very low rate at which bacteria can break down spilled oil in polar conditions and the general low recovery rate of polar ecosystems mean that damage from such pollution would be very serious. Furthermore, the response and clear-up infrastructure found in other ocean basins is largely lacking today around the Arctic Ocean. Those factors would make such problems even worse. Over time, the increased commercial shipping traffic through the Arctic Ocean and the noise disturbance it creates may also displace marine mammals away from critical habitats.⁴²

B. Higher mortality and less successful reproduction of marine biotas

Captures of fish stocks at levels above maximum sustainable yield

Globally, the levels of capture fisheries are near the ocean's productive capacity, with catches on the order of 80 million tons. Exploitation inevitably reduces total population biomass through removals. As long as the fish stock can compensate through increased productivity because the remaining individuals face less competition for access to food and therefore grow faster and produce more progeny, then fishing can be sustained. However, when the rate of exploitation becomes faster than the stock can compensate through increasing growth and reproduction, the removal level becomes unsustainable and the stock declines.

The concept of "maximum sustainable yield", entrenched in international legal instruments such as the United Nations Convention on the Law of the Sea and the Agreement for the Implementation of the Provisions of the United Nations Convention on the Law of the Sea of 10 December 1982 relating to the Conservation and Management of Straddling Fish Stocks and Highly Migratory Fish Stocks,⁴³ is based on the inherent trade-off between increasing harvests and decreasing the ability of a smaller resulting population to compensate for the removals.

At present, about one quarter of all assessed fish stocks are being overfished and more are still recovering from past overfishing. This is undermining the contribution that they could make to food security. Ending overfishing is a precondition for allowing stocks to rebuild. Other stocks may still be categorized as "fully exploited" despite being on the borderline of overfishing. Those could produce greater yields if effectively managed.

There are only a few means available to increase yields. Ending overfishing, eliminating illegal, unreported and unregulated fishing, bringing all fishery yields under effective management and rebuilding depleted resources may result in an increase of as much as 20 per cent in potential yield, provided that the transitional economic and social costs of rebuilding depleted stocks can be addressed.

Overfishing can also undermine the biodiversity needed to sustain marine ecosystems. Without careful management, such impacts on biodiversity will endanger some of the most vulnerable human populations and marine habitats around the world, as well as threaten food security and other important socioeconomic aspects (such as livelihoods).⁴⁴

⁴² See chaps. 20 and 36G.

⁴³ United Nations, *Treaty Series*, vol. 2167, No. 37924.

⁴⁴ See chaps. 10, 11 and 15.

Impacts of changes in breeding and nursery areas

Changes in breeding and nursery areas are best documented for the larger marine predators. For seabirds, globally, the greatest pressure is caused by invasive species (mainly rats and other predators acting at breeding sites). That pressure potentially affects 73 threatened seabird species — 75 per cent of the total and nearly twice as many as any other single threat. The remaining most significant pressures are fairly evenly divided between those faced mainly at breeding sites, namely problematic native species, human disturbance and the loss of historical breeding and nursery sites to urban development (commercial, residential or infrastructural), and those faced mainly at sea, particularly by-catch in longlines, gillnets and trawl fisheries, when birds are foraging or moulting, migrating or in aggregations. The ingestion of marine plastic debris is also significant. For marine reptiles, decades of overharvesting of marine turtle eggs on nesting beaches have driven the long-term decline of some breeding populations. In some areas, tourist development has also affected reproductive success at historical turtle nesting beaches. All this has rendered them more vulnerable to fishery by-catch and other threats. Similar pressures apply to marine mammals.⁴⁵

Levels of by-catch (non-target fish, marine mammals, reptiles and seabirds), discards and waste

Current estimates of the number of overfished stocks do not take into account the broader effects of fishing on marine ecosystems and their productivity. In the past, large numbers of dolphins drowned in fishing nets. This mortality greatly reduced the abundance of several dolphin species in the latter half of the twentieth century. Thanks to international efforts, fishing methods have changed and the by-catch has been reduced significantly. Commercial fisheries are the most serious pressure at sea that the world's seabirds face, although there is evidence of some reductions of by-catch in some key fisheries. Each year, incidental by-catch in longline fisheries is estimated to kill at least 160,000 albatrosses and petrels, mainly in the southern hemisphere. For marine reptiles, a threat assessment scored fishery by-catch as the highest threat across marine turtle subpopulations, followed by harvesting (that is, for human consumption) and coastal development.

The mitigation of those causes of mortality can be effective, even though the lack of reliable data can hamper the targeting of mitigation measures. Depending on the particular species and fishery methods, mitigation may include the use of acoustic deterrents, gear modifications, time or area closures and gear switching (for example, from gillnets to hooks and lines). In particular, the global moratorium on all large-scale pelagic drift-net fishing called for by the General Assembly in 1991 was a major step in limiting the by-catch of several marine mammal and seabird species that were especially vulnerable to entanglement.⁴⁶

Impact of hazardous substances and eutrophication problems on reproduction and survival

Each of the reviews of regional biodiversity in part VI of the present Assessment reported at least some instances of threats from hazardous substances. To give some examples, in the South Pacific, localized declines in species densities, assemblages and spatial distributions are being observed, particularly in areas close to population centres where overfishing, pollution from terrestrial run-off and sewage and damage from coastal developments are occurring. In the North Atlantic, impacts on the benthos have been particularly well documented, although their nature depends on the type, intensity and duration of the pollution or nutrient input. Persistent pressures of that type have been documented to alter greatly the species composition and biomass of the benthos directly and indirectly, through processes such as the formation of dead zones and hypoxic zones as a result of eutrophication problems and seawater circulation

⁴⁵ See chaps. 28 and 37-39.

⁴⁶ See chaps. 11 and 37-39.

changes driven by climate change. Even in the open ocean, evidence is increasing for chemical contamination of deep-pelagic animals. Although the pathways for such contaminations are not well known, high concentrations of heavy metals and persistent organic pollutants have been reported.⁴⁷

Impacts of disturbance from noise

Anthropogenic noise in the ocean increased in the last half of the past century. Commercial shipping is the main source, and the noise that it produces is often in frequency bands used by many marine mammals for communication. Many other types of marine biotas have also been shown to be affected by anthropogenic noise. Other significant sources of noise are seismic exploration for the offshore hydrocarbon industry and sonar. The impact of noise can be both to disrupt communication among animals and to displace them from their preferred breeding, nursery or feeding grounds, with consequent potential effects on their breeding success and survival.⁴⁸

Impacts of recreational fishing

Recreational fishing is a popular activity in many industrialized countries, in which up to 10 per cent of the adult population may participate. The impact of that type of fishing is only sometimes taken into account in fishery management, although the quantities caught can be significant for the management of stocks experiencing overfishing. In several countries, there is a substantial industry supporting the recreational catching of sport fish (including trophy fish, such as marlins, swordfish and sailfish), but catch statistics are generally not available.⁴⁹

Implications for human well-being and biodiversity

Food resources

The overfishing of some fish stocks is reducing the yield realized from those stocks. Such reductions in yield are likely to undermine food security. The role of fisheries in food security is further considered below.⁵⁰

Species structure of highly productive sea areas

Many human activities have been documented to have impacts on marine life living on the seabed (benthic communities). The adverse effects of mobile bottom-contacting fishing gear on coastal and shelf benthic communities have been documented essentially everywhere that such gear has been used. Bottom trawling has caused the destruction of a number of long-lived cold-water coral and sponge communities that are unlikely to recover before at least a century. Many reviews show that, locally, the nature of those impacts and their duration depend on the type of substrate and frequency of trawling. Those effects have been found in all the regional assessments.⁵¹

With regard to fish and pelagic invertebrate communities, much effort has been devoted to teasing apart the influences of exploitation and of environmental conditions as drivers of change in fish populations and communities, but definitive answers are elusive. Most studies devote attention to explaining variation among coastal fish-community properties in terms of features of the physical and chemical habitats (including temperature, salinity, oxygen and nutrient levels, clarity of, and pollutants in, the water column) and of depth, sediment types, benthic communities, contaminant levels, oxygen levels and disturbance of the sea floor. All of those factors have been shown to influence fish-community composition and structure in at least some coastal areas of each ocean basin.

⁴⁷ See chaps. 36A-H.

⁴⁸ See chaps. 17, 21 and 37.

⁴⁹ See chaps. 28, 40 and 41.

⁵⁰ See chap. 11.

⁵¹ See chaps. 36A-H, 42, 51 and 52.

The scale at which a fish-community structure is determined and its variation is documented can be even more local, because some important drivers of change in coastal fish communities are themselves very local in scale, such as coastal infrastructure development. Other obvious patterns are recurrent, such as increasing mortality rates (whether from exploitation or coastal pollution) leading both to fish communities with fewer large fish and to an increase in species with naturally high turnover rates. However, some highly publicized projections of the loss of all commercial fisheries or of all large predatory fish by the middle of the current century have not withstood critical review.⁵²

C. Food security and food safety

Seafood products, including finfish, invertebrates and seaweeds, are a major component of food security around the world. They are the major source of protein for a significant fraction of the global population, in particular in countries where hunger is widespread. Even in the most developed countries, the consumption of fish is increasing both per capita and in absolute terms, with implications for both global food security and trade.⁵³

Fisheries and aquaculture are a major employer and source of livelihoods in coastal States. Significant economic and social benefits result from those activities, including the provision of a key source of subsistence food and much-needed cash for many of the world's poorest peoples. As a mainstay of many coastal communities, fisheries and aquaculture play an important role in the social fabric of many areas. Small-scale fisheries, particularly those that provide subsistence in many poor communities, are often particularly important. Many such coastal fisheries are under threat because of overexploitation, conflict with larger fishing operations and a loss of productivity in coastal ecosystems caused by a variety of other impacts. Those include habitat loss, pollution and climate change, as well as the loss of access to space as coastal economies and uses of the sea diversify.⁵⁴

Capture fisheries

Globally, capture fisheries are near the ocean's productive capacity, with catches on the order of 80 million metric tons. Only a few means to increase yield are available. Addressing sustainability concerns more effectively (including ending overfishing, eliminating illegal, unreported and unregulated fishing, rebuilding depleted resources and reducing the broader ecosystem impacts of fisheries and the adverse impacts of pollution) is an important aspect of improving fishery yields and, therefore, food security. For example, ending overfishing and rebuilding depleted resources may result in an increase of as much as 20 per cent in potential yield, provided that the transitional costs of rebuilding depleted stocks can be addressed.⁵⁵

In 2012, more than one quarter of fish stocks worldwide were classified by the Food and Agriculture Organization of the United Nations as overfished. Although those stocks will clearly benefit from rebuilding once overfishing has ended, other stocks may still be categorized as fully exploited despite being on the borderline of overfishing. Such stocks could yield more if effective governance mechanisms were in place.

Current estimates of the number of overfished stocks do not take into account the broader effects of fishing on marine ecosystems and their productivity. Those impacts, including by-catch, habitat modification and effects on the food web, significantly affect the ocean's capacity to continue to produce food sustainably and must be carefully

⁵² See chaps. 10, 11, 15, 34, 36A-H and 52.

⁵³ See chap. 10.

⁵⁴ See chap. 15.

⁵⁵ See chaps. 11, 13, 36A-H and 52.

managed. Fish stock propagation may provide a tool to help to rebuild depleted fishery resources in some instances.⁵⁶

Fishing efforts are subsidized by many mechanisms around the world, and many of those subsidies undermine the net economic benefits to States. Subsidies that encourage overcapacity and overfishing result in losses for States, and those losses are often borne by communities dependent on fishery resources for their livelihood and food security.⁵⁷

Aquaculture

Aquaculture production, including seaweed culture, is increasing more rapidly than any other source of food production in the world. Such growth is expected to continue. Aquaculture, not including the culture of seaweeds, now provides half of the fish products covered in global statistics. Aquaculture and capture fisheries are codependent in some ways, as feed for cultured fish is in part provided by capture fisheries, but they are competitors for space in coastal areas, markets and, potentially, other resources. Significant progress has been made in replacing feed sources from capture fisheries with agricultural production. Aquaculture itself poses some environmental challenges, including potential pollution, competition with wild fishery resources, potential contamination of gene pools, disease problems and loss of habitat. Examples of those challenges, and measures that can mitigate them, have been observed worldwide.⁵⁸

Social issues

In both capture fisheries and aquaculture, gender and other equity issues arise. A significant number of women are employed in both types of activities, either directly or in related activities along the value chain. Women are particularly prominent in product processing, but often their labour is not equitably compensated and working conditions do not meet basic standards. Poor communities are often subject to poorer market access, unsafe working conditions and other inequitable practices.⁵⁹

Food safety

Food safety is a key worldwide challenge for all food production and delivery sectors, including all parts of the seafood industry, from capture or culture to retail marketing. That challenge is of course also faced by subsistence fisheries. In the food chain for fishery products, potential problems need to be assessed, managed and communicated to ensure that they can be addressed. The goal of most food safety systems is to avoid risk and prevent problems at the source. The risks come from contamination from pathogens (particularly from discharges of untreated sewage and animal waste) and toxins (often from algal blooms). The severity of the risk also depends on individual health, consumption levels and susceptibility. There are international guidelines to address those risks but substantial resources are required in order to continue to build the capacity to implement and monitor safety protocols from the water to the consumer.

D. Patterns of biodiversity

A basic, but key, conclusion of the present Assessment is that there are clear patterns of biodiversity, both globally and regionally. A key question is whether there are consistent large-scale patterns of biodiversity, governed by underlying factors that constrain the distribution of the wide range of marine life across the wide variety of habitats. Global-scale studies to explore this question began long ago and have grown substantially in the past decade. The enormous amounts of data collected and compiled by the Census

⁵⁶ See chap. 13.

⁵⁷ See chap. 15.

⁵⁸ See chap. 12.

⁵⁹ See chap. 15.

of Marine Life enable exploration and the mapping of patterns across more taxonomic groups than ever before, thus facilitating an understanding of the consistency of patterns of biodiversity.

Perhaps the most common large-scale biodiversity pattern on the planet is the “latitudinal gradient”, typically expressed as a decline in the variety of species from the equator to the poles. Adherence to that pattern varies among marine taxa. Although coastal species generally peak in abundance near the equator and decline towards the poles, seals show the opposite pattern. Furthermore, strong longitudinal gradients (east-west) complicate patterns, with hotspots of biodiversity across multiple species groups in the coral triangle of the Indo-Pacific, in the Caribbean and elsewhere.

Oceanic organisms, such as whales, differ in pattern entirely, with species numbers consistently peaking at mid-latitudes between the equator and the poles. This pattern defies the common equator-pole gradient, suggesting that different factors are at play. Various processes may also control the difference in species richness between the oceanic and coastal environments (for example, in terms of dispersal, mobility or habitat structure), but general patterns appear to be reasonably consistent within each group.

However, across all groups studied, ocean temperature is consistently related to species diversity, making the effects of climate change likely to be felt as a restructuring factor of marine community diversity.

Although the patterns above hold for the species studied, numerous groups and regions have not yet been examined. For example, global-scale patterns of diversity in the deep sea remain largely unknown. Knowledge of diversity and distribution is biased towards large, charismatic species (for example, whales) or economically valuable species (for example, tuna). Our knowledge of patterns in microbial organisms remains particularly limited relative to the considerable biodiversity of those species. Enormous challenges remain even to measure this. Viruses remain another critical part of the oceanic system of which we lack any global-scale biodiversity knowledge.

Patterns of global marine biodiversity, other than species richness, are only just beginning to be explored. For example, investigations suggest that, globally, the higher the latitude at which a reef is located, the greater the evenness in the number of individuals of each species tend to be in that reef. Such a pattern, in turn, affects functional richness, which relates to the diversity of function in reef fish, a potentially important component of ecosystem productivity, resilience and provision of goods and services.⁶⁰

Implications

Location of biodiversity hotspots and their relationship to the location of high levels of ecosystem services

Although marine life is found everywhere in the ocean, biodiversity hotspots exist where the number of species and the concentration of biotas are consistently high relative to adjacent areas. Some are subregional, such as the coral triangle in the Indo-Pacific, the coral reefs in the Caribbean, the cold-water corals in the Mediterranean and the Sargasso Sea. Some are more local and associated with specific physical conditions, such as biodiversity-rich habitat types. Key drivers of biodiversity are complex three-dimensional physical structures that create a diversity of physical habitats (associated with rocky sea floors), dynamic oceanographic conditions causing higher bottom-up productivity, effects of land-based inputs extending far out to sea (such as the inputs from the River Amazon) and special vegetation features creating unique and productive habitats near the shore. Those complex habitats, however, are often highly vulnerable to disturbance.

⁶⁰ See chaps. 34, 35 and 36A-H.

The high relative and absolute biodiversity of those hotspots often directly supports the extractive benefits of fishing and other harvests, providing a direct link between biodiversity and the provision of services by the ocean. The areas supporting high relative and absolute levels of biodiversity not only harbour unique species adapted to their special features, but also often serve as centres for essential life-history stages of species with wider distributions. For example, essentially all the biodiversity hotspots that have been identified have also been found to harbour juvenile fish, which are important for fisheries in adjacent areas.

Hotspots for primary productivity are necessarily also hotspots for production of oxygen as a direct result of photosynthesis. Furthermore, underlying the high biodiversity is often a high structural complexity of the habitats that support it. That structure often contributes other services, such as coastal protection and regeneration. In addition, it is the concentrated presence of iconic species in an area which adds to aesthetic services (supporting tourism and recreation) and spiritual and cultural services.⁶¹

Biodiversity and economic activity

Sometimes, because of the special physical features that contribute to high biodiversity, and sometimes because of the concentration of biodiversity itself, many societies and industries are most active in areas that are also biodiversity hotspots. As on land, humanity has found the greatest social and economic benefits in the places in the ocean that are highly productive and structurally complex. For example, 22 of the 32 largest cities in the world are located on estuaries; mangroves and coral reefs support small-scale (artisanal) fisheries in developing countries. Biodiversity hotspots tend to attract human uses and become socioeconomic hotspots. Hence biodiversity-rich areas have a disproportionately high representation of ports and coastal infrastructure, other intensive coastal land uses, fishing activities and aquaculture. This is one of the major challenges to the sustainable use of marine biodiversity.⁶²

Some marine features, such as seamounts, often found in areas beyond national jurisdiction, have high levels of biodiversity, frequently characterized by the presence of many species not found elsewhere. Significant numbers of the species mature late, and therefore reproduce slowly. High levels of fishing have rapidly undermined the biodiversity of many such features, and risk continuing to do so in the absence of careful management.⁶³

New forms of economic activity in the open ocean, such as seabed mining, and the expansion of existing forms of activity, such as hydrocarbon extraction, have the potential to have major impacts on its biodiversity, which is to date poorly known. Without careful management of those activities, there is a risk that the biodiversity of areas affected could be destroyed before it is properly understood.⁶⁴

E. Increased use of ocean space

The world is seeing a greatly intensified use of ocean space. Since around the middle of the nineteenth century, there has been a great growth in the range of human activities in the ocean, each demanding its share of ocean space. At the same time, and in consequence, the regulation of activities in the ocean has increased. In a campaign to draw attention to this, the fishermen of the Netherlands coined the slogan “Fishing on a postage stamp”, arguing that, by the time that all the other uses of the exclusive economic zone of the Netherlands (shipping lanes, offshore oil and gas extraction, sand and gravel extraction, dumping of dredged material, offshore wind-power installations, submarine cables and pipelines, etc.) had been allocated their spaces, not much space

⁶¹ See chaps. 8, 34, 36A-H and 52.

⁶² See chaps. 26, 34 and 36A-H.

⁶³ See chaps. 36F and 51.

⁶⁴ See chaps. 21-23 and 36F.

was left for their traditional fishing activities. Whether or not their activities were actually restricted, their slogan drew attention to a challenge faced all around the world as increasing demands are made for space for ocean-based activities.

Not all the uses of ocean space within national jurisdictions have the same implications. Some uses effectively exclude most other concurrent uses, for example where fishing rights for benthic species (such as oysters) in areas of national jurisdiction have been allocated to individual proprietors, where tourism would be hampered by other developments or where “no-take” marine protected areas have been created. Others may have a global distribution, but may have a lesser impact, such as shipping lanes and submarine cables. Yet others have, at least so far, only localized impacts, usually determined by the availability of some local resource. Those are likely to be intensive, limiting other uses in the areas where they occur, for example aquaculture, offshore oil and gas extraction, sand and gravel extraction and offshore wind-power installations.

Those differing implications of the developments in human uses of the ocean are important for policy decisions on how, and at what level (national, regional, global), activities should be best managed.⁶⁵

Increased coastal population and urbanization (including tourism)

A large proportion of humans live in the coastal zone: 38 per cent of the world's population live within 100 km of the shore, 44 per cent within 150 km, 50 per cent within 200 km, and 67 per cent within 400 km. This proportion is steadily increasing. Consequently, there are growing demands for land in the coastal zone. Land reclamation has therefore been taking place on a large scale in many countries, particularly by reclaiming salt marshes, intertidal flats and mangroves. At the same time, where coastal land is threatened by erosion, large stretches of natural coastline have been replaced by “armoured”, artificial coastal structures. Those can significantly affect coastal currents and the ability of marine biotas to use the coast as part of their habitat. Tourist developments have also significantly increased the lengths of artificial coastline. Changes in river management, such as the construction of dams, and the building of coastal infrastructures, such as ports, can significantly change the sedimentation pattern along coasts. Such changes can increase coastal erosion and promote other coastal changes, sometimes with the effect that coastal land is lost for its current use, producing demands for replacement space.⁶⁶

Aquaculture and marine ranching

Increases in aquaculture, which is growing rapidly, and in marine ranching, which has substantial growth potential, require extensive ocean space as well as clean waters and, often, the dedicated use of an unpolluted seabed. Those requirements can result in conflicts with other uses, including, in some cases, the aesthetic or cultural values of sea areas. Similar demands for ocean space are also made by industries concerned with the production of cultural goods, such as pearls. Problems will result if management of such expansion is not integrated with that of other sectors.

Shipping routes and ports

World shipping has been growing consistently for the past three decades. Between 1980 and 2013, the annual tonnage carried in the five main shipping trades increased by 158 per cent. Although the use of ocean space by a ship is not continuous, on the more densely trafficked routes, shipping lanes cannot be used safely for other activities, even where those activities themselves are intermittent. Some of the ranges of the largest populations of seabirds in the northern hemisphere are intersected by major shipping routes, with consequent risk of disturbance to the wildlife and mortality from chronic or catastrophic oil and other spills.

⁶⁵ See chaps. 12, 17, 19, 21-24 and 28.

⁶⁶ See chaps. 18, 26, 28, 48 and 49.

The fundamental change in general cargo shipping (from loose bulk to containerized) has also produced a total change in the nature of the ports that act as terminals for that traffic, as large areas of flat land are needed for handling containers, both on departure and arrival. That land has, in many cases, been provided by means of land reclamation. As shipping traffic continues to grow, further substantial areas of land will be required. Dredging to create ports and to maintain navigation channels produces large amounts of dredged material that has to be disposed of. Most of that material is dumped at sea, where it smothers any biota on the seabed.⁶⁷

Submarine cables and pipelines

The vital role that submarine cables now play in all forms of communication through the Internet — whether for academic, commercial, governmental or recreational purposes — means that there will continue to be a demand for more capacity, and hence for more submarine cables. Although submarine cables (and any protective corridors around them) cover only very narrow strips of seabed, they introduce a line break across the seabed that prevents other activities from spreading across it. Submarine cables will therefore continue to neutralize increasing segments of the seabed for any purpose that impinges on the seabed. Submarine pipelines are unlikely ever to venture into the open-ocean areas where many submarine cables have to be laid, but they have a growing role for transporting oil and gas through coastal zones and between continents and their adjacent islands. In some ways, therefore, their increased demand for seabed space is likely to be in areas where there are demands from other uses.⁶⁸

Offshore hydrocarbon industries

The growth of the offshore oil and gas industry has increased the demand by that sector for access to ocean space within areas under national jurisdiction (including space for pipelines to bring the hydrocarbon products ashore). More than 620,000 km² (almost 9 per cent) of the exclusive economic zone (EEZ) of Australia is subject to oil and gas leases. In the United States, about 550,000 km² of the whole EEZ is subject to current oil and gas leases, including 470,000 km² in the Gulf of Mexico, representing 66 per cent of the EEZ of the United States in that area. When such significant proportions of the ocean areas under national jurisdiction are thus subject to such prior claims, overlaps in sectoral interests become inevitable.

Offshore mining

Offshore mining is currently confined to shallow-water coastal regions, although growing exploration activity is focused on deep-sea minerals. About 75 per cent of the world's tin, 11 per cent of gold, and 13 per cent of platinum are extracted from the placer deposits near the surface of the coastal seabed, where they have been concentrated by waves and currents. Diamonds are also an important mining target. Aggregates (sand, coral, gravel and seashells) are also important: the United Kingdom, the world's largest producer of marine aggregates, currently extracts approximately 20 million tons of marine aggregate per year, meeting around 20 per cent of its demand. Those activities are all concentrated in coastal waters, where other demands for space are high. Deep-water deposits that have generated continuing interest, but are not currently mined, include ferromanganese nodules and crusts, polymetallic sulphides, phosphorites, and methane hydrates. Demands for deep-sea space are likely to develop in the future.⁶⁹

Offshore renewable energy

Offshore renewable energy generation is still in its early stages, although substantial offshore wind farms have been installed in some parts of the world. Most forms of

⁶⁷ See chaps. 17 and 18.

⁶⁸ See chap. 19.

⁶⁹ See chap. 22.

marine-based renewable energy require ocean space, and wind farms already cover significant areas in the coastal North Sea. Wave and tidal energy will make equal, if not larger, demands. The location of wind, wave and tidal installations can have significant effects on marine biotas. Special care is needed in siting installations that can affect migration routes or feeding, breeding or nursery areas. This is therefore a field in which the requirements of the new energy sources for ocean space could be important competitors with other, longer-established uses or with the need to conserve marine biodiversity.⁷⁰

Fishery management areas

Capture fisheries have a very long history, predating newer ocean uses, such as aquaculture, offshore energy infrastructure, submarine cables, pipelines or tourism. The fishermen exploiting those long-practised fisheries usually have a feeling of “ownership”, even though they rarely have had any established legal rights to exclude others from their customary fishing grounds. There is a growing trend, however, as part of fishery management within national jurisdictions, for fishing enterprises or fishing communities (including indigenous fishing communities) to be recognized as having some form of rights to fish to a defined extent in a defined area. Those benefiting from such rights frequently see constraints on fishing from other activities in those defined areas as invasions of what they consider as entitlements. This is the “front line” of conflicts in uses. If it is not directly addressed, some ocean uses will find it difficult to thrive.⁷¹

Marine protected areas

The Plan of Implementation of the World Summit on Sustainable Development (Johannesburg Plan of Implementation),⁷² adopted in 2002, called for the implementation of marine protected areas. Although a marine protected area does not necessarily imply an area in which all human activities are excluded, in many cases it does imply that some, or most, such activities will be at least controlled or regulated. The commitment made by many States to a target for such protected areas of at least 10 per cent of the areas under their jurisdiction⁷³ will be a factor in future use of ocean space, given that, at present, marine protected areas represent a much smaller part of the ocean area under national jurisdiction.

Implications of demands for ocean space

That long list of types of human activity shows there are simply too many demands for all to be accommodated in a way that will not constrain some aspect of their operation. The allocation of ocean space is a much more complex task than that of land-use planning onshore. In the first place, the ocean is three-dimensional. Some uses can be in the same area but vertically separated, thus ships, for example, can pass over submarine cables without any problem, except in shallow water. Secondly, some uses are transient: ships and fishing vessels in particular pass and repass, and other uses may take place in the intervals between them. Thirdly, there is no general tradition of permanent rights of private ownership, even in areas under national jurisdiction. However, the more intense the shipping or fishing, the more difficult it is for other uses to be accommodated. Developing effective ways of organizing the allocation of ocean space is not an easy task, given the wide range of interests that need to be considered and reconciled.

F. Increasing inputs of harmful material

Land-based inputs

The agricultural and industrial achievements of the past two centuries in feeding, clothing and housing the world's population have been at the price of seriously degrading important parts of the planet, including much of the marine environment, especially near the coast. Urban growth, unaccompanied in much of the world by adequate disposal of human bodily wastes, has also imposed major pressures on the ocean. Land-based inputs to the ocean have thus contributed much to the degradation of the marine environment. The Global Programme of Action for the Protection of the Marine Environment from Land-based Activities of 1995 highlighted the need for action to deal with sewage (including industrial wastes that are mixed with human bodily wastes) in developing countries. Although much has been done to implement national plans adopted under the Programme, particularly in South America, the lack of sewage systems and wastewater treatment plants is still a major threat to the ocean. This is particularly the case for very large urban settlements.⁷⁴

Several aspects have to be considered in relation to the increasing inputs of harmful material from the land into the ocean.

Heavy metals and other hazardous substances

From the point of view of industrial development, many industrial processes have brought with them serious environmental damage, especially when the concentration of industries have led to intense levels of inputs to the sea of wastes which could not be assimilated. That damage is largely caused by heavy metals (especially lead, mercury, copper and zinc). With the development of organic chemistry, new substances have been created to provide important services in managing electricity (for example, polychlorinated biphenyls) and as pesticides. Chlorine has also been widely used in many industrial processes (such as pulp and paper production), producing hazardous by-products. Many of those chemical products and processes have proved to have a wide range of hazardous side-effects.

There are also problems from imperfectly controlled incineration, which can produce polycyclic aromatic hydrocarbons and, where plastics are involved, dioxins and furans. All those substances have adverse effects on the marine environment. As well as the long-known hazardous substances, there is evidence that some substances (often called endocrine disruptors), which do not reach the levels of toxicity, persistence and bioaccumulation⁷⁵ in the accepted definitions of hazardous substances, can disrupt the endocrine systems of humans and animals, with adverse effects on their reproductive success. Action is already being taken on several of those, but more testing is needed to clarify whether action is needed on others.

Over time, steps have been taken to reduce or, where possible, eliminate many of the impacts of heavy metals and hazardous substances. In some parts of the world, the efforts of the past 40 years have been successful, and concentrations in the ocean of many of the most seriously damaging heavy metals and other hazardous substances are now diminishing, for example in the North-East Atlantic, even though problems persist in some local areas. New technologies and processes have also been widely developed that have the ability to avoid those problems, but there are gaps in the capacities to apply those newer processes, often because of the costs involved.

The differential growth in industrial production between countries bordering the North Atlantic, on the one hand, and those bordering the South Atlantic, the Indian Ocean and the Pacific, on the other hand, means that much of that growth is now taking place in parts of the world that had not previously had to deal with industrial discharges on the

⁷⁴ See chap. 20.

⁷⁵ Bioaccumulation is the process whereby substances are ingested by animals and other organisms, but not broken down or excreted, and thus build up in their bodies.

current scale. In the past, industrial production had been dominated by the countries around the North Atlantic basin and its adjacent seas, as well as Japan. Over the past 25 years, the rapid growth of industries along the rest of the western Pacific rim and around the Indian Ocean has dramatically changed that situation. The world's industrial production and the associated waste discharges are rapidly growing in the South Atlantic, the Indian Ocean and the western Pacific. Even if the best practicable means are used to deal with heavy metals and hazardous substances in the waste streams from those growing industries, the growth in output and consequent discharges will increase the inputs of heavy metals and other hazardous substances into the ocean. It is therefore urgent to apply new less-polluting technologies, where they exist, and means of removing heavy metals and other hazardous substances from discharges, if the level of contamination of the ocean, particularly in coastal areas, is not to increase.

Frameworks have also emerged at the international level for addressing some of the problems caused by heavy metals and hazardous substances. In particular, the Stockholm Convention on Persistent Organic Pollutants⁷⁶ and the Minamata Convention on Mercury⁷⁷ provide agreed international frameworks for the States party to them to address the issues that they cover. Implementing them, however, will require much capacity-building.⁷⁸

Oil

Although pollution from oil and other hydrocarbons is most obviously linked to offshore production and their maritime transport, substantial inputs of hydrocarbons occur from land-based sources, particularly oil refineries. In some parts of the world, it has proved possible to reduce such pressures on the marine environment substantially.⁷⁹

Agricultural inputs

The agricultural revolution of the last part of the twentieth century, which has largely enabled the world to feed its rapidly growing population, has also brought with it problems for the ocean in the form of enhanced run-off of both agricultural nutrients and pesticides, as well as the airborne and waterborne inputs of nutrients from waste from agricultural stock. In the case of fertilizers, their use is rapidly growing in parts of the world where only limited use had occurred in the past. That growth has the potential to lead to increased nutrient run-off to the ocean if the increased use of fertilizers is not managed well. There are therefore challenges in educating farmers, promoting good husbandry practices that cause less nutrient run-off and monitoring what is happening to agricultural run-off alongside sewage discharges. In the case of pesticides, the issues are analogous to those of industrial development. Newer pesticides are less polluting than older ones, but there are gaps in the capacity to ensure that these less-polluting pesticides are used, in terms of educating farmers, enabling them to afford the newer pesticides, supervising the distribution systems and monitoring what is happening in the ocean.

Eutrophication

Eutrophication resulting from excess inputs of nutrients from both agriculture and sewage causes algal blooms. Those can generate toxins that can make fish and other seafood unfit for human consumption. Algal blooms can also lead to anoxic areas (i.e. dead zones) and hypoxic zones. Such zones have serious consequences from environmental, economic and social aspects. The anoxic and hypoxic zones drive fish away and kill the benthic wildlife. Where those zones are seasonal, any regeneration that happens is usually at a lower trophic level, and the ecosystems are therefore

⁷⁶ United Nations, *Treaty Series*, vol. 2256, No. 40214.

⁷⁷ United Nations Environment Programme, document UNEP(DTIE)/Hg/CONF/4, annex II.

⁷⁸ See chap. 20.

⁷⁹ See chap. 20.

degraded. This seriously affects the maritime economy, both for fishermen and, where tourism depends on the attractiveness of the ecosystem (for example, around coral reefs), for the tourist industry. Social consequences are then easy to see, both through the economic effects on the fishing and tourist industries and in depriving the local human populations of food.⁸⁰

Radioactive substances

In the case of radioactive discharges into the ocean, there have been, in the past, human activities that have given rise to concern, but responses to those concerns, and the actions taken, have largely removed the underlying problems, even though there is a continuing task to monitor what is happening to radioactivity in the ocean. In particular, the ending of atmospheric tests of nuclear weapons and, more recently, the improvements made in the controls on discharges from nuclear reprocessing plants have ended or reduced the main sources of concern. What remains is the risk voiced in the Global Programme of Action that public reaction to concerns about marine radioactivity could result in the rejection of fish as a food source, with consequent harm to countries that have a large fishery sector and damage to the world's ability to use the important food resources provided by the marine environment.⁸¹

Solid waste disposal

The dumping of waste at sea was the first activity capable of causing marine pollution to be brought under global regulation, in the form of the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, 1972⁸² (the London Convention), regulating the dumping of wastes and other matter at sea from ships, aircraft and man-made structures. The controls under that agreement have been progressively strengthened, particularly in the 1996 Protocol to the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, 1972⁸³ which introduced the approach of a total ban on dumping, subject to limited exemptions. If the Convention or the Protocol were effectively and consistently implemented, that source of inputs of harmful substances would be satisfactorily controlled. However, there are gaps in knowledge about their implementation. Over half of the States party to the London Convention and the Protocol thereto do not submit reports on dumping under their control. This may mean that there is no such dumping, but it may also mean that the picture presented by the reports that are submitted is incomplete. Some of the world's largest economies have not become party to either agreement, and nothing is known of what is happening with respect to dumping under their control. The reported dumping is very largely of dredged material, most of it from the creation or maintenance of ports. Clear guidance under the London Convention lays down the conditions under which that material may be dumped. To the extent that that guidance is followed, there should be no significant impact on the marine environment, except for the smothering of the seabed, and to the extent that the dump sites are in areas with dynamic tidal activity, even that impact will be limited. There is also some evidence that illegal dumping is taking place, including that of radioactive waste, but complete proof of this has not been obtained.⁸⁴

Marine debris

Marine debris is present in all marine habitats, from densely populated regions to remote points far from human activities, from beaches and shallow waters to the deepest ocean trenches. It has been estimated that the average density of marine debris varies between 13,000 and 18,000 pieces per square kilometre. However, data on plastic accumulation in the North Atlantic and Caribbean from 1986 to 2008 showed

⁸⁰ See chap. 20.

⁸¹ See chap. 20.

⁸² United Nations, *Treaty Series*, vol. 1046, No. 15749.

⁸³ International Maritime Organization, document IMO/LC.2/Circ.380.

⁸⁴ See chap. 24.

that the highest concentrations (more than 200,000 pieces per square kilometre) occurred in the convergence zones between two or more ocean currents. Computer model simulations, based on data from about 12,000 satellite-tracked floats deployed since the early 1990s as part of the Global Ocean Drifter Program, confirm that debris will be transported by ocean currents and will tend to accumulate in a limited number of subtropical convergence zones or gyres.

Plastics are by far the most prevalent debris item recorded, contributing an estimated 60 to 80 per cent of all marine debris. Plastic debris continues to accumulate in the marine environment. The density of microplastics within the North Pacific Central Gyre has increased by two orders of magnitude in the past four decades. Marine debris commonly stems from shoreline and recreational activities, commercial shipping and fishing, and dumping at sea. The majority of marine debris (approximately 80 per cent) entering the sea is considered to originate from land-based sources.⁸⁵

Nanoparticles are a form of marine debris, the significance of which is emerging only now. They are minuscule particles with dimensions of 1 to 100 nanometres (a nanometre is one millionth of a millimetre). A large proportion of the nanoparticles found in the ocean are of natural origin. It is the anthropogenic nanoparticles that are of concern. Those come from two sources: on the one hand, from the use of nanoparticles created for use in various industrial processes and cosmetics and, on the other hand, from the breakdown of plastics in marine debris, from fragments of artificial fabrics discharged in urban wastewater, and from leaching from land-based waste sites. Recent scientific research has highlighted the potential environmental impacts of plastic nanoparticles: they appear to reduce the primary production and the uptake of food by zooplankton and filter-feeders. Nanoparticles of titanium dioxide, which is widely used in paints and metal coatings and in cosmetics, are of particular concern. When nanoparticles of titanium dioxide are exposed to ultraviolet radiation from the sun, they transform into a disinfectant and have been shown to kill phytoplankton, which are the basis of primary production. The scale of the threats from nanoparticles is unknown, and further research is required.⁸⁶

Shipping

Pollution from ships takes the form of both catastrophic events (shipwrecks, collisions and groundings) and chronic pollution from regular operational discharges. Good progress has been made over the past 40 years in reducing both. There have been large increases in the global tonnage of cargo carried by sea and in the distances over which those cargoes are carried. There have also been steady increases in the number of passengers carried on cruise ships and ferries. In spite of this, the absolute number of ship losses has steadily decreased. Between 2002 and 2013, the number of losses of ships of over 1,000 gross tonnage thus dropped by 45 per cent to 94. This is largely due to efforts under the three main international maritime safety conventions: the International Convention on the Safety of Life at Sea,⁸⁷ dealing with ship construction and navigation, the International Convention on Standards of Training, Certification and Watchkeeping for Seafarers, 1978,⁸⁸ dealing with crew, and the International Convention for the Prevention of Pollution from Ships (MARPOL).

Pollution from oil has been the most significant type of marine pollution from ships. The number of spills exceeding 7 tons has dropped steadily, in spite of the growth in the quantity carried and the length of voyages, from over 100 spills in 1974 to under five in 2012. The total quantity of oil released in those spills has also been reduced by an even greater factor. Progress has also been made in improving response capabilities, though much remains to be done, especially as coastal States have to bear the capital cost of acquiring the necessary equipment. Reductions in oil pollution have resulted from more

⁸⁵ See chap. 25.

⁸⁶ See chaps. 6 and 25.

⁸⁷ United Nations, *Treaty Series*, vol. 1184, No. 18961.

⁸⁸ United Nations, *Treaty Series*, vol. 1361, No. 23001.

effective enforcement of the MARPOL requirements, particularly in western Europe. The changes in arrangements for reparation for any damage caused by oil pollution from ships have improved the economic position of those affected.

In spite of all that progress, oil discharges from ships remain an environmental problem, for example, around the southern tip of Africa and in the North-West Atlantic. Off the coast of Argentina, however, a solution to the impact of those discharges on penguin colonies seems to have been found by rerouting coastal shipping. The likely opening of shipping routes through the Arctic between the Atlantic and the Pacific risks introducing that form of pollution into a sea area where response infrastructure is lacking, oil recovery in freezing conditions is difficult and the icy water temperature inhibits the microbial breakdown of the oil.⁸⁹

Pollution from cargoes of hazardous and noxious substances appears to be a much smaller problem, even though there are clearly problems with misdescriptions of the contents of containers. Losses of containers, however, appear to be relatively small: in 2011, the losses were estimated at 650 containers out of about 100 million carried in that year.

Sewage pollution from ships is mainly a problem with cruise ships: with up to 7,000 passengers and crew, they are the equivalent of a small town and can contribute to local eutrophication problems. The local conditions around the ship are significant for the impact of any sewage discharges. The increased requirements under MARPOL on the discharges of ship sewage near the shore are likely to reduce the problems, but the identification of the cases where ships have contributed to eutrophication problems will remain difficult.

The dumping of garbage from ships is a serious element of the problem of marine debris. In 2013, new, more stringent controls under MARPOL came into force. Steps are being taken to improve the enforcement of those requirements. For example, the World Bank has helped several small Caribbean States to set up port waste-reception facilities, which has made it possible for the Wider Caribbean to be declared a special area under annex V of the Convention, under which stricter requirements apply. Other States (for example the Member States of the European Union) have introduced requirements for the delivery of waste ashore before a ship leaves port and have removed economic incentives to avoid doing so. It is, however, too early to judge how far those various developments have succeeded in reducing the problem.⁹⁰

Offshore hydrocarbon industries

Major disasters in the offshore oil and gas industry have a global, historical recurrence of one about every 17 years. The most recent is the Deepwater Horizon blowout of 2010, which spilled 4.4 million barrels (about 600,000 tons) of oil into the Gulf of Mexico. The other main harmful inputs from that sector are drilling cuttings (contaminated with drilling muds) resulting from the drilling of exploration and production wells, “produced water” (the water contaminated with hydrocarbons that comes up from wells, either of natural origin or through having been injected to enhance hydrocarbon recovery), and various chemicals that are used and discharged offshore in the course of exploration and exploitation.

Those materials can be harmful to marine life under certain circumstances. However, it is possible to take precautions to avoid such harm, for example by prohibiting the use of the most harmful drilling muds, by limiting the proportion of oil in the produced water that is discharged or by controlling which chemicals can be used offshore. Such regulation has been successfully introduced in a number of jurisdictions. Nonetheless, given the growth in exploration and offshore production, there is no doubt that those inputs are increasing over time, even though exact figures are not available globally.

⁸⁹ See chap. 17.

⁹⁰ See chaps. 17 and 25.

Produced water, in particular, increases in quantity with the age of the field being exploited.⁹¹

Offshore mining

The environmental impacts of near-shore mining are similar to those of dredging operations. They include the destruction of the benthic environment, increased turbidity, changes in hydrodynamic processes, underwater noise and the potential for marine fauna to collide with vessels or become entangled in operating gear.⁹²

Implications for human well-being and biodiversity

Human health, food security and food safety

Marine biotas are under many different pressures from hazardous substances on reproductive success. Dead zones and low-oxygen zones resulting from eutrophication and climate change can lead to systematic changes in the species structure at established fishing grounds. Either can reduce the extent to which fish and other species used as seafood will continue to reproduce at their historical rates. When those effects are combined with those of excessive fishing on specific stocks, there are risks that the traditional levels of the provision of food from the sea will not be maintained.

In addition, heavy metals and other hazardous substances represent a direct threat to human health, particularly through the ingestion of contaminated food from the sea. The episode of mercury poisoning at Minamata, in Japan, is probably the most widely known event of that kind, and the reason why the global convention to address such problems is named after the town. There are places around the world where local action has been taken to prevent or discourage the consumption of contaminated fish and other seafood. In other places, monitoring suggests that levels of contamination dangerous for human health are being reached. In yet other places, there are inadequate monitoring systems to check on risks of that kind. Ensuring linkages between adequate systems for controlling the discharge and emissions of hazardous substances and the systems for controlling the quality of fish and other seafood available for human consumption is therefore an important issue. In the case of subsistence fishing, the most effective approach is to ensure that contamination does not occur in the first place.

The lack of proper management of wastewater and human bodily wastes causes problems for human health, both directly through contact with water containing pathogens and through bacteriological contamination of food from the sea, and indirectly by creating the conditions in which algal blooms can produce toxins that infect seafood. Those problems are particularly significant in and near large and growing conurbations without proper sewage treatment systems, such as found in many places in developing countries.⁹³

Impacts on marine biodiversity

Part of the standard definition of hazardous substances in the context of marine pollution is that they are bioaccumulative — that is, once they are taken into an organism, they are not broken down or expelled, and continue to accumulate in it. Because of that characteristic, they also are accumulated more in the higher levels of the food web. As creatures at the lower levels are eaten by those at higher levels, the hazardous substances in the former are retained and accumulated by the latter. Some of those substances affect the reproductive success of the biota in which they have accumulated. There are also some effects on immune systems, with the result that individuals and populations become less resistant to outbreaks of disease. The deaths of many seals in the North-East Atlantic in the 1990s from the phocine distemper virus

⁹¹ See chap. 21.

⁹² See chap. 23.

⁹³ See chaps. 4-6, 10-12, 15 and 20.

have thus been linked to impaired immune systems. Likewise, improvements in a fish-health index in the same area in the 2000s have been attributed to reductions in the local concentrations of various hazardous substances.

The combined effects of hazardous substances, marine debris, oil and eutrophication (including the large and growing number of dead zones) resulting from the input of harmful material, waste and excessive amounts of nutrients into the ocean therefore represent a significant pressure on marine biodiversity.⁹⁴

G. Cumulative impacts of human activities on marine biodiversity

When the many pressures described above, from fishing and other types of marine harvesting to demand for ocean space and inputs of harmful materials, are brought together, the result is a complex but dangerous mix of threats to marine biodiversity. To those threats must be added several other significant factors. Those arise from a number of separate sources, including noise from ships and seismic exploration and the introduction of competing non-native species by aquaculture and long-distance shipping (and their further distribution by recreational boats). Taken altogether, those factors represent a massive set of pressures on marine biodiversity.⁹⁵

Implications for marine biodiversity

Such cumulative impacts of human uses are reported in all the regional biodiversity assessments in part VI of the present Assessment. There are indeed well-documented examples of cases where habitats, lower-trophic-level productivity, benthic communities, fish communities and seabird or marine mammal populations have been severely altered by pressures from a specific activity or factors (such as overfishing, pollution, nutrient loading, physical disturbance or the introduction of non-native species). However, many impacts on biodiversity, particularly at larger scales, are the result of the cumulative and interactive effects of multiple pressures from multiple drivers. It has repeatedly proved difficult to disentangle the effects of the individual pressures, which impedes the ability to address the individual causes.⁹⁶

Even in the Arctic Ocean, where human settlements are relatively few and small, the potentially synergistic effects of multiple stressors come together. Furthermore, those stressors operate against a background of pressures from a changing climate and increasing human maritime activity, primarily related to hydrocarbon and mineral development and to the opening of shipping routes. Those changes bring risks of direct mortality, displacement from critical habitats, noise disturbance and increased exposure to hunting, which are superimposed on high levels of contaminants, notably organochlorines and heavy metals, as a result of the presence of those substances in the Arctic food web.⁹⁷

In the open ocean (remote from land-based inputs), shifts in bottom-up forcing (that is, primary productivity) and competitive or top-down forcing (that is, by large predators) will also produce complex and indirect effects on ecosystem services. The stress imposed by low oxygen, low pH (that is, higher acidity) or elevated temperatures can reduce the resilience of individual species and ecosystems through shifts in organism tolerance and community interactions. Where this happens, it retards recovery from disturbances caused by human activities, such as oil spills, trawling and (potentially in the future) seabed mining. Slower growth of carbonate skeletons due to increased ocean acidification, delayed development under hypoxic conditions and increased respiratory demands with declining food availability illustrate how climate change could

⁹⁴ See chaps. 4-6, 20, 21, 25, 36A-H and 52.

⁹⁵ See chaps. 11, 12, 17-23 and 25-27.

⁹⁶ See chaps. 36A-H and 53.

⁹⁷ See chap. 36G.

exacerbate anthropogenic impacts and compromise deep-sea ecosystem structures and functions, and ultimately its benefits to human welfare.⁹⁸

Those multiple pressures interact in ways that are poorly understood but that can amplify the effects expected from each pressure separately. The North Atlantic has been, comparatively, the subject of much scientific research. It has many long-term ocean-monitoring programmes and a scientific organization that has functioned for over a century to promote and coordinate scientific and technical cooperation among the countries around the North Atlantic. Even there, however, experts are commonly unable to disentangle consistently the causation of unsustainable uses of, and impacts on, marine biodiversity. This may initially seem to be discouraging. Nevertheless, well-documented examples exist of the benefits that can follow from actions to address past unsustainable practices, even if other perturbations are also occurring in the same area.⁹⁹

Marine mammals, marine reptiles, seabirds, sharks, tuna and billfish

Cumulative effects are comparatively well documented for species groups of the top predators in the ocean, including marine mammals, seabirds and marine reptiles. Many of those species tend to be highly mobile and some migrate across multiple ecosystems and even entire ocean basins, so that they can be exposed to many threats in their annual cycle. Some of those species are the subject of direct harvesting, particularly some pinnipeds (seals and related species) and seabirds, and by-catch in fisheries can be a significant mortality source for many species. However, in addition to having to sustain the impact of those direct deaths, all of those species suffer from varying levels of exposure to pollution from land-based sources and increasing levels of noise in the ocean. Land-nesting seabirds, marine turtles and pinnipeds also face habitat disturbance, such as through the introduction of invasive predators on isolated breeding islands, the disturbance of beaches where eggs are laid or direct human disturbance from tourism, including ecotourism.¹⁰⁰

Some global measures have been helpful in addressing specific sources of mortality, such as the global moratorium on all large-scale pelagic drift-net fishing called for by the General Assembly in 1991, which was a major step in limiting the by-catch of several marine mammal and seabird species that were especially vulnerable to entanglement. However, for seabirds alone, at least 10 different pressures have been identified that can affect a single population throughout its annual cycle, with efforts to mitigate one pressure sometimes increasing vulnerability to others. Because of the complexity of those issues, conservation and management must therefore be approached with care and alertness to the nature of the interactions among the many human interests, the needs of the animals and their role in marine ecosystems.¹⁰¹

Ecosystems and habitats identified for special attention

Just as species can face the effects of multiple pressures over their annual cycle as they migrate (sometimes around an entire ocean basin), habitats can integrate the effects of multiple pressures across the interacting species that use them. Many cases are presented in the chapters on specialized habitats, which are often sites of concentrated human activities. For example, warm-water corals face major threats, such as extractive activities, sewage and other pollution, sedimentation, physical destruction and the effects of anthropogenic climate change, including increased coral bleaching. Such stressors often interact synergistically with one another and with natural stressors, such as storms. Likewise, cold-water corals are often challenged by the synergistic effects of

⁹⁸ See chaps. 4-6, 11, 17, 20, 36F, 37-39 and 52.

⁹⁹ See chap. 36A.

¹⁰⁰ See chaps. 27, 37-39 and 52.

¹⁰¹ See chaps. 11 and 38.

low oxygen and increasing acidification, as well as by physical damage from fishing practices.¹⁰²

All coastal habitats, including kelp forests, seagrass beds and mangroves, face multiple interacting threats from land-based sources, species invasions and direct anthropogenic pressures. For example, mangroves may face the aggregate effects of coastal and urban development, sewage and other pollutants, solid waste disposal, damage from extreme events, such as hurricanes, as well as conversion to aquaculture or agriculture and climate change. Each of the chapters on specific habitats presents similar lists of pressures, often present on the same sites. Although protection from direct human uses of areas where habitats occur (such as bans on converting mangroves to aquaculture or port facilities) can often produce immediate benefits, pressures such as land-based runoff, diseases and invasive species require coordinated efforts far beyond the specific habitats for which the protection is intended.¹⁰³

Considering specific types of important marine and coastal habitats, estuaries and deltas are categorized globally as in poor overall condition, based on published assessments of them for 101 regions. In 66 per cent of cases, their condition has worsened in recent years. There are around 4,500 large estuaries and deltas worldwide, of which about 10 per cent benefit from some level of environmental protection. About 0.4 per cent is protected as strict nature reserves or wilderness areas (categories Ia and Ib of the categories of protected areas as defined by the International Union for Conservation of Nature).¹⁰⁴

Mangroves are being lost at the mean global rate of 1-2 per cent a year, although losses can be as high as 8 per cent a year in some countries. While the primary threat to mangroves is overexploitation of resources and the conversion of mangrove areas to other land uses, climate-change-induced sea-level rise is now identified as a global threat to them, especially in areas of growing human settlements and coastal development.¹⁰⁵

Kelp and seagrass habitats are declining worldwide for different reasons. The overfishing of dominant predators and climate change have reportedly caused changes in kelp community structures and distribution over time. Kelp forests are more affected by temperature changes owing to the narrow range in which their sexual reproduction can occur. Seagrass meadows are more affected by anthropogenic activities, such as siltation, pollution and reclamation.¹⁰⁶

Fishing on seamounts has targeted fish aggregations to depths of 1,500 m. Aggregations on spatially limited topographic features are highly vulnerable, and many target species are slow-growing and long-lived, therefore exhibiting little resilience to disturbance. Furthermore, most fisheries use bottom trawls, gear that is highly destructive to benthic communities. Little recolonization is observed years after closure to fishing. Most sites of deep-water bottom fisheries have been overfished in the past, but there are now increased efforts to seek to regulate their use and to protect deep-water benthic habitats.¹⁰⁷

¹⁰⁷ See chaps. 36F and 51.

Tourism and aesthetic, cultural, religious and spiritual marine ecosystem services

The changes in marine biodiversity can have consequential effects on the ecosystem services that humans obtain from the ocean. Particularly important is the link between the health of warm-water corals and tourism. Warm-water corals represent a major component of the attractiveness of many tourist resorts in the Caribbean, the Red Sea, the Indian Ocean and South-East Asia, and that attractiveness will be seriously undermined if tourists can no longer enjoy the corals. The same applies to other resorts (even in cold-water areas) where one of the attractions is scuba-diving to enjoy the marine wildlife. A different linkage is that to recreational fishing, where a significant industry relies on the availability of large sport fish such as marlins, swordfish and sailfish. In that case, there is a lack of information on which estimates of fish stocks and, consequently, judgements on the sustainable scale of the activity can be based.¹⁰⁸

The disappearance or, more commonly, the reduction in numbers of iconic species can likewise adversely affect traditional practices. For example, native people on the North-East Pacific coast have seen their traditional whale-hunting halted because of the past overharvesting of grey whales carried out by other people. That hunting was an integral part of their cultural heritage and the affected tribes consider the cultural loss to be very serious. Pollution can have similar effects. For example, the Faroese authorities (Denmark) are taking measures to control the traditional food obtained in the islands from pilot whales because of the high levels of pollutants accumulated in their tissues.¹⁰⁹

H. Distribution of ocean benefits and disbenefits

In assessing the social and economic aspects of the ocean, it is necessary to consider how different parts of the world, different States and different parts of society are gaining benefits (or suffering disbenefits) as a result of the ways in which human activities linked to the oceans are changing.

Changes in the universal ecosystem services from the ocean

The most obvious distributional effects of climate change relate to the rise in sea level. Some small island States are predicted to become submerged completely and some heavily populated deltas and other low-lying areas also risk inundation. Another important distributional effect is the poleward extension of major areas of storms, which is likely to lead to cyclones, hurricanes and typhoons in areas previously not seriously affected by them. Changes in patterns of variability of oscillations (such as the El Niño-Southern Oscillation) will bring climatic changes to many places and affect new areas, with consequent effects on agriculture and agricultural earnings.¹¹⁰

The changes in ocean conditions will affect many other ecosystem services indirectly. For example, some models predict that the warming ocean will increase the fish biomass available for harvesting in higher latitudes and decrease it in equatorial zones. This will shift provisioning services to benefit the middle and moderately high latitudes (which are often highly developed) at the expense of low latitudes, where small-scale (subsistence) fishing is often important for food security.¹¹¹

Developments in fish and seafood consumption

The Food and Agriculture Organization of the United Nations (FAO) estimates that total fish consumption, including all aquaculture and inland and marine capture fisheries, has been rising from 9.9 kg per capita in the 1960s to 19.2 kg per capita in 2012 — an average increase of 3.2 per cent a year over half a century. The distribution of

¹⁰⁸ See chaps. 27, 41 and 43.

¹⁰⁹ See chaps. 8 and 20.

¹¹⁰ See chaps. 4 and 5.

¹¹¹ See chaps. 11 and 15.

consumption per capita varies considerably, from Africa and Latin America and the Caribbean (9.7 kg) to Asia (21.6 kg), North America (21.8), Europe (22.0 kg) and Oceania (25.4 kg). Marine capture fisheries represent 51 per cent and marine aquaculture 13 per cent of the total production of fish (154 million tons), of which 85 per cent is used for food.

The annual consumption of fishery products per capita has grown steadily in developing regions (from 5.2 kg in 1961 to 17.0 kg in 2009) and low-income food-deficit countries (from 4.9 kg in 1961 to 10.1 kg in 2009). This is still considerably lower than in more developed regions, even though the gap is narrowing. A sizeable share of fish consumed in developed countries consists of imports and, owing to steady demand and declining domestic fishery production (down 22 per cent in the period 1992-2012), their dependence on imports, in particular from developing countries, is projected to grow.

FAO estimates indicate that small-scale fisheries contribute about half of global fish catches. When considering catches destined for direct human consumption, the share contributed by the subsector increases, as small-scale fisheries generally make broader direct and indirect contributions to food security (through affordable fish) and employment for populations in developing countries. As well as direct consumption, many small-scale fishermen sell or barter their catch. It is doubtful that much of that trade is covered by official statistics. However, studies have shown that selling or trading even a portion of their catch represents as much as one third of the total income of subsistence fishermen in some low-income countries. Thus an increase in imports of fish by more developed countries from less developed countries has the potential to increase inequities in food security and nutrition, unless those considerations are taken into account in global trade arrangements.¹¹²

Developments in employment and income from fisheries and aquaculture

The global harvest of marine capture fisheries has expanded rapidly since the early 1950s and is currently estimated to be about 80 million tons a year. That harvest is estimated to have a first (gross) value on the order of 113 billion dollars. Although it is difficult to produce accurate employment statistics, estimates using a fairly narrow definition of employment have put the figure of those employed in fisheries and aquaculture at 58.3 million people (4.4 per cent of the estimated total of economically active people), of which 84 per cent are in Asia and 10 per cent in Africa. Women are estimated to account for more than 15 per cent of people employed in the fishery sector. Other estimates, probably taking into account a wider definition of employment, suggest that capture fisheries provide direct and indirect employment for at least 120 million persons worldwide.

Small-scale fisheries employ more than 90 per cent of the world's capture fishermen and fish workers, about half of whom are women. When all dependants of those taking full- or part-time employment in the full value chain and support industries (boatbuilding, gear construction, etc.) of fisheries and aquaculture are included, one estimate concludes that between 660 and 820 million persons have some economic or livelihood dependence on fish capture and culture and the subsequent direct value chain. No sound information appears to be available on the levels of death and injury of those engaged in capture fishing or aquaculture, but capture fishing is commonly characterized as a dangerous occupation.

Over time, a striking shift has occurred in the operation and location of capture fisheries. In the 1950s, capture fisheries were largely undertaken by developed fishing States. Since then, developing countries have increased their share. As a broad illustration, in the 1950s, the southern hemisphere accounted for no more than 8 per cent of landed values. By the last decade, the southern hemisphere's share had risen to 20 per cent. In 2012, international trade represented 37 per cent of the total fish

¹¹² See chaps. 10, 11 and 15.

production in value, with a total export value of 129 billion dollars, of which 70 billion dollars (58 per cent) was exports by developing countries.¹¹³

Aquaculture is responsible for the bulk of the production of seaweeds. Worldwide, reports show that 24.9 million tons was produced in 2012, valued at about 6 billion dollars. In addition, about 1 million tons of wild seaweed were harvested. Few data were found on international trade in seaweeds, but their culture is concentrated in countries where consumption of seaweeds is high.¹¹⁴

Developments in maritime transport

All sectors of maritime transport (cargo trades, passenger and vehicle ferries and cruise ships) are growing in line with the world economy. It is not possible to estimate the earnings from those activities, as the structure of the companies owning many of the ships involved is opaque. It seems likely that many of the major cargo-carrying operators were making a loss in 2012, as a result of overcapacity resulting from the general economic recession. On the other hand, cruise operators reported profits. According to estimates by the United Nations Conference on Trade and Development, owners from five countries (China, Germany, Greece, Japan and the Republic of Korea) together accounted for 53 per cent of the world tonnage in 2013. It seems likely that profits and losses are broadly proportional to ownership. Among the top 35 ship-owning countries and territories, 17 are in Asia, 14 in Europe and 4 in the Americas.

Worldwide, there are just over 1.25 million seafarers, only about 2 per cent of whom are women, mainly in the ferry and cruise-ship sectors. The crews are predominantly from countries members of the Organization for Economic Cooperation and Development and Eastern Europe (49 per cent of the officers and 34 per cent of the ratings) and from Eastern and Southern Asia (43 per cent of the officers and 51 per cent of the ratings). Africa and Latin America are noticeably underrepresented, providing only 8 per cent of the officers and 15 per cent of the ratings. Pay levels of officers differ noticeably according to their origin, with masters and chief officers from Western Europe receiving on average a fifth or a quarter, respectively, more than those from Eastern Europe or Asia, while pay levels for engineer officers are more in line with one another. The recent entry into force of the Maritime Labour Convention, 2006 should be noted in the context of the social conditions of seafarers.

Statistics on the deaths of and injuries to seafarers are unreliable, and the Secretary-General of the International Maritime Organization has called for efforts to improve them. In general, it would appear that the levels of death and injury are worse than for many land-based industries. Over the past three decades, piracy and armed robbery have re-emerged as a serious risk to seafarers. Much attention has been focused on such attacks on ships in waters off Eastern Africa, but reports show that the problem is more widespread. In the past three years, action against attacks off Eastern Africa appears to have had some success, but attacks elsewhere are also of concern, especially in the South China Sea, the location of over half the incidents reported in 2013, and West Africa.¹¹⁵

Developments in offshore energy businesses

Global offshore oil production in mid-2014 was about 28 million barrels per day, which was worth about 3.2 billion dollars per day, and the industry directly employs about 200,000 people globally, mostly in the Gulf of Mexico (where about 60 per cent of the industry is located) and the North Sea. In the same year, the industry accounted for about 1.5 per cent of the gross domestic product (GDP) of the United States, 3.5 per cent of the GDP of the United Kingdom, 21 per cent of the GDP of Norway and 35 per cent of the GDP of Nigeria. The large majority of offshore hydrocarbon production is in the hands of international corporations or national companies usually working in

¹¹³ See chaps. 11 and 15.

¹¹⁴ See chap. 14.

¹¹⁵ See chap. 17.

partnership with them. This makes the tracking of the distribution of benefits from this sector, other than direct employment in extraction and processing, very difficult.¹¹⁶

Developments in offshore mining

There is limited information about the value of the offshore mining industry and the number of people it employs, but it is unlikely to be significant at present in comparison with terrestrial mining. For example, in the United Kingdom, which is the world's largest producer of marine aggregates, the industry directly employs approximately 400 people.¹¹⁷

Developments in tourism

Tourism has generally been increasing fairly steadily for the past 40 years (with occasional setbacks or slowing down during global recessions). In 2012, international tourism expenditure exceeded 1 billion dollars for the first time. Total expenditure on tourism, domestic as well as international, is several times that amount. The direct turnover of tourism contributed 2.9 per cent of gross world product in 2013, rising to 8.9 per cent when the multiplier effect on the rest of the economy is taken into account. The Middle East is the region where tourism plays the smallest part in the economy (6.4 per cent of GDP, including the multiplier effect), and the Caribbean is the region where it plays the largest part (13.9 per cent of GDP, including the multiplier effect).

Most reports of tourism revenues do not differentiate revenues from tourism directly related to the sea and the coast from other types of tourism. Even where tourism in the coastal zone can be separated from tourism inland, it may be generated by the attractions of the sea and coast or its maritime history, as it may be based on other attractions not linked to the marine environment. Consequently, the value of ocean-related tourism is a matter of inference. However, coastal tourism is a major component of tourism everywhere. In small island and coastal States, coastal tourism is usually predominant because it can only take place in the coastal zone in those countries. Particularly noteworthy is the way in which international tourism is increasing in Asia and the Pacific, both in absolute terms and as a proportion of world tourism. This implies that pressures from tourism are becoming of significantly more concern in those regions.

Tourism is also a significant component of employment. Globally, it is estimated that, in 2013, tourism provided 3.3 per cent of employment, when looking at the number of people directly employed in the tourism industry, and 8.9 per cent when the multiplier effect is taken into account. In the different regions, the proportion of employment supported by tourism is approximately the same as the share of GDP contributed by tourism, although, again, what proportion is based on the attractions of the sea and coast is not well known.¹¹⁸

Use of marine genetic material

The commercial exploitation of marine genetic resources had very modest beginnings in the twentieth century, particularly when measured against some estimates of the potential of the great diversity of species and biomolecules in the sea. Since 2000, the first drugs derived from marine organisms have been put into commerce (although, using the United States Food and Drug Administration approvals as a measure, only seven have so far received that approval). There has also been considerable growth in the use of marine natural products as food supplements and for other non-medical purposes. Economic and social aspects of the use of marine genetic material are therefore only just beginning to develop.¹¹⁹

¹¹⁶ See chap. 21.

¹¹⁷ See chap. 23.

¹¹⁸ See chap. 27.

¹¹⁹ See chap. 29.

Satellite national accounts

Information on the distribution of economic benefits from the ocean is hard to compile from current information sources. The work of the United Nations Statistics Division in developing a System of Environmental-Economic Accounting and an Experimental Ecosystem Accounting System seems likely to help to fill that information gap. In the same way, national satellite accounts dealing with tourism and fisheries should help to fill information gaps in those fields.¹²⁰

I. Integrated management of human activities affecting the ocean

The Regular Process is to provide an assessment of all the aspects of the marine environment relevant to sustainable development: environmental, economic and social. Even though the marine environment covers seven tenths of the planet, it is still only one component of the overall Earth system. As far as environmental aspects are concerned, major drivers of the pressures producing change in the ocean are to be found outside the marine environment. In particular, most of the major drivers of anthropogenic climate change are land-based. Likewise, the main drivers of increased pressures on marine biodiversity and marine environmental quality include the demand for food for terrestrial populations, international trade in products from land-based agriculture and industries and coastal degradation from land-based development and land-based sources.

Thus, as far as social and economic aspects of the marine environment are concerned, many of the most significant drivers are outside the scope of the present Assessment. For example, the levels of cargo shipping are driven mainly by world trade, which is determined by demand and supply for raw materials and finished products. The extent of cruising and other types of tourism is determined by the levels around the world of disposable income and leisure time. The patterns of trade in fish and other seafood and in cultural goods from the ocean are set by the location of supply and demand and the relative purchasing power of local markets as compared with international ones, modified by national and international rules on the exploitation of those resources. A wide range of factors outside the marine environment are thus relevant to policymaking for the marine environment.

The present Assessment of the marine environment cannot therefore reach conclusions on some of the main drivers affecting the marine environment without stepping well outside the marine environment and the competences of those carrying out the Assessment. It is essential to note, however, that the successful management of human activities affecting the marine environment will require the consideration of the full range of factors relating to human activities affecting the ocean.

Even within the scope of what has been requested, it has not proved possible to come to conclusions on one important aspect: a quantitative picture of the extent of many of the non-marketed ecosystem services provided by the ocean. Quantitative information is simply insufficient to enable an assessment of the way in which different regions of the world benefit from those services. Nor do current data-collection programmes appear to make robust regional assessments of ocean ecosystem services likely in the near future, especially for the less developed parts of the planet.¹²¹

The assessment of what is happening to aesthetic, cultural, religious and spiritual values is also very difficult. In essentially every coastal or island culture, the indigenous peoples have spiritual links to the sea. They often also have links with species or places, or both, that have high iconic values. The spiritual significance of those marine species and places may be part of their self-identification and reflects their beliefs about the origins of their culture. That is particularly true of island cultures, which are often intimately bound to the sea. Expressions of loss of, or threats to, such cultures and

¹²⁰ See chaps. 3 and 9.

¹²¹ See chaps. 54 and 55.

identities are readily found, but the marine component is not easily separated. Even populations that are economically fully developed with largely urbanized lifestyles still look to the ocean for spiritual and cultural benefits that have proven hard to value monetarily.¹²²

Nevertheless, there is an overall message that the world has reached the end of the period when human impacts on the sea were minor in relation to the overall scale of the ocean. Human activities now have so many and such great impacts on the ocean that the limits of its carrying capacity are being (or, in some cases, have been) reached. It is instructive to look at the ways in which this has happened in one specific sector: fisheries. In the late nineteenth century, the regulation of fisheries was regarded by many as unnecessary: Thomas Huxley, the great defender of Charles Darwin's theory of natural selection and a leading marine biologist, speaking at the London Fisheries Exhibition, in 1883, said: "In relation to our present modes of fishing, a number of the most important sea fisheries ... are inexhaustible. ... [The] multitude of those fishes is so inconceivably great that the number that we catch is relatively insignificant; and secondly, ... the magnitude of the destructive agencies at work on them is so prodigious, that the destruction effected by the fisherman cannot sensibly increase the death rate".

In less than 50 years, his qualification "in relation to our present modes of fishing" proved to be prophetic. Modes of fishing had changed to such an extent that international efforts were under way to regulate individual fisheries. We now know that those efforts were even then overdue. Furthermore, experience thereafter showed that the successful management of fisheries required a much broader approach. First to be acknowledged was the need for a multispecies approach: it was necessary to regulate the fisheries not only for each target species individually, but also to take into account the species on which the target species preyed and the species that preyed on it.

In the 1990s, it became clear that the effects of fisheries on other biotas made an ecosystem approach to fishery management necessary, taking into account how a fishery might directly kill other species through by-catches, alter habitats and change relationships in the food web. Since then, the increasing use of the ocean has shown how fisheries managers need to work with other sectors to manage their effects on each other and, collectively, on the ocean that they share.

When various conclusions in parts III to VI of the present Assessment are linked together, they clearly show that a similar broadening of the context of management decisions will produce similar benefits in and among other sectors of human activities that affect the ocean. Examples of such interactions of pressures on the environment include:

(a) The lack of adequate sewage treatment in many large coastal conurbations, especially in developing countries, and other excessive inputs of nutrients (especially nitrogen) are producing direct adverse impacts on human health through microbial diseases as well as eutrophication problems. In many cases, they are creating harmful algal blooms, which are not only disrupting ecosystems, but also, as a consequence, damaging fisheries, especially small-scale fisheries and the related livelihoods and, in some cases, poisoning humans through algal toxins;¹²³

(b) Plastic marine debris results from the poor management of waste streams on land and at sea. There is a clear impact of such debris in its original form on megafauna (fish caught in "ghost" nets, seabirds with plastic bags around their necks, etc.) and on the aesthetic appearance of coasts (with potential impacts on tourism). Less obviously, impacts on zooplankton and filter-feeding species have also been demonstrated from the nanoparticles into which those plastics break down, with potentially serious effects all the way up the food web. Likewise, nanoparticles from titanium dioxide (the base of

¹²² See chap. 8.

¹²³ See chap. 20.

white pigments found in many waste streams) have been shown to react with the ultraviolet component of sunlight and to kill phytoplankton;¹²⁴

(c) Although much is being done to reduce pollution from ships, there is scope for more attention to the routes that ships choose and the effects of those routes in terms of noise, chronic oil pollution and operational discharges;¹²⁵

(d) The cumulative effects of excessive nutrient inputs from sewage and agriculture and the removal of herbivorous fish by overfishing can lead to excessive algal growth on coral reefs. Where coral reefs are a tourist attraction, such damage can undermine the tourist business;¹²⁶

(e) The ocean is acidifying rapidly and at an unprecedented rate in the Earth's history. The impact of ocean acidification on marine species and food webs will affect major economic interests and could increasingly put food security at risk, particularly in regions especially dependent on seafood protein.¹²⁷

Better integrated management of human activities affecting the ocean can, in many cases, be achieved with existing knowledge. However, application of that knowledge in many countries requires improvements in the skills of those involved. The last section of the present summary deals with the gaps that have been identified in capacity-building. Furthermore, in many cases, better information is required. Significant knowledge gaps that would need to be filled in order to achieve more general improved and integrated management of human activities affecting the ocean are set out in the penultimate section of the summary.

J. Urgency of addressing threats to the ocean

The greatest threat to the ocean comes from a failure to deal quickly with the manifold problems that have been described above. Many parts of the ocean have been seriously degraded. If the problems are not addressed, there is a major risk that they will combine to produce a destructive cycle of degradation in which the ocean can no longer provide many of the benefits that humans currently enjoy from it.

In particular, the cumulative impact of many of the problems described in the present Assessment must be considered. As always, addressing one aspect of a challenge without considering the other factors involved risks undermining what can be achieved. This means that addressing some challenges may require also addressing the problems of fragmented data collection, which makes it difficult to obtain a clear picture of the overall problem, and uncoordinated action in different fields (in either geographic or thematic terms).

On the other hand, the Assessment contains many examples of efforts made to address individual problems that have resulted in improved ecosystems, economic benefits and improved livelihoods, even though other pressures could not be addressed at the same time. Feasible sectoral improvements do not need to be delayed until the benefits of integrated planning and management can be achieved. They can even facilitate action to address other pressures, either by demonstrating the gains from investing in improved management, or through bringing into clearer focus the costs imposed by other pressures.¹²⁸

Some of the specific threats (such as the intensification of typhoons and hurricanes and changes in the stratification of seawater) are inextricably bound with the problems of climate change and acidification and can only be addressed as part of those issues.

¹²⁴ See chaps. 6 and 25.

¹²⁵ See chap. 17.

¹²⁶ See chaps. 27 and 43.

¹²⁷ See chaps. 4, 5, 10 and 52.

¹²⁸ See, for example, chap. 36A.

However, many other threats derive from problems that are more local and constitute global problems simply because the same type of problem and threat occurs in many places. For most of those problems, techniques have been developed that can successfully address them. Implementing them successfully is then a question of building the capacities in infrastructure resources, organizational arrangements and technical skills.

Problems of that kind that can be addressed include:

- (a) Reducing inputs of hazardous substances, waterborne pathogens and nutrients;¹²⁹
- (b) Preventing maritime disasters due to the collision, foundering and sinking of ships, and implementing and enforcing international agreements on preventing adverse environmental impacts from ships;¹³⁰
- (c) Improving fishery management;¹³¹
- (d) Managing aquaculture;¹³²
- (e) Controlling tourism developments that will have adverse impacts on the future of the tourism industry in the locality where they occur;¹³³
- (f) Controlling solid waste disposal that can reach and affect the marine environment;¹³⁴
- (g) Improving the control of offshore hydrocarbon industries and offshore mining;¹³⁵
- (h) Establishing and maintaining marine protected areas.¹³⁶

VI. Knowledge gaps

Humans have been exploring the three tenths of the planet that is land for millennia. Serious scientific examination of the land and its plants and animals has been in progress for at least 500 years. Although humans have been using the ocean for millennia, it is only in the past 120 years or so that serious exploration of the seven tenths of the planet covered by the sea (other than charting coasts) has been in progress. It is therefore not surprising that our knowledge of the ocean is much more limited than our knowledge of the land. As the chapters of the present Assessment demonstrate, much is known about much of the ocean, but nowhere do we have the detailed knowledge desirable for the effective future management of human use of the ocean. In some parts of the world, we do not even have sufficient knowledge to apply properly the techniques that have been successfully developed elsewhere. We have a basic framework of understanding, but there are many gaps to be filled in.

The information that we need to understand the ocean can be divided into four main categories: (a) the physical structure of the ocean; (b) the composition and movement of the ocean's waters; (c) the biotas of the ocean; and (d) the ways in which humans interact with the ocean. The identification of the gaps in that knowledge is best based on a survey of the gaps revealed in the chapters of the Assessment. In general, we know least about the Arctic Ocean and the Indian Ocean. The parts of the Atlantic Ocean and the Pacific Ocean in the northern hemisphere are better studied than those in the

¹²⁹ See chap. 20.

¹³⁰ See chap. 17.

¹³¹ See chap. 11.

¹³² See chap. 12.

¹³³ See chap. 27.

¹³⁴ See chaps. 24 and 25.

¹³⁵ See chaps. 21 and 23.

¹³⁶ See chap. 44.

southern hemisphere and, again in general, the North Atlantic and its adjacent seas are probably the most thoroughly studied — and even there major gaps remain.¹³⁷

Physical structure of the ocean

Chapter 1 (Planet, ocean and life) of the Assessment includes a map characterizing the geomorphic features of the ocean. The detail summarized in that map has been greatly enriched over the past quarter century by local and global studies. Although charting the oceans has been in progress for more than seven centuries in coastal waters and for 250 years along the main routes across the open ocean, many features still require more detailed examination. The designation of exclusive economic zones (EEZs) has led many countries to carry out more detailed surveys as a basis for managing their activities in those zones. Ideally, all coastal States would have such detailed surveys as a basis for their EEZ management.

Because of the significance of ocean acidification for carbonate formation, better information on the formation and fate of reef islands and shell beaches is desirable. It is possible to characterize the physical structure of the ocean in areas beyond national jurisdictions, but the reliability and detail of such characterizations varies considerably among different parts of the ocean: improvements in information of that kind are highly desirable to understand the interaction between the physical structure and the biotas, both in terms of conserving biodiversity and in terms of managing living marine resources.¹³⁸

Waters of the ocean

Gaps persist in understanding sea temperature (both at the surface and at depth), sea-level rise, salinity distribution, carbon dioxide absorption, and nutrient distribution and cycling. The atmosphere and the ocean form a single linked system. Much of the information needed to understand the ocean is therefore also needed to understand climate change. Research promoted by the Intergovernmental Panel on Climate Change will look at many of those questions. It will thus be important to ensure that oceanic and atmospheric research is coordinated.

Ocean acidification is a consequence of carbon dioxide absorption, but understanding the implications for the ocean requires more than just a general understanding of how carbon dioxide is being absorbed, as the degree of acidification varies locally. The causes and implications of those variations are important for understanding the impact on the marine biotas.

In order to track primary production (on which the overwhelming majority of the ocean food web relies), routine and sustained measurements are highly desirable across all parts of the ocean of chlorophyll a (as an important marker of primary production), dissolved nitrogen and biologically active dissolved phosphorus (as the latter two are frequent limiting factors of primary production or causes of algal blooms).¹³⁹

Biotas of the ocean

The Census of Marine Life has been an essential tool for ocean research in clarifying the biodiversity of the ocean and the number and distribution of species. Like all censuses, its value will decrease as time passes until it becomes a snapshot of a particular point in time, and less of an up-to-date picture of what is currently happening. It will be important for the Census to be regularly updated and improved. Improvement is particularly desirable for areas around and between Africa and Central and South America, across the Indian Ocean and in the South Pacific.¹⁴⁰

¹³⁷ See chap. 30.

¹³⁸ See chap. 9.

¹³⁹ See chap. 9.

¹⁴⁰ See chap. 35.

Plankton are fundamental to life in the ocean. Information on their diversity and abundance is important for many purposes. Such information has been collected for over 70 years in some parts of the ocean (such as the North Atlantic) through continuous plankton recorder surveys. Nine organizations currently collaborate in extending such surveys, but the desirable comprehensive global coverage has not yet been achieved.

As well as information on biodiversity in the ocean and the number and distribution of the many marine species, information is also highly desirable on the health and reproductive success of separate populations. Many species contain separate populations that have limited interconnections. It is therefore important to understand how the local influences specific to each population are affecting them. As the regional surveys in part VI show, much is already known about the population health and reproductive success of many species, but there are also large gaps in knowledge, particularly in the southern hemisphere.¹⁴¹

Fish stock assessments are essential to the proper management of fisheries. A good proportion of the fish stocks fished in large-scale fisheries are the object of regular stock assessments. However, many important fish stocks of that kind are still not regularly assessed. More significantly, stocks important for small-scale fisheries are often not assessed, which has adverse effects in ensuring the continued availability of fish for such fisheries. This is an important knowledge gap to fill. Likewise, there are gaps in information about the interactions between large-scale and small-scale fisheries for stocks over which their interests overlap, and between recreational fishing and other fisheries for some species, such as some trophy fish (marlins, sailfish and others) and other smaller species.¹⁴²

The present Assessment sets out the main specific issues for which there are gaps in our knowledge of marine biotas, in particular of all the species and habitats that have been scientifically identified as threatened, declining or otherwise in need of special attention or protection. Those species include, with some indications of important issues identified in part VI: marine mammals, sea turtles, seabirds (particularly migration routes), sharks and other elasmobranchs (especially the lesser-known species and certain tropical areas), tuna and billfish (particularly the non-principally marketed species), cold-water corals (especially where they are found in the Indian Ocean), warm-water corals (particularly at locations in deeper water), estuaries and deltas (particularly integrated assessments of them), high-latitude ice, hydrothermal vents (especially the extent to which they are found in the Indian Ocean), kelp forests and seagrass beds (especially the degree of loss of kelp and the pathology of the diseases affecting them), mangroves (especially the taxonomy of associated species and their interactions with salt marshes), salt marshes (especially the ecosystem services that they provide) and the Sargasso Sea (especially the links with distant ecosystems).¹⁴³

Ways in which humans interact with the ocean

Some of the issues relating to the ocean and to the ocean biotas (for example, ocean acidification and fish stock assessments) are linked to the way in which humans affect some aspects of the ocean (for example, through carbon-dioxide emissions or fisheries). However, there are many more areas in which we do not yet know enough about human activities that affect or interact with the ocean to enable us to manage those activities sustainably.

For shipping, much information is available about where ships go, their cargo and the economics of their operations. However, important gaps remain in our knowledge about how their routes and operations affect the marine environment. Those issues include primarily the noise that they make, chronic discharges of oil and the extent to which non-native invasive species are being transported. Other information gaps relate to the

¹⁴¹ See chaps. 36A-H.

¹⁴² See chaps. 11 and 27.

¹⁴³ See chaps. 42 to 51.

social aspects of shipping: in particular, little is known about the levels of death and injury of seafarers, an issue recently raised by the Secretary-General of the International Maritime Organization.¹⁴⁴

Land-based inputs to the ocean have serious implications for both human health and the proper functioning of marine ecosystems. In some parts of the world, those have been studied carefully for over 40 years. In others, little systematic information is found. There are two important gaps in current knowledge. The first is how to link different ways of measuring discharges and emissions. Much information is available from local studies about inputs, but those are frequently measured and analysed in different ways, thereby making comparison difficult or impossible. There are sometimes good reasons for using different techniques, but ways of improving the ability to achieve standardized results and to make comparisons are essential to give a full global view. Secondly, different regions of the world have developed different systems for assessing the overall quality of their local waters. Again, good reasons for such differences almost certainly exist, but knowledge of how to compare the different results would be helpful, particularly in assessing priorities among different areas.¹⁴⁵

Another area where there are important gaps in knowledge is the extent to which people are suffering from diseases that are either the direct result of inputs of waterborne pathogens or toxic substances, or the indirect result of toxins from algal blooms generated by excessive levels of nutrients. As well as gaps in information on the effects of such health hazards, there are also large gaps in knowledge of their economic effects.

The offshore hydrocarbon industries in some parts of the world collect and publish wide-ranging information on how their activities are affecting the local marine environment. In other parts of the world, little or no such information is found. Because the processes are very similar in most areas, filling the gaps in knowledge in what is happening around the world would be helpful.

The existing offshore mining industries are very diverse and, consequently, their impacts on the marine environment do not have much in common. Where they occur in the coastal zone, it is important that those responsible for integrated coastal zone management have good information on what is happening, particularly in relation to discharges of tailings and other disturbances of the marine environment. As offshore mining expands into deeper waters and areas beyond national jurisdiction, it will be important to ensure that information about their impacts on the marine environment is collected and published.¹⁴⁶

Information on the disposal of solid waste at sea (dumping) is very patchy. Where reports under the London Convention and the Protocol thereto are not submitted, it is not clear whether dumping does not occur or occurs but is not reported. This represents an important gap in knowledge. The absence of information on dumping, if any, in other jurisdictions also impedes the understanding of the impact on the marine environment of that form of waste disposal.¹⁴⁷

Our knowledge of marine debris has many gaps. Unless we understand better the sources, fates, and impacts of marine debris, we shall not be able to tackle the problems that it raises. Although the monitoring of marine debris is currently carried out in several countries around the world, the protocols used tend to be very different, preventing comparisons and the harmonization of data. Because marine debris is so mobile, the result is a significant gap in knowledge. There is also a gap in information for evaluating the impacts of marine debris on coastal and marine species, habitats, economic well-being, human health and safety, and social values. Because of their ability to enter into marine food chains, with a potential impact on human health, more

¹⁴⁴ See chap. 17.

¹⁴⁵ See chap. 20.

¹⁴⁶ See chap. 23.

¹⁴⁷ See chap. 24.

information on the origin, fate and effects of plastic microparticles and nanoparticles is highly desirable. Likewise, because of their potential effects on phytoplankton, there is a gap in knowledge about titanium dioxide nanoparticles.¹⁴⁸

Many aspects of integrated coastal zone management still present important knowledge gaps. Those responsible for managing coastal areas need information on, at least, coastal erosion, land reclamation from the sea, changes in sedimentation as a result of coastal works and changes in river regimes (such as damming rivers or increased water abstraction), the ways in which the local ports are working and dredging is taking place and the ways in which tourist activity is developing (and is planned to develop), and the impacts that those developments and plans are likely to have on the local marine ecosystem (and, for that matter, the local terrestrial ecosystems). It will help the development and effectiveness of integrated coastal management if recognized standards are set and followed for all such information, so that systematic best practices can be developed.¹⁴⁹

The aesthetic, cultural, religious and spiritual ways in which humans relate to the ocean are also linked to some gaps in our knowledge. Over the centuries, many cultures have built up broad traditional knowledge of the ocean. Such knowledge is often under pressure and will be lost if it is not recorded. For example, Polynesian traditional navigational knowledge was disappearing fast and has been recorded only just in time. Cultural practices (such as traditional Chinese and Iranian boatbuilding) are also disappearing and risk being lost for future generations.¹⁵⁰

Our knowledge of human interaction with the ocean is also very partial in terms of the ways in which we benefit from it. As has been noted above, it is not yet possible to place a value on the non-marketed ecosystem services derived from the ocean. There are many gaps in the information needed for such an exercise. Information on the effects of changes in the ways in which the planetary ecosystem works needs to be collected and evaluated, in order to permit an economic valuation of the choices for action that may have repercussions on non-marketed ecosystem services. The areas where such information seems particularly closely related to management decisions are integrated coastal zone management (including marine spatial management), offshore hydrocarbon exploitation, offshore mining, shipping routes, port development and waste disposal.¹⁵¹

Even with market-related ecosystem services and human activities, there are major information gaps. Such gaps include consistent definitions of what the ecosystem services and human activities cover, how to estimate the value of services and activities that are on the margins of the markets and, even more, the capture of the related data. Gaining a good understanding of the true overall economic situation of such activities as fishing, shipping and tourism would help to improve decision-making in those fields.¹⁵²

Closing those gaps in our knowledge would amount to an ambitious programme of research. Research is already taking place on many more issues on which more information is desirable (for example, on how the genetic resources of the ocean can be used and what the practical possibilities are for seabed mining). Collaboration and sharing will be important for making the best uses of scarce research resources.¹⁵³

VII. Capacity-building gaps

The knowledge gaps identified in the present Assessment all point to gaps in the capacities needed to fill them and to apply the resulting knowledge. On the basis of the

¹⁴⁸ See chaps. 6 and 25.

¹⁴⁹ See chaps. 4, 18 and 27.

¹⁵⁰ See chap. 8.

¹⁵¹ See chap. 55.

¹⁵² See chaps. 3, 9 and 55.

¹⁵³ See chap. 30.

information currently available, it is impossible to say what gaps currently exist in arrangements to build such capacities. Conclusions on where the capacity-building gaps exist could only be reached by conducting a survey, country by country, of the capacity-building arrangements that currently exist and of how suitable they are for each country's needs. The preliminary inventory of capacity-building for assessments¹⁵⁴ compiled by the Division for Ocean Affairs and the Law of the Sea as part of the Regular Process provides some initial information on which to base such a survey, but it would take a much more detailed study than has been possible in the first cycle of the Regular Process to match that information with the needs of each country. The present section therefore looks at the capacities that are desirable, rather than the gaps in capacities for building them.

The outline for the First Global Integrated Marine Assessment requires that capacities be identified to assess the status of the marine environment and to benefit from the various human activities that take place in the marine environment.

Certain capacities are desirable for multiple purposes. The most obvious of that kind of capacity is marine research vessels. Such vessels can provide multipurpose platforms capable of supporting geological and biota surveys, habitat mapping and similar tasks. The present Assessment reviews the current distribution of research vessels around the world. Such vessels may be run by Governments, government institutes, universities, independent research institutes or commercial enterprises. Shared use, for example at a regional level, may be feasible.¹⁵⁵

Turning from those points to the elements identified as knowledge gaps, the following are the main desirable capacity-building activities.

Physical structure of the ocean

Surveys of the physical structure of the ocean require both sea-going survey capacities and the laboratory and technical staff capabilities to analyse and interpret the resulting data. Both are essential to fill knowledge gaps about the physical structure of the ocean within and beyond national jurisdictions.

Waters of the ocean

Understanding the water column requires capacities to sample, analyse and interpret the ocean in terms of temperature, salinity, stratification, chemical composition and acidity. Much of that can be gathered by autonomous floating devices, such as the floats used by the Array for Real-time Geostrophic Oceanography, which are described in the present Assessment.

Understanding primary production and the implications of sea-level rise requires information on sea levels and chlorophyll a. Such information is most effectively gathered from satellite sensors. Much of it is already available through the Internet, but the equipment and skills needed to access and interpret it are needed to be able to investigate local situations.

Ocean biotas

Better understanding of the ocean biotas demands capacities to organize the regular collection of sampling data on their number, distribution, health and reproductive success, to compile such data into databases (at the national or regional level), to analyse and interpret the data (for instance, taxonomic expertise is required to identify species) and to carry out assessments based on that information. Capacity to carry out marine scientific research is also highly desirable to improve the scientific understanding on which such monitoring is based.

¹⁵⁴ See [A/66/189](#), annex V, and [A/67/87](#), annex V.

¹⁵⁵ See chap. 30.

The capacity to manage fisheries effectively requires ships, equipment and skills to monitor and assess fish stocks. Based on those assessments, capacities are then required to develop, apply and enforce appropriate fishery management policies. Such capacities are likely to include fishery protection vessels to monitor what is happening at sea, access to satellite data to monitor the movements of fishing vessels through transponders, institutional structures to regulate markets in fish and other seafood (including their freedom from contaminants and pathogens) and the necessary enforcement mechanisms at all stages from ocean to table.

Ways in which humans interact with the ocean

Many human activities affecting the oceans are carried out by commercial enterprises. Those can be expected to develop the capacities to generate the knowledge and infrastructure that they need to run their businesses and to comply with relevant regulations. For public authorities, however, capacities will be needed to ensure that they can create appropriate regulations to safeguard social and environmental interests and that they can deal effectively with such commercial enterprises (many of which are international companies). This may be particularly difficult when the public authority concerned is relatively local.

In developing ecosystem-based approaches to the management of human activities affecting the ocean (in parallel to those being developed for fisheries), capacities are necessary to gather and process information relating to the activity and to all the facets of the ocean ecosystems with which the activity in question interacts. The precise information required will vary from activity to activity. Examples of capacities likely to be needed in some specific human activities are those required in order to:

- (a) Identify when ship-routing measures are needed to protect the marine environment, specify them and implement such measures;
- (b) Plan and implement emergency response plans for maritime disasters. Such plans are likely to require significant capital investment in ships, aircraft, machinery and supplies;
- (c) Develop and manage ports capable of handling international maritime traffic. Currently, many such port developments are being carried out and managed by commercial enterprises, in which case the proper regulation of those undertakings will be required;
- (d) Ensure adequate port waste-reception facilities to enable ships to discharge their waste without being delayed;
- (e) Carry out port State inspections of vessels and follow up any shortcomings detected;
- (f) Sample, analyse and interpret land-based inputs to the ocean. Those capabilities need to be able to cover liquid and semi-liquid discharges by pipelines directly into the sea, discharges of liquids and suspended solids to rivers and the water quality of rivers at their mouths, and emissions into the air that may reach and affect the sea. In the case of emissions into the air, it is also desirable to be able to distinguish anthropogenic inputs from natural emissions;
- (g) Ensure that new, cleaner technologies are applied to chemical and other production processes, so as to reduce the discharges and emissions of heavy metals and other hazardous substances;
- (h) Manage solid waste placed in landfills, so as to prevent the leaching of heavy metals or other hazardous substances that can reach and affect the sea, and manage the incineration of waste to minimize emissions of heavy metals and other hazardous substances in the exhaust gases;
- (i) Provide the necessary infrastructure and equipment for the proper handling of land-based industrial discharges, emissions and sewage, so as to minimize the

content of heavy metals and other hazardous substances, to remove waterborne pathogens where they could pollute bathing waters and contaminate seafood and to prevent excessive nutrient discharges;

(j) Promote the proper handling of agricultural waste and slurry and the proper use of agricultural fertilizers and pesticides;

(k) Deliver the organization, equipment and skills to monitor and control other human activities that impact on the marine environment;

(l) Manage the coastal zone in an integrated way. Where tourism is significant, those capacities need to include the ability to monitor and regulate tourist developments and activities, so as to keep them within acceptable limits in relation to the carrying capacities of the local ecosystems.

A general gap exists in capacities for an integrated assessment of the marine environment. An integrated assessment needs to bring together: (a) environmental, social and economic aspects; (b) all the relevant sectors of human activities; and (c) all the components (fixed and living) of the relevant ecosystems. The idea of an integrated assessment in that sense is relatively recent. It presents a challenging requirement, which requires specialists in many different fields to work together.

In building capacities for integrated assessments, it is necessary to think further about the concept of an integrated marine assessment. The present assessment is the first global integrated assessment of the marine environment. The Group of Experts who are collectively responsible for it are convinced that the further development and refinement of techniques for making integrated assessments are needed.

Part II

The Context of the Assessment

Chapter 1. Introduction – Planet, Oceans and Life

Contributors: Peter Harris (Lead member and Convenor), Joshua Tuhumwire (Co-Lead member)

1. Why the ocean matters

Consider how dependent upon the ocean we are. The ocean is vast – it covers seven-tenths of the planet. On average, it is about 4,000 metres deep. It contains 1.3 billion cubic kilometres of water (97 per cent of all water on Earth). But there are now about seven billion people on Earth. So we each have just one-fifth of a cubic kilometre of ocean to provide us with all the services that we get from the ocean. That small, one-fifth of a cubic kilometre share produces half of the oxygen each of us breathes, all of the sea fish and other seafood that each of us eats. It is the ultimate source of all the freshwater that each of us will drink in our lifetimes. The ocean is a highway for ships that carry across the globe the exports and imports that we produce and consume. It contains the oil and gas deposits and minerals on and beneath the seafloor that we increasingly need to use. The submarine cables across the ocean floor carry 90 per cent of the electronic traffic on which our communications rely. Our energy supply will increasingly rely on wind, wave and tide power from the ocean. Large numbers of us take our holidays by the sea. That one-fifth of a cubic kilometre will also suffer from the share of the sewage, garbage, spilled oil and industrial waste which we produce and which is put into the ocean every day. Demands on the ocean continue to rise: by the year 2050 it is estimated that there will be 10 billion people on Earth. So our share (or our children's share) of the ocean will have shrunk to one-eighth of a cubic kilometre. That reduced share will still have to provide each of us with sufficient amounts of oxygen, food and water, while still receiving the pollution and waste for which we are all responsible.

The ocean is also home to a rich diversity of plants and animals of all sizes – from the largest animals on the planet (the blue whales) to plankton that can only be seen with powerful microscopes. We use some of these directly, and many more contribute indirectly to our benefits from the ocean. Even those which have no connection whatever with us humans are part of the biodiversity whose value we have belatedly recognized. However, the relationships are reciprocal. We intentionally exploit many components of this biodiverse richness. Carelessly (for example, through inputs of waste) or unknowingly (for example, through ocean acidification from increased emissions of carbon dioxide), we are altering the circumstances in which these plants and animals live. All this is affecting their ability to thrive and, sometimes, even to survive. These impacts of humanity on the oceans

are part of our legacy and our future. They will shape the future of the ocean and its biodiversity as an integral physical-biological system, and the ability of the ocean to provide the services which we use now and will increasingly need to use in the future. The ocean is vital to each of us and to human well-being overall.

Looking in more detail at the services that the ocean provides, we can break them down into three main categories. First, there are the economic activities in providing goods and services which are often marketed (fisheries, shipping, communications, tourism and recreation, and so on). Secondly, there are the other tangible ecosystem services which are not part of a market, but which are vital to human life. For example, marine plants (mainly tiny floating diatoms) produce about 50 per cent of atmospheric oxygen. Mangroves, salt marshes and sea grasses are also natural carbon sinks. Coastal habitats, including coral reefs, protect homes, communities and businesses from storm surges and wave attack. Thirdly, there are the intangible ecosystem services. We know that the ocean means far more to us than just merely the functional or practical services that it provides. Humans value the ocean in many other ways: for aesthetic, cultural or religious reasons, and for just being there in all its diversity – giving us a “sense of place” (Halpern et al., 2012). Not surprisingly, given the resources that the ocean provides, human settlements have grown up very much near the shore: 38 per cent of the world’s population live within 100 km of the shore, 44 per cent within 150 km, 50 per cent within 200 km, and 67 per cent within 400 km (Small et al 2004).

All these marine ecosystem services have substantial economic value. While there is much debate about valuation methods (and whether some ecosystem services can be valued) and about exact figures, attempts to estimate the value of marine ecosystem services have found such values to be on the order of trillions of US dollars annually (Costanza, et al., 1997). Nearly three-quarters of this value resides in coastal zones (Martínez, et al., 2007). The point is not so much the monetary figure that can be estimated for non-marketed ecosystem services, but rather the fact that people do not need to pay anything for them – these services are nature’s gift to humanity. But we take these services for granted at our peril, because the cost of replacing them, if it were possible to do so, would be immense and in many cases, incalculable.

There are therefore very many good reasons why we each need to take very good care of our-fifth of a cubic kilometre share of the ocean!

2. Structure of this Assessment

It is this significance of the ocean as a whole, and the relatively fragmented way in which it is studied and in which human activities impacting upon it are managed, that led in 2002 the World Summit on Sustainable Development to recommend (WSSD 2002), and the United Nations General Assembly to agree (UNGA 2002), that there should be a regular process for the global reporting and assessment of the marine environment, including socioeconomic aspects. Under the arrangements

developed for this purpose, this Assessment is the first global integrated assessment of the marine environment (see further in Chapter 2).

Three possible focuses exist for structuring this Assessment: the ecosystem services (market and non-marketed, tangible and intangible) that the marine environment provides; the habitats that exist within the marine environment, and the pressures that human activities exert on the marine environment. All three have advantages and disadvantages.

Using ecosystem services as the basis for structuring the Assessment would follow the approach of the Millennium Ecosystem Assessment (2005). This has the advantage of broad acceptance in environmental reporting. It would cover provisioning services (food, construction materials, renewable energy, coastal protection), while highlighting regulating services and quality-of-life services that are not captured using a pressures or habitats approach to structuring the Assessment. It would have the disadvantage that some important human activities using the ocean (for example, shipping, ports and minerals extraction) would be covered only incidentally.

Using marine habitats as the basis for structuring the Assessment would have the advantage that habitats are the property that inherently integrates many ecosystem features, including species at higher and lower trophic levels, water quality, oceanographic conditions and many types of anthropogenic pressures (AoA, 2009). The cumulative aspect of multiple pressures affecting the same habitat, that is often lost in sector-based environmental reporting (Halpern et al., 2008), is captured by using habitats as reporting units. It would have the disadvantage that consideration of human activities would be fragmented between the many different types of habitats.

Using pressures as the basis for structuring the Assessment would have the advantage that the associated human activities are commonly linked with data collection and reporting structures for regulatory compliance purposes. For instance, permits that are issued for offshore oil and gas development require specific monitoring and reporting obligations to be met by operators. It would have the disadvantage that many important ecosystem services would only be covered in relation to the impacts of the human activities.

Given that all three approaches have their own particular advantages and disadvantages, the United Nations General Assembly endorsed a structure for this Assessment that combined all three approaches, thereby structuring the World Ocean Assessment into seven main Parts, as follows.

Part I. Summary

The Summary is intended to bring out the way in which the assessment has been carried out, the overall assessment of the scale of human impact on the oceans and the overall value of the oceans to humans, and the main threats to the marine environment and human economic and social well-being. As guides for future action it also describes the gaps in capacity-building and in knowledge.

Part II. The context of the Assessment

This chapter is intended as a broad, introductory survey of the role played by the ocean in the life of the planet, the way in which they function, and humans' relationships to them. Chapter 2 explains in more detail the rationale for the Assessment and how it has been produced.

Part III. Assessment of major ecosystem services from the marine environment (other than provisioning services)

Part III looks at the non-marketed ecosystem services provided to the planet by the ocean. It considers, first, the scientific understanding of such ecosystem services and then looks at the earth's hydrological cycle, air/sea interactions, primary production and ocean-based carbonate production. Finally it looks at aesthetic, cultural, religious and spiritual ecosystem services (including some cultural objects which are traded). Where relevant, it draws heavily on the work of Intergovernmental Panel on Climate Change (IPCC) – the aim is to use the work of the IPCC, not to duplicate or challenge it.

Part IV. Assessment of the cross-cutting issues: food security and food safety

The aim of Part IV is to look at all aspects of the vital function of the ocean in providing food for humans. It draws substantially on information collected by the Food and Agriculture Organization of the United Nations (FAO). The economic significance of employment in fisheries and aquaculture and the relationship these industries have with coastal communities are addressed, including gaps in capacity-building for developing countries.

Part V. Assessment of other human activities and the marine environment

All human activities that can impact on the oceans (other than those relating to food) are covered in Part V of the assessment. Each chapter describes the location and scale of activity, the economic benefits, employment and social role, environmental consequences, links to other activities and capacity-building gaps.

Part VI. Assessment of marine biological diversity and habitats

The aim of Part VI is: (a) to give an overview of marine biological diversity and what is known about it; (b) to review the status and trends of, and threats to, marine ecosystems, species and habitats that have been scientifically identified as threatened, declining or otherwise in need of special attention or protection; (c) to review the significant environmental, economic and/or social aspects in relation to the conservation of marine species and habitats; and (d) to find gaps in capacity to identify marine species and habitats that are viewed as threatened, declining or otherwise in need of special attention or protection and to assess the

environmental, social and economic aspects of the conservation of marine species and habitats.

Part VII. Overall assessment

Part VII finally looks at the overall impact of humans on the ocean, and the overall benefit of the ocean for humans.

3. The physical structure of the ocean

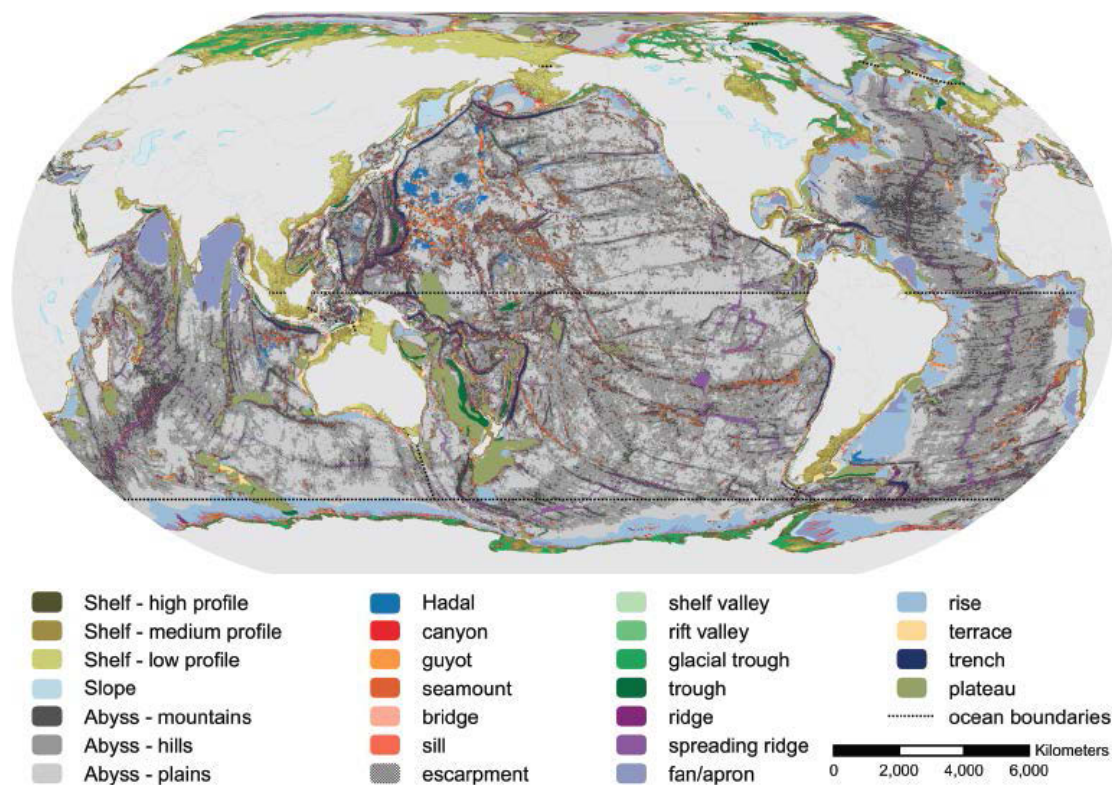

Looking at a globe of the earth one thing that can be easily seen is that, although different names appear in different places for different ocean areas, these areas are all linked together: there is really only one world ocean. The seafloor beneath the ocean has long remained a mystery, but in recent decades our understanding of the ocean floor has improved. The publication of the first comprehensive, global map of seafloor physiography by Bruce Heezen and Marie Tharp in 1977 provided a pseudo-three-dimensional image of the ocean that has influenced a long line of scholars. That image has been refined in recent years by new bathymetric maps (Smith and Sandwell, 1997) which are used to illustrate globes, web sites and the maps on many in-flight TV screens when flying over the ocean.

A new digital, global seafloor geomorphic features map has been built (especially to assist the World Ocean Assessment) using a combination of manual and ArcGIS methods based on the analysis and interpretation of the latest global bathymetry grid (Harris et al., 2014; Figure 1). The new map includes global spatial data layers for 29 categories of geomorphic features, defined by the International Hydrographic Organization and other authoritative sources.

The new map shows the way in which the ocean consists of four main basins (the Arctic Ocean, the Atlantic Ocean, the Indian Ocean and the Pacific Ocean) between the tectonic plates that form the continents. The tectonic plates have differing forms at their edges, giving broad or narrow continental shelves and varying profiles of the continental rises and continental slopes leading from the abyssal plain to the continental shelf. Geomorphic activity in the abyssal plains between the continents gives rise to abyssal ridges, volcanic islands, seamounts, guyots (plateau-like seamounts), rift valley segments and trenches. Erosion and sedimentation (either submarine or riverine when the sea level was lower during the ice ages) has created submarine canyons, glacial troughs, sills, fans and escarpments. Around the ocean basins there are marginal seas, partially separated by islands, archipelagos or peninsulas, or bounded by submarine ridges. These marginal seas have sometimes been formed in many ways: for example, some result from the interaction between tectonic plates (for example the Mediterranean), others from the sinking of former dry land as a result of isostatic changes from the removal of the weight of the ice cover in the ice ages (for example, the North Sea).

The water of the ocean circulates within these geological structures. This water is not uniform: there are very important physical and chemical variations within the

sea water. Salinity varies according to the relativity between inputs of freshwater and evaporation. Sea areas such as the Baltic Sea and the Black Sea, with large amounts of freshwater coming from rivers and relatively low evaporation have low salinity – 8 parts per thousand and 16 parts per thousand, respectively, as compared with the global average of 35 parts per thousand (HELCOM 2010, Black Sea Commission 2008). The Red Sea, in contrast, with low riverine input and high insolation, and therefore high evaporation, has a mean surface salinity as high as 42.5 parts per thousand (Heilman et al 2009). Seawater can also be stratified into separate layers, with different salinities and different temperatures. Such stratification can lead to variations in both the oxygen content and nutrient content, with critical consequences in both cases for the biota dependent on them. A further variation is in the penetration of light. Sunlight is essential for photosynthesis of inorganic carbon (mainly CO₂) into the organic carbon of plants and mixotrophic species¹. Even clear water reduces the level of light that can penetrate by about 90 per cent for every 75 metres of depth. Below 200 metres depth, there is not enough light for photosynthesis (Widder 2014). The upper 200 metres of the ocean are therefore where most photosynthesis takes place (the euphotic zone). Variations in light level in the water column and on the sea bed are caused by seasonal fluctuation in sunlight, cloud cover, tidal variations in water depth and (most significantly, where it occurs) turbidity in the water, caused, for example, by resuspension of sediment by tides or storms or by coastal erosion. Where turbidity occurs, it can reduce the penetration of light by up to 95 per cent, and thus reduce the level of photosynthesis which can take place (Anthony 2004).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

¹ That is, plankton species that both photosynthesize and consume other biota.

Figure 1. Geomorphic features map of the world's oceans (after Harris et al., 2014). Dotted black lines mark boundaries between major ocean regions. Basins are not shown.

The new map provides the basis for global estimates of physiographic statistics (area, number, mean size, etc.): for example, it can be estimated that the global ocean covers 362 million square kilometres and the ocean floor contains: 9,951 seamounts covering 8.1 million square kilometres; 9,477 submarine canyons covering 4.4 million square kilometres; and the mid-ocean spreading ridges cover 6.7 million square kilometres with an additional 710,000 square kilometres of rift valleys where hydrothermal vent communities occur (Harris et al., 2014).

There is an important distinction to be made between the terminology used in scientific description of the ocean and the legal terminology used to describe States' rights and obligations in the ocean. Some important terms that will be used throughout this Assessment include the "continental shelf", "open ocean" and "deep sea".

Unless stated otherwise, "continental shelf" in this Assessment refers to the geomorphic continental shelf (as shown in Figure 1) and not to the continental shelf as defined by the United Nations Convention on the Law of the Sea. The geomorphic continental shelf is usually defined in terms of the submarine extension of a continent or island as far as the point where there is a marked discontinuity in the slope and the continental slope begins its fall down to the continental rise or the abyssal plain (Hobbs 2003). In total, continental shelves cover an area of 32 million square kilometres (out of a total ocean area of 362 million square kilometres).

The term "open ocean" in this Assessment refers to the water column of deep-water areas that are beyond (that is, seawards of) the geomorphic continental shelf. It is the pelagic zone that lies in deep water (generally >200 m water depth).

The term "deep sea" in this Assessment refers to the sea floor of deep-water areas that are beyond (that is, seawards of) the geomorphic continental shelf. It is the benthic zone that lies in deep water (generally >200 m water depth).

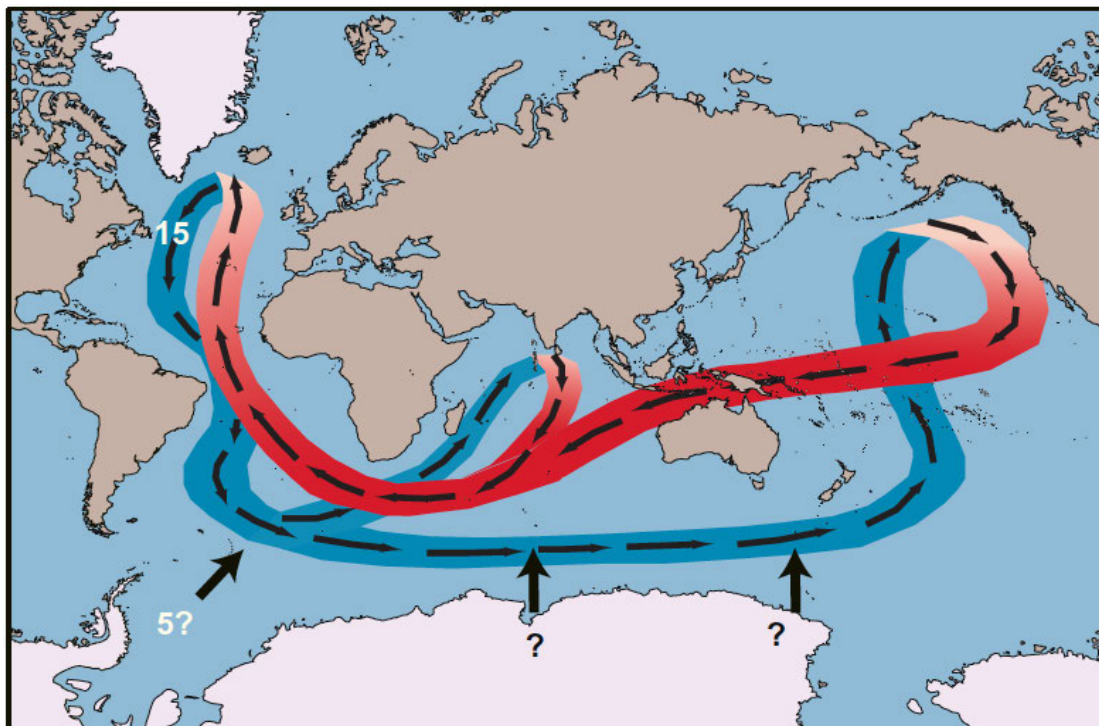

4. Seawater and the ocean/climate interaction

The Earth's ocean and atmosphere are parts of a single, interactive system that controls the global climate. The ocean plays a major role in this control, particularly in the dispersal of heat from the equator towards the poles through ocean currents. The heat transfer through the ocean is possible because of the larger heat-capacity of water compared with that of air: there is more heat stored in the upper 3 metres of the global ocean than in the entire atmosphere of the Earth. Put another way, the oceans hold more than 1,000 times more heat than the atmosphere. Heat transported by the major ocean currents dramatically affects regional climate: for example, Europe would be much colder than it is without the warmth brought by the Gulf Stream current. The great ocean boundary currents transport heat from the equator to the polar seas (and cold from the polar seas towards the equator), along

the margins of the continents. Examples include: the Kuroshio Current in the northwest Pacific, the Humboldt (Peru) Current in the southeast Pacific, the Benguela Current in the southeast Atlantic and the Agulhas Current in the western Indian Ocean. The mightiest ocean current of all is the Circumpolar Current which flows from west to east encircling the continent of Antarctica and transporting more than 100 Sverdrups (100 million cubic meters per second) of ocean water (Rintoul and Sokolov, 2001). As well as the boundary currents, there are five major gyres of rotating currents: two in the Atlantic and two in the Pacific (in each case one north and one south of the equator) and one in the Indian Ocean.

The winds in the atmosphere are the main drivers of these ocean surface currents. The interface between the ocean and the atmosphere and the effect of the winds also allows for the ocean to absorb oxygen and, more importantly, carbon dioxide from the air. Annually, the ocean absorbs 2,300 gigatonnes of carbon dioxide (IPCC, 2005; see Chapter 5).

In addition to this vast surface ocean current system, there is the ocean thermohaline circulation (ocean conveyor) system (Figure 3). Instead of being driven by winds and the temperature difference between the equator and the poles (as are the surface ocean currents), this current system is driven by differences in water density. The most dense ocean water is cold and salty which sinks beneath warm and fresh seawater that stays near the surface. Cold-salty water is produced in sea ice “factories” of the polar seas: when seawater freezes, the salt is rejected (the ice is mostly fresh water), which makes the remaining liquid seawater saltier. This cold saltier water sinks into the deepest ocean basins, bringing oxygen into the deep ocean and thus enabling aerobic life to exist.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. The global ocean “conveyor” thermohaline circulation (Broecker, 1991). Bottom water is formed in the polar seas via sea-ice formation in winter, which rejects cold, salty (dense) water. This sinks to the ocean floor and flows into the Indian and North Pacific Oceans before returning to complete the loop in the North Atlantic. Numbers indicate estimated volumes of bottom water production in “Sverdrups” (1 Sverdrup = 1 million m³/s), which may be reduced by global warming because less sea ice will be formed during winter. Blue indicates cold currents and red indicates warm currents. The black question marks indicate sites long the Antarctic margin where bottom water may be formed but of unknown volumes. The question mark after the “5” indicates that this value is certain.

Wind-driven mixing affects only the surface of the ocean, mainly the upper 200 metres or so, and rarely deeper than about 1,000 metres. Without the ocean’s thermohaline circulation system, the bottom waters of the ocean would soon be depleted of oxygen, and aerobic life there would cease to exist.

Superimposed on all these processes, there is the twice-daily ebb and flow of the tide. This is, of course, most significant in coastal seas. The tidal range varies according to local geography: the largest mean tidal ranges (around 11.7 metres) are found in the Bay of Fundy, on the Atlantic coast of Canada, but ranges only slightly less are also found in the Bristol Channel in the United Kingdom, on the northern coast of France, and on the coasts of Alaska, Argentina and Chile (NOAA 2014).

Global warming is likely to affect many aspects of ocean processes. Changes in sea-surface temperature, sea level and other primary impacts will lead, among other things, to increases in the frequency of major tropical storms (cyclones, hurricanes and typhoons) bigger ocean swell waves and reduced polar ice formation. Each of these consequences has its own consequences, and so on (Harley et al., 2006; Occhipinti-Ambrogi, 2007). For example, reduced sea ice production in the polar seas will mean less bottom water is produced (Broecker, 1997) and hence less oxygen delivered to the deep ocean (Shaffer et al., 2009).

5. The ocean and life

The complex system of the atmosphere and ocean currents is also crucial to the distribution of life in the ocean, since it regulates, among other factors, (as said above) temperature, salinity, oxygen content, absorption of carbon dioxide and the penetration of light and (in addition to these) the distribution of nutrients.

The distribution of nutrients throughout the ocean is the result of the interaction of a number of different processes. Nutrients are introduced to the ocean from the land through riverine discharges, through inputs direct from pipelines and through airborne inputs (see Chapter 20). Within the ocean, these external inputs of nutrients suffer various fates and are cycled. Nutrients that are adsorbed onto the surface of particles are likely to fall into sediments, from where they may either be remobilised by water movement or settle permanently. Nutrients that are taken up by plants and mixotrophic biota for photosynthesis will also eventually sink towards the seabed as the plants or biota die; *en route* or when they reach the seabed, they

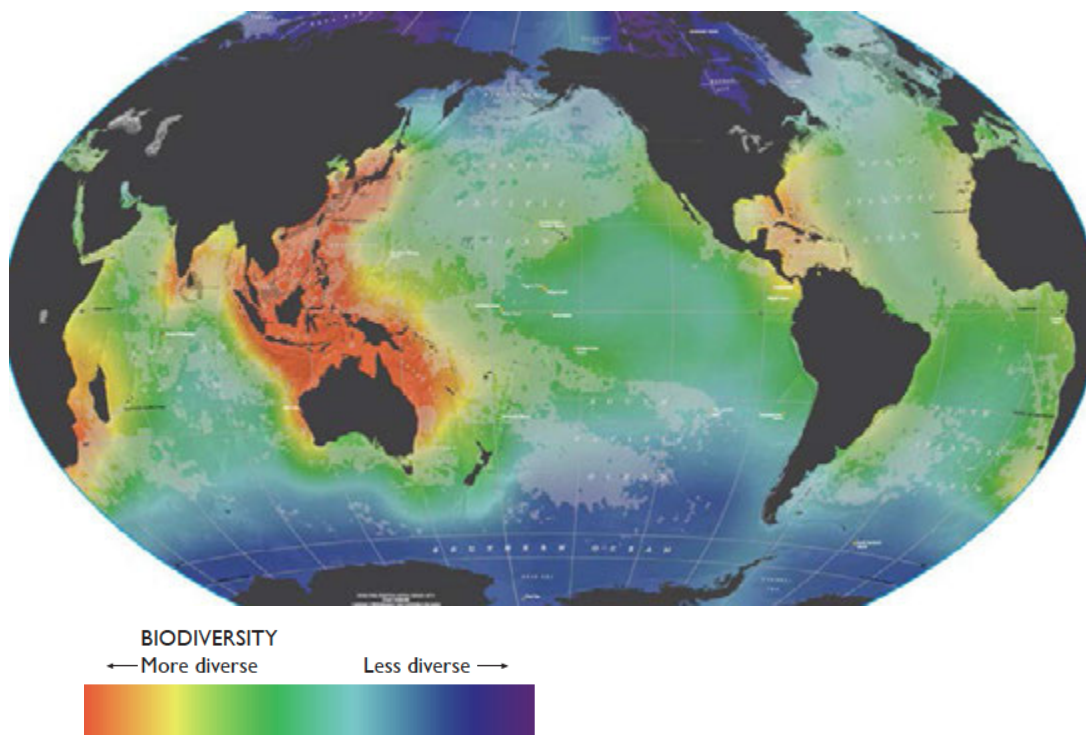

will be broken up by bacteria and the nutrients released. As a result of these processes, the water in lower levels of the ocean is richer in nutrients.

Upwelling of these nutrient-rich waters is caused by the interaction of currents and wind stress. In simple terms, along coasts (especially west-facing coasts with narrow continental shelves), coastal, longshore wind stress results in rapid upwelling; further out to sea, wind-stress produces a slower, but still significant, upwelling (Rykaczewski et al., 2008). Upwelled, nutrient-rich water is brought up to the euphotic zone (see previous section), where most photosynthesis takes place (see Chapter 6). The reality is far more complex, and upwelling is influenced by numerous other factors such as stratification of the water column and the influence of coastal and seafloor geomorphology, such as shelf-incising submarine canyons (Sobarzo et al., 2001). Other important factors are river plumes and whether the upwelling delivers the nutrient that is the local limiting factor for primary productivity (for example, nitrogen or iron; Kudela et al., 2008). Ocean upwelling zones commonly control primary productivity hotspots and their associated, highly productive fisheries, such as the anchoveta fishery off the coast of Peru. The Peruvian upwelling varies from year to year, resulting in significant fluctuations in productivity and fisheries yields. The major factor producing these variations is the El Niño Southern Oscillation, which is the best studied of the recurring variations in large-scale circulation, and its disruptive effects on coastal weather and fisheries are well-known (Barber and Chavez, 1983).

The major ocean currents connect geographic regions and also exert control on ocean life in other ways. Currents form natural boundaries that help define distinct habitats. Such boundaries may isolate different genetic strains of the same species as well as different species. Many marine animals (for example, salmon and squid) have migration patterns that rely upon transport in major ocean current systems, and other species rely on currents to distribute their larvae to new habitats. Populations of ocean species naturally fluctuate from year to year, and ocean currents often play a significant role. The survival of plankton, for example, is affected by where the currents carry them. Food supply varies as changing circulation and upwelling patterns lead to higher or lower nutrient concentrations.

The heterogeneity of the oceans, its water masses, currents, ecological processes, geological history and seafloor morphology, have resulted in great variations in the spatial distribution of life. In short, biodiversity is not uniformly distributed across the oceans: there are local and regional biodiversity “hotspots” (see Chapters 33 and 35). Figure 3 shows a way in which the diversity of species is consequently distributed around the world. Various classification systems have been devised to systematize this variety, including the European Nature Information System (EUNIS) (Davies and Moss, 1999; Connor et al., 2004) and the Global Open Ocean and Deep Sea-habitats (GOODS) classification and its refinements (Agnostini 2008; Rice et al 2011).

Part VI (Assessment of marine biodiversity and habitats) describes in more detail the diversity that is found across the ocean, and the way in which it is being affected by human activities.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 3. Distribution of biodiversity in the oceans. Biodiversity data: Tittensor et al., 2010. Human impact data: Halpern et al., 2008, Map: Census of Marine Life, 2010; Ausubel et al., 2010; National Geographic Society, 2010).

6. Human uses of the ocean

Humans depend upon the ocean in many ways and our ocean-based industries have had impacts on ocean ecosystems from local to global spatial scales. In the large majority of ocean ecosystems, humans play a major role in determining crucial features of the way in which the ecosystems are developing.

The impacts of climate change and acidification are pervasive through most ocean ecosystems. These, and related impacts, are discussed in Part III (Assessment of major ecosystem services from the marine environment (other than provisioning services)), together with the non-marketed ecosystem services that we enjoy from the ocean and the ways in which these may be affected by the pervasive impacts of human activities.

For wide swathes of the Earth's population, fish and other sea-derived food is a provisioning ecosystem of the highest importance. Part IV (Assessment of the cross-cutting issues: food security and food safety) examines the extent to which humans rely on the ocean for their food, the ways in which capturing, growing and marketing that food is impacting on ecosystems and the social and economic position of those engaged in these activities and the health risks to everyone who enjoys this food.

The wide range of other human activities is examined in Part V (Assessment of human activities and the marine environment): these activities include the growing importance of worldwide transport in the world economy; the major role of the

seabed in providing oil and gas and other minerals; the non-consumptive uses of the ocean to provide renewable energy; the potential for non-consumptive use of marine genetic resources; the uses of seawater to supplement freshwater resources; and the vital role of the ocean in tourism and recreation. In addition, it is necessary to consider the way in which human activities that produce waste can affect the marine environment as the wastes are discharged, emitted or dumped into the marine environment, and the effects of reclaiming land from the sea and seeking to change the natural processes of erosion and sedimentation. Finally, we need to consider the marine scientific research that is the foundation of all our attempts to understand the ocean and to manage the human activities that affect it.

7. Conclusion

Our planet is seven-tenths ocean. From space, the blue of the ocean is the predominant colour. This Assessment is an attempt to produce a 360° review of where the ocean stands, what the range of natural variability underlies its future development and what are the pressures (and their drivers) that are likely to influence that development. As the description of the task set out in Chapter 2 (Mandate, information sources and method of work) shows, the Assessment does not attempt to make recommendations or analyse the success (or otherwise) of current policies. Its task is to provide a factual basis for the relevant authorities in reaching their decisions. The aim is that a comprehensive, consistent Assessment will provide a better basis for those decisions.

Chapter 2. Mandate, Information Sources and Method of Work

Contributors: Alan Simcock (Lead member and Convenor), Amanuel Ajawin, Beatrice Ferreira, Sean Green, Peter Harris, Jake Rice, Andy Rosenberg, and Juying Wang (Co-lead members).

The World Summit on Sustainable Development, held in Johannesburg, South Africa, in 2002, recommended that there should be established a Regular Process for the Global Reporting and Assessment of the Marine Environment, including Socioeconomic Aspects (WSSD, 2002). This recommendation was endorsed by the United Nations General Assembly (UNGA) in 2002 (UNGA, 2002).

After considerable preparatory work, including as a first phase the production of the assessment of assessments (AoA, 2009), the United Nations General Assembly approved in 2009 the framework for the Regular Process developed by its Ad Hoc Working Group of the Whole. This framework for the Regular Process consisted of: (a) the overall objective for the Regular Process, (b) a description of the scope of the Regular Process, (c) a set of principles to guide its establishment and operation and (d) the best practices on key design features for the Regular Process as identified by the group of experts established for the assessment of assessments (see below). The framework further provided that capacity-building, sharing of data, information and transfer of technology would be crucial elements of the framework. The following paragraphs set out these elements in the terms approved by the General Assembly (AHWG, 2009; UNGA, 2009).

1. Overall objective

The Regular Process, under the United Nations, would be recognized as the global mechanism for reviewing the state of the marine environment, including socioeconomic aspects, on a continual and systematic basis by providing regular assessments at the global and supraregional levels and an integrated view of environmental, economic and social aspects. Such assessments would support informed decision-making and thus contribute to managing in a sustainable manner human activities that affect the oceans and seas, in accordance with international law, including the United Nations Convention on the Law of the Sea¹ and other applicable international instruments and initiatives.

The Regular Process would facilitate the identification of trends and enable appropriate responses by States and competent regional and international organizations.

The Regular Process would promote and facilitate the full participation of developing countries in all of its activities.

¹ United Nations, *Treaty Series*, vol. 1833, No. 31363.

Ecosystem approaches would be recognized as a useful framework for conducting fully integrated assessments.

2. Capacity-building and technology transfer

The Regular Process would promote, facilitate and ensure capacity-building and transfer of technology, including marine technology, in accordance with international law, including the United Nations Convention on the Law of the Sea and other applicable international instruments and initiatives, for developing and other States, taking into account the criteria and guidelines on the transfer of marine technology of the Intergovernmental Oceanographic Commission.

The Regular Process would promote technical cooperation, including South-South cooperation.

States and global and regional organizations would be invited to cooperate with each other to identify gaps and shared priorities as a basis for developing a coherent programme to support capacity-building in marine monitoring and assessment.

The value of large-scale and comprehensive assessments, notably in the Global Environment Facility's international waters large-marine ecosystems initiatives, in identifying and concentrating on capacity-building priorities would be recognized.

Opportunities for capacity-building would be identified, in particular on the basis of existing capacity-building arrangements and the identified capacity-building priorities, needs and requests of developing countries.

States and relevant international organizations, bodies and institutions would be invited to cooperate in building the capacity of developing countries in marine science, monitoring and assessment, including through workshops, training programmes and materials and fellowships.

Quality assurance procedures and guidance would be developed to assist Governments and international organizations to improve the quality and comparability of data.

3. Scope

The scope of the Regular Process is global and supraregional, encompassing the state of the marine environment, including socioeconomic aspects, both current and foreseeable.

In the first cycle, the scope of the Regular Process would focus on establishing a baseline. In subsequent cycles, the scope of the Regular Process would extend to evaluating trends.

The scope of individual assessments under the Regular Process would be identified by Member States in terms of, inter alia, geographic coverage, an appropriate analytical framework, considerations of sustainability, issues of vulnerability and

future scenarios that may have implications for policymakers.

4. Principles

The Regular Process would be guided by international law, including the United Nations Convention on the Law of the Sea and other applicable international instruments and initiatives, and would include reference to the following principles:

- (a) Viewing the oceans as part of the whole Earth system;
- (b) Regular evaluation by Member States of assessment products and the regular process itself to support adaptive management;
- (c) Use of sound science and the promotion of scientific excellence;
- (d) Regular analysis to ensure that emerging issues, significant changes and gaps in knowledge are detected at an early stage;
- (e) Continual improvement in scientific and assessment capacity, including the promotion and development of capacity-building activities and transfer of technology;
- (f) Effective links with policymakers and other users;
- (g) Inclusiveness with respect to communication and engagement with all stakeholders through appropriate means for their participation, including appropriate representation and regional balance at all levels;
- (h) Recognition and utilization of traditional and indigenous knowledge and principles;
- (i) Transparency and accountability for the regular process and its products;
- (j) Exchange of information at all levels;
- (k) Effective links with, and building on, existing assessment processes, in particular at the regional and national levels;
- (l) Adherence to equitable geographical representation in all activities of the regular process.

5. Reasons for these decisions

This framework largely reflected the recommendations of a group of experts, established by the General Assembly in 2005 (UNGA, 2005) and in place by the end of 2006, to carry out (under the guidance of an ad hoc steering group and with the assistance of the lead agencies, United Nations Environmental Programme (UNEP) and Intergovernmental Oceanographic Commission/United Nations Educational, Scientific and Cultural Organization (IOC-UNESCO)) an “assessment of assessments”, reviewing the way in which past assessments, particularly of the marine environment at global and regional levels, had been carried out, in order to establish

the approaches which could ensure that assessments under the Regular Process would be relevant, legitimate and credible – the three necessary conditions for an influential assessment.

The report of the assessment of assessments (AoA, 2009) summarised the justification for the Regular Process as follows:

“5.1 Marine ecosystems provide essential support to human well-being. However, they are undergoing unprecedented environmental changes, driven by human activities, and becoming depleted and disrupted... Keeping the world’s oceans and seas under continuing review will help to improve the responses from national governments and the international community to the challenges posed by these changes. Reviews based on sound science can help the world as a whole understand better what is happening, what is causing it, [and] what the impacts are.”

The report saw an urgent need for a more integrated approach, at the global level as well as at the regional and sub-regional levels. It indicated that such an integrated approach was feasible, and would help to develop a more coherent overview of the state of the global marine environment and its interactions with the world economy and human society. A better understanding is needed of how human activities themselves interact and cumulatively affect different parts of marine ecosystems. Baselines, reference points and reference values would also be needed as a basis for evaluating status and trends over time. More consistent information, both in coverage and quality, and integrated analyses would improve understanding of the rapid changes that are occurring in the oceans and their possible causes. The resulting knowledge would facilitate decisions to manage in a sustainable manner human activities affecting the oceans. Assessment is a necessary, integral part of the cycle of adaptive management of human activities that affect the oceans.

The report went on to explain the benefits from a Regular Process that could be a means for integrating existing information from different disciplines to show new and emerging patterns and to stimulate further development of the information base.

The elements relevant to the framework established by the General Assembly include actions to:

- (a) Demonstrate the importance of oceans to human life and as a component of the planet;
- (b) Integrate, analyze and assess environmental, social and economic aspects of all oceans components and interactions among all sectors of human activity affecting them; it could thus support sustainable, ecosystem-based management throughout the oceans;
- (c) Promote well-designed assessment processes, conducted to the highest standards and fully documented by those responsible for them;
- (d) Promote international collaboration to build capacity;
- (e) Improve the quality, availability, accessibility, interoperability and usefulness of information for ocean assessment; it would also increase consistency in the selection and use of indicators, reference points and reference values;

- (f) Support better policy and management at the appropriate scale by providing sound and integrated scientific analyses for decision-making by the relevant authorities;
- (g) Build on existing assessment frameworks, processes and institutions and thus provide a base for cooperation among governments and at the level of international institutions.

The essential features which differentiate this assessment from earlier assessments are that it is global in scope, that it is to integrate the different sectors that are involved with the ocean and that it is to integrate environmental, social and economic aspects of the ocean. This is an ambitious project, and it has been clear from the outset that the first assessment of this kind would be breaking new ground, and that there would therefore be scope for improvement in future cycles of the Regular Process.

6. Timing

In 2009, the Ad Hoc Working Group of the Whole recommended that the Regular Process should involve a series of cycles and that the first cycle of the Regular Process should cover the five years from 2010 to 2014. This was endorsed by the General Assembly in 2009, on the basis that there would be two phases of the first cycle, the first phase up to the end of 2012 to agree the issues to be covered and the second phase from 2013 to 2014 to produce the first assessment (AHWG, 2009; UNGA, 2009).

7. Modalities

In 2010, the General Assembly endorsed a series of recommendations from the Ad Hoc Working Group of the Whole on the modalities for the way in which the work of the Regular Process should be organized and implemented (AHWG, 2009; AHWG, 2010; UNGA, 2010). The modalities, consisting of key features, capacity-building and institutional arrangements, were developed further in a series of decisions of the General Assembly, on the basis of recommendation of the Ad Hoc Working Group of the Whole of the General Assembly (AHWG, 2011a; UNGA, 2011a; AHWG, 2011b; UNGA, 2011b; AHWG, 2012; UNGA, 2012; AHWG, 2013; UNGA, 2013; AHWG, 2014; UNGA, 2014), informed, among other things, by material prepared by the initial group of experts appointed in 2009. The arrangements for the Group of Experts of the Regular Process were set out in the Terms of Reference and Working Methods (AHWG, 2012; UNGA, 2012), and various paragraphs of the relevant General Assembly resolutions.

The main institutional arrangements thus established are as follows:

- (a) *The Ad Hoc Working Group of the Whole on the Regular Process for Global Reporting and Assessment of the State of the Marine Environment, including Socioeconomic Aspects:*

The Regular Process is to be overseen and guided by an Ad Hoc Working Group of the Whole of the General Assembly comprised of representatives of Member States. Relevant intergovernmental and non-governmental organizations with consultative status recognized by the Economic and Social Council are to be invited to participate in the meetings of the Ad Hoc Working Group. Relevant scientific institutions and major groups identified in Agenda 21 may request an invitation to participate in the meetings of the Ad Hoc Working Group. In 2011, the Ad Hoc Working Group agreed on the establishment of a Bureau to put in practice its decisions and guidance during the intersessional period (AHWG, 2011b; UNGA, 2011b).

- (b) *The Group of Experts of the Regular Process:* The general task of the Group of Experts, as set out in the Terms of Reference and Working Methods approved by the General Assembly, is “to carry out any assessments within the framework of the Regular Process at the request of the General Assembly under the supervision of the Ad Hoc Working Group of the Whole”. It was noted that an assessment would only be carried out at the request of the General Assembly. Within this general task, the Group of Experts were to draw up a draft implementation plan and timetable, a draft outline of the assessment, proposals for writing teams for each chapter and proposals for independent peer review. Lead Members for each chapter, drawn from the Group of Experts, are to have a general task of managing each chapter, and a convenor of the writing team from the chapter (who might also be the Lead Member) is to be responsible for ensuring the proper development of the chapter. The Terms of Reference and Working Methods make clear that the Group of Experts is collectively responsible for the Assessment, and was to agree on a final text of any assessment for submission through the Bureau to the Ad Hoc Working Group of the Whole, and to present that text to the Ad Hoc Working Group of the Whole.

The Group of Experts, originally appointed in 2009 to develop thinking on the “basic building blocks” identified by the Assessment of Assessments, were invited to continue for the first cycle of the Regular Process pursuant to a series of decisions of the General Assembly.

The Group could be constituted of a maximum of 25 members, five appointed by each regional group within the General Assembly. One regional group only made two appointments, and therefore the full membership of the Group has been 22. In accordance with the Terms of Reference and Working Methods, the Group appointed two coordinators from within its membership, one from a developed country and one from a developing country. The members of the Group of Experts are volunteers or are supported by their parent institutions.

- (c) *The Pool of Experts:* The General Assembly approved criteria for the appointment of experts to a Pool of Experts to assist in the preparation of the first assessment and to cover the wide range of issues that an assessment of the ocean integrated across sectors and across

environmental, social and economic aspects would have to address. This assistance would include several distinct potential roles: convenors and members of the writing teams, commentators to enable expertise about parts of the world not covered by the writing teams to be brought in to the Assessment without making writing teams unmanageably large, and peer reviewers to review the complete draft of the Assessment. These experts have been nominated by States through the chairs of the regional groups of the United Nations. In addition, members of the Group of Experts and writing teams could consult widely with relevant experts.

- (d) *Secretariat:* On the recommendation of the Ad Hoc Working Group of the Whole, the General Assembly requested the Secretary-General to designate the Division of Ocean Affairs and Law of the Sea as the secretariat of the Regular Process. Since no additional staff was allocated specifically for this work, the secretariat function has been provided by the existing staff.
- (e) *Technical and Scientific Support:* Technical and scientific support for the Regular Process has been available from the IOC-UNESCO, UNEP, the International Maritime Organization (IMO) and the Food and Agriculture Organization of the United Nations (FAO), and the International Atomic Energy Agency (IAEA). These agencies were invited by the General Assembly, together with other competent United Nations specialized agencies, to provide such support as appropriate. A dedicated web-based platform was set up to make information about this Assessment available and to provide a means of communication between members of the Group of Experts and the members of the Pool of Experts. Agreement was reached between Australia, Norway and the United Nations Environment Programme to host such a website at GRID/Arendal in Norway.
- (e) *Workshops:* In addition to the Pool of Experts, steps were taken to convene workshops as forums where experts (including government officials) could make an input to the planning and development of the Assessment. The General Assembly approved guidelines for these workshops, which were held in Santiago in September 2011 (at the invitation of the Government of Chile), in Sanya in February 2012 (at the invitation of the Government of China), in Brussels in June 2012 (at the invitation of the Government of Belgium, supported by the European Union), in Miami in November 2012 (at the invitation of the Government of the United States of America), in Maputo in December 2012 (at the invitation of the Government of Mozambique), in Brisbane in February 2013 (at the invitation of the Government of Australia), in Grand Bassam in October 2013 (at the invitation of the Government of Côte d'Ivoire) and in Chennai in January 2014 (at the invitation of the Government of India). The workshops were open to representatives of all States, although participation was mainly from experts in the respective regions. Each workshop aimed to consider the scope and methods of this

Assessment, the information available in the region where it was held, and capacity-building needs in that region. Reports of each workshop were made available on the website of the Division of Ocean Affairs and Law of the Sea and on the website of the first Assessment.

8. Finance

The General Assembly decided that the costs of the first cycle of the Regular Process should be financed from a voluntary trust fund, and invited the Secretary-General to establish such a fund for the purpose of supporting the operations of the first five-year cycle of the Regular Process, including for the provision of assistance to members of the Group of Experts from developing countries. The Trust Fund is managed and administered by the Division of Ocean Affairs and Law of the Sea. Contributions to this fund have been made by Belgium, China, Côte d'Ivoire, Iceland, Ireland, Jamaica, New Zealand, Norway, Portugal and the Republic of Korea. In addition, Australia, Belgium, Canada, Chile, China, Côte d'Ivoire, India, Mozambique, the Republic of Korea, the United Kingdom of Great Britain and Northern Ireland and the United States of America have supported workshops in the region and/or the travel and accommodation costs of members of the Group of Experts from their countries. Generous support to the Regular Process has also been provided, financially and technically, by the European Union, IOC-UNESCO and UNEP.

9. Guidance

On the advice of the Group of Experts, the Ad Hoc Working Group decided that there should be comprehensive guidance for the Regular Process. Accordingly it prepared such guidance, covering the responsibilities of the Group of Experts, the members of the Pool of Experts, the writing teams and their convenors, the commentators and the peer reviewers, the approaches to achieve integration and to deal with uncertainty, risk, ethical questions and style. This was approved by the General Assembly (UNGA, 2012), and can be found in AHWGW, 2012.

10. Collection of information

When the methods of work were being developed, it was thought that there would be time for a number of working papers to bring together detailed information and thus to serve as the basis for the preparation of this Assessment. In practice, the time available has not proved sufficient to adopt this approach generally. In some cases, detailed background information has been included in appendices to the relevant chapter.

11. Development of the first World Ocean Assessment

The starting point for each substantive chapter has been the outline developed by the Ad Hoc Working Group of the Whole, on the basis of proposals from the Group of Experts, approved by the General Assembly (AHWG, 2012; UNGA, 2012) and slightly amended by the Ad Hoc Working Group of the Whole in 2014 (AHWG, 2014). The writing teams, constituted as described above, elaborated this outline and, in some cases, assigned drafting duties within the Group. A draft chapter was prepared, reviewed by the Lead Member (where not part of the writing team), by other members of the Group of Experts to ensure consistency among chapters, and (in some cases) by a panel of commentators chosen from the Pool of Experts, but not otherwise part of the writing team. The writing teams responded as necessary to comments from these reviews and prepared a consensus draft chapter. The consensus draft was submitted to the Group of Experts and secretariat. The Group of Experts collectively reviewed all these consensus draft chapters, in order to ensure consistency and to prepare the synthesis chapters for each Part of this Assessment and Part I (the summary). An editor overseen by the secretariat reviewed each chapter for format and consistency, raising questions for clarification with the writing team where necessary. After any concerns raised by the copy editor had been addressed, the secretariat circulated the entire draft of the first Assessment for review by States, by a team of peer reviewers assigned by the Bureau of the Ad Hoc Working Group of the Whole, on a proposal from the Group of Experts and by intergovernmental organizations. In March 2015, close to 5000 comments were received. The Group of Experts and the writing teams then proceeded to respond to the comments and revise the draft chapters accordingly. At the end of April 2015, the Group of Experts met again in New York to discuss the finalization of the responses and the revision of the chapters. Following a review by the secretariat of the responses and revisions, all chapters of the Assessment were ready for submission to the Bureau by mid-July. The Assessment, including its summary² is to be considered by the Ad Hoc Working Group of the Whole in September 2015.

Part III

Assessment of Major Ecosystem Services from the Marine Environment (Other than Provisioning Services)

Chapter 3. Scientific Understanding of Ecosystem Services

Contributors: Marjan van den Belt (Lead author and Convenor), Elise Granek, Françoise Gaill, Benjamin Halpern, Michael Thorndyke, Patricio Bernal (Lead member)

1. Introduction to the concept of ecosystem services from oceans

Humanity has always drawn sustenance from the ocean through fishing, harvesting and trade. Today 44 per cent of the world's population lives on or within 150 kilometres from the coast (United Nations Atlas of Oceans). However this fundamental connection between nature and people has only very recently been incorporated into trans-disciplinary thinking on how we manage and account for the human benefits we get from nature. Today, when a product taken from an ecosystem¹, for example, fibres, timber or fish, enters the economic cycle (i.e., a part of the human system), it receives a monetary value that accounts at least for the costs associated with its extraction and mobilization. If that natural product is the result of cultivation, as in the case of agriculture, forestry and aquaculture, the monetary value also includes the production costs. However, the extraction of natural products and other human benefits from ecosystems has implicit costs of production and other ancillary costs associated with preserving the integrity of the natural production system itself. Traditionally these benefits and costs have been hidden within the “natural system,” and are not accounted for financially; such hidden costs and benefits are considered “externalities” by neoclassical economists. While the neoclassical economic toolbox includes non-market valuation approaches, an ecosystem services approach emphasizes that ‘price’ is not equal to “value” and highlights human well-being, as a normative goal. The emergence and evolution of the ecosystem services concept offers an explicit attempt to better capture and reflect these hidden or unaccounted benefits and associated costs when the natural “production” system is negatively affected by human activities. The ecosystem services approach has proven to be very useful in the management of multi-sector processes and already informs many management and regulatory processes around the world (e.g. United Kingdom National Ecosystem Assessment, 2011).

Ecosystems, including marine ecosystems, provide services to people, which are life-sustaining and contribute to human health and well-being (Millennium Ecosystem

¹ Synonyms for ‘ecosystems’ in the literature are: natural systems, natural capital, nature, natural assets, ecological resources, natural resources, ecological infrastructure.

Assessment, 2005; de Groot, 2011). The Millennium Ecosystem Assessment defines an ecosystem as “a dynamic complex of plant, animal and micro-organism communities and their non-living environment interacting as a functional unit” and goes on to define ecosystem services as “the benefits that humans obtain from ecosystems” (p. 27). This definition encompasses both the benefits people perceive and those benefits that are not perceived (van den Belt et al., 2011b). In other words, a benefit from ecosystems does not need to be explicitly perceived (or empirically quantified) to be considered relevant in an ecosystem services approach. Similarly, ecosystems and their processes and functions can be described in biophysical (and other) relationships whether or not humans benefit from them. Ecosystem services reflect the influence of these processes on society’s wellbeing; including people’s physical and mental well-being. While ecosystems provide services not only to people, the evaluations of services are, by definition anthropocentric.

The deliberate interlinking between human and natural systems is not new, but over the past few decades interest in “ecosystem services” as a concept has surged, with research and activities involving natural and social scientists, governments and businesses alike (Costanza et al., 1997; Daily, 1997; Braat and de Groot, 2012). This interest is in part driven by the growing recognition that the collective impact of humans on the earth is pushing against the biophysical limits of many ecosystems to sustain the well-being of humankind. Such pressures are well recognized (e.g., Halpern et al., 2008; Rockstrom et al., 2009) and are felt by pelagic, coastal, and intertidal ecosystems.

The human system – comprising built, human and social capital² –ultimately is fully dependent on natural capital. Ecosystems can exist without humans in them, but humans cannot survive without ecosystems. Therefore, the human system can usefully be considered as a sub-system of natural capital. An ecosystem services approach then becomes an organizing principle to make visible the relative contribution of natural capital toward the goal of human well-being. The use of such an organizing principle can be the basis for investments to maintain and enhance natural capital to ensure a flow of ecosystem services (Costanza et al., 2014).

Natural capital is the natural equivalent of the human-made agricultural and aquaculture production systems mentioned above (Daly and Cobb, 1989). In essence, natural capital refers to ecosystems (i.e., coastal shelves, kelp forests, mangroves, coral reefs and wetlands) as a network of natural production systems in the most fundamental sense. Humans with our many production systems are part of this natural capital and collectively have much to gain or lose from maintaining or neglecting, respectively, its sustainability.

The normative goal underpinning the ecosystem services concept is to maintain long-term sustainability, as well as local and immediate enhancement of human well-being within the carrying capacity of the biophysical system. To continue

² Built Capital refers to human-made infrastructure. Human Capital refers to the ability to deal with complex societal challenges, including education, institutions and health. Social Capital refers to the networks of relationships among people who live and work in a particular society, enabling that society to function effectively.

receiving a sustainable flow of ecosystem services, it is crucial to manage the scale of the human system relative to its natural capital base (Rockstrom et al., 2009). The ecosystem services approach acknowledges natural capital as the paradigm in which the human subsystem exists, highlighting (but not limiting to) the anthropocentric aspect of this concept (Costanza et al., 2014). At the same time the ecosystem services approach draws into decision-making the less visible aspects of sustainable development, such as supporting, regulating and cultural services. Through an ecosystem services approach, people, governments and businesses are increasingly using this approach as an organizing principle for finding new ways to invest their human, social and built capital in this common goal (Döring and Egelkraut, 2008).

The magnitude of human pressures on the earth's natural systems and acknowledgement of the interconnectedness between ecosystems and human subsystems has revealed a need to transition from an emphasis on single-species or single-sector management to multi-sector, ecosystem-based management (TEEB, 2010a; Kelble et al., 2013) across multiple geographic (Costanza, 2008) and temporal (Shaw and Wlodarz, 2013) dimensions. Intensification of use of natural capital increases interactions between sectors and production systems that in turn increase the number of mutual impacts (i.e., externalities). This requires accountability among tradeoffs in a way that was, perhaps, not as necessary when the use of natural capital was less intense. On land, negative impacts can be partially managed or contained in space. However, in the ocean, due to its fluid nature, impacts may broadcast far from their site of origin and are more difficult to contain and manage. For example, there is only one Ocean when considering its role in climate change through the ecosystem service of "gas regulation".

An ecosystem services approach supports assessment and decision-making across land and seascapes; i.e., to consider benefits from ecosystems in natural, urban, rural, agricultural, coastal and marine environments in an integrated way, and ultimately to understand the potential and nature of tradeoffs among services given different management actions. An example derived from Food and Agriculture Organization (FAO) states that 50 billion United States dollars is lost annually from global income derived from marine fisheries, compared to a more sustainable fishing, due to fish stocks over-exploitation, when viewed through an ecosystem services lens (FAO, 2012).

Principles for sustainable governance of oceans³ are straightforward (Costanza et al., 1998; Crowder et al., 2008,), but use of an ecosystem services approach has the potential to provide a basis for collaborative investments (in monetary or governance efforts), based on common ground and shared values. In other words,

³ 'Lisbon' Principles for Sustainable Development of Oceans: 1) Responsibility: ability to respond to social and ecological goals. 2) Scale-matching: ensuring flow of ecological and social information allows for timely and appropriate action across scales. 3) Precaution: in the face of uncertainty about potentially irreversible ecological impacts, decisions about natural capital err on the side of precaution. The burden of proof shifts to those whose activities potentially damage natural capital. 4) Adaptive management: decision-makers collect and integrate socio-cultural-economic-ecological information, adapting their decisions accordingly. 5) Full-cost accounting: where appropriate, external costs allow markets to reflect full costs. 6) Participation: foster stakeholder awareness and collaboration.

the ecosystem services approach has the potential to provide a new “currency” or organizing principle to consider multi-scale and cross-sectoral synergies and tradeoffs.

Several recently developed and evolving frameworks outline an ecosystem services approach and its underlying connection between natural and human systems. Although the essence of the ecosystem services concept is the dependence of human well-being on ecosystems, there are diverse definitions of the concept, reflecting differing worldviews on how human systems relate to ecosystems. For example, ecological economists emphasize that human societies are a sub-set of ecosystems and as a consequence assume limited substitutability between built/manufactured and natural capital (Daly and Farley, 2004; van den Belt 2011a; Braat and de Groot, 2012; Farley, 2012). Some definitions of ecosystem services emphasize the functional aspects of ecosystems from which people derive benefits (Costanza et al., 1997; Daily, 1997) and others put more emphasis on their utilitarian aspects and seek conformity with economic accounting (Boyd and Banzhaf, 2007; United Nations Statistics Division, 2013). Still others emphasize human health and well-being (Fisher et al., 2009) and values (TEEB, 2010a).

The ecosystem services approach aims to address and make explicit the inherent complexity of the coupling between biophysical and human systems. For example, it allows regulating ecosystem services at a global scale, such as climate regulation and sea level rise, to be integrated into local decision-making (Berry and Bendor, 2015). An important point here is that though climate change is perceived as a broadly global phenomenon, its impacts will be local, depending on a host of local/regional drivers that will interact with global climate changes. This means that assessments of natural capital and ecosystem services are best done at multiple scales. At the same time, integration across and between regions is essential to ensure shared best practices, agreed protocols and data-access policies, etc. This is an important function for governance at the global level.

The ecosystem services approach has been embraced by different fields and perspectives. For example, those concerned with biodiversity (e.g., TEEB, 2009; TEEB, 2010a; TEEB, 2010b; TEEB, 2010c; Intergovernmental Panel for Biodiversity and Ecosystem Services-IPBES) and climate change (e.g., Intergovernmental Panel for Climate Change-IPCC) have generally aligned themselves with this approach. Many international organizations (e.g., United Nations, World Bank, the Organization for Economic Cooperation and Development (OECD), The Nature Conservancy, International Union for the Conservation of Nature(IUCN), FAO), governments (e.g., European Union, United Kingdom, United States of America), and increasingly companies (e.g., Dow Chemical and potentially those connected to the World Oceans Council) are collaborating to explore the potential for efficient and effective decision-making offered by an ecosystem services approach. An example of intergovernmental collaboration on ecosystem services is the Group on Earth Observations (GEO)⁴ and particularly GEO’s Biodiversity Network (GEO BON), a voluntary partnership among intergovernmental, non-governmental and governmental organizations (www.earthobservations.org/geobon). The

⁴ GEO, the Group on Earth Observations has today 89 member states and the European Commission.

Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) enhances this integration effort at sub-regional, regional and global levels (Larigauderie and Mooney, 2010; www.ipbes.net).

Although the concept has achieved broad acceptance, caution is needed in implementing ecosystem services approaches to avoid a simplistic or biased commodification of ecosystems that prioritizes some elements of nature that are economically useful to the detriment of overall ongoing preservation of those ecosystems for their intrinsic value. An unbalanced approach focused primarily on assigning monetary values can exacerbate power asymmetries and increase socio-ecological conflicts (e.g., Beymer-Farris and Bassett, 2012). Giving equal focus to non-market/non-use services within the ecosystem services framework is both a desirable approach and a strength of this method for decision-making (Chan et al., 2012). When ecosystem services are approached as an organizing principle, this includes the development of common units of measurement for decision support, beyond application of existing tools in the natural and social science toolboxes. It needs to be acknowledged that we don't, and may never, fully understand social-ecological systems to the point that people can confidently predict changes and impact or 'optimize' these systems. A precautionary stance regarding management and governance for maintenance of resilience of social-ecological systems is highlighted (Bigagli, 2015).

The ecosystem services approach gained momentum in the late 1990s, when monetary values associated with ecosystem services from natural capital were conservatively estimated (at a rate double that of global Gross Domestic Product (GDP) to highlight the potential economic and societal value of previously unvalued ecosystem services (Costanza et al., 1997). These values were globally expressed with a single spatial dimension, a snapshot of which is shown in Figure 1. These values only provided a starting point of a necessary debate, as they relied on many and generally conservative assumptions about how to, in a broader sense, value services globally. Although they expressed these services in monetary values, the authors did not claim that these services were suitable for exchange in the market system (Costanza et al., 1997). A recent re-assessment of these global values indicated that the values of global ecosystem services have increased with additional studies on ecosystem services, but these values simultaneously have decreased where natural capital has been converted to other types of capital (Costanza et al., 2014).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Global map of values of estimated ecosystem services in 1997. Source: Costanza et al., 1997.

An ecosystem services approach certainly isn't without controversy and critique is offered by neoclassical economists and ecologists (McCauley, 2006), albeit for different reasons. Some critiques of an ecosystem services approach are highlighting the utilitarian manner in which this approach has been implemented (Wegner and Pascual, 2011; Bscher et al., 2012). Ecosystem services, or "nature's benefits" provide a strengths-based, organizing principle to more deliberately and systematically consider the contributions biophysical communities (including biodiversity and habitat) provide to human well-being (including health). A weak application of an ecosystem services approach builds on traditional natural resource management tools by considering a broader appreciation of the advantages provided by natural systems to include social, economic, health and ecological benefits. This approach is then used to analyze, in more detail, aspects of ecosystem services currently considered externalities and builds upon natural resource management strategies of the 20th century. This may incrementally expand the quality and quantity of relevant indicators considered when making decisions about tradeoffs. In a strong application of an ecosystem services approach, it can be used to synthesize systemic aspects of managing the human sub-system *within* an ecosystem. A strong application of an ecosystem services approach requires the design of tools and skill sets suitable to support multi-faceted management and governance strategies fit for the 21st century.

The Millennium Ecosystem Assessment (2005) classified ecosystem services as: provisioning services (e.g., food – including food traded in formal markets and subsistence trade and barter -, pharmaceutical compounds, building material); regulating services (e.g., climate regulation, moderation of extreme events, waste treatment, erosion protection, maintaining populations of species); supporting

services (e.g., nutrient cycling, primary production) and cultural services (e.g., spiritual experience, recreation, information for cognitive development, aesthetics).

Supporting services are often considered at an ‘intermediate’ level as support functions toward “final ecosystem services” (Landers and Nahlik, 2013). While the intermediate nature of supporting services makes accounting more challenging, i.e. avoiding double counting, it is also important to acknowledge the “unaccountable” characteristics of ecosystems for three reasons. First, the complexity of ecosystems is such that applying accounting practices modelled in accordance with traditional economic accounting is often both impossible and inappropriate. In other words, while economic activities can be aggregated to a certain extent⁵, attributes of ecosystems and their functions do not lend themselves well to aggregation. Second, supporting services or support functions underlie all other services (e.g., provisioning and cultural services are made available in part by supporting services). Third, supporting services are often considered to be most important from cultural and spiritual perspectives, which have their own specific value (Chan et al 2012).

Scientific publications concerning ecosystem services have grown exponentially since the late 1990s. As shown in Figure 2, the marine and coastal ecosystem services (MCES) literature is no exception. Liqueete et al. (2013) recently categorized 145 articles on the current status of MCES.

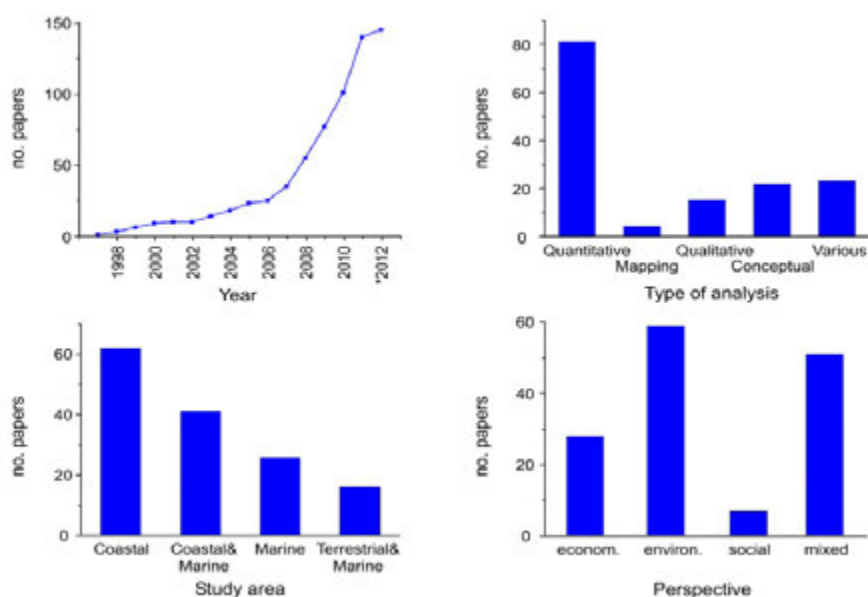

Figure 2. Data and analysis from 145 MCES assessments by Liqueete et al. (2013). A. Number of publications per year. *The year 2012 covers 1 January to 4 April. B. Number of studies per type of analysis. C. Number of papers per type of environment analyzed. D. Number of publications per scientific discipline.

The analysis by Liqueete et al. (2013) found that most of the MCES case studies they reviewed: 1) were concentrated in Europe and North America; 2) did not cover the

⁵ The System of National Accounts does not account for everything either.

area beyond the continental shelf edge, with benthic habitats generally lacking, and 3) focused on mangroves for supporting and provisioning services and on coastal wetlands for regulating and supporting services. A primary focus on local or regional geographic location raises a concern for MCEs, as biophysical events and conditions are generated further afield. For example, patterns of upwelling and migratory species will be influenced by benthic and oceanic conditions that might occur at some distance from the affected region and thus will be difficult to predict. As in other domains, decision-makers have to make decisions under conditions of high uncertainty with limited ability to conclusively consider all risks. An ecosystem services approach has the advantage of making visible the non-linear behaviour⁶ of ecosystems and draw attention in decision-making to fundamentally different alternatives (Barbier et al., 2008). Such alternatives may lead to synergies (i.e., shared values across sectors as a basis for social-ecological enterprises and poverty alleviation) or to difficult trade-offs between different uses or user groups. A valuation spectrum should include “all that is important to people”, whether the people themselves perceive this or not (van den Belt et al., 2011b) and regardless of whether the value is monetary, spiritual, cultural, or otherwise.

2. Evolving ecosystem services frameworks, principles and methods

An overview follows of accepted typologies, principles and methods currently used for assessing and measuring ecosystem services in the rapidly growing international literature. Although concepts and methodologies show a consistent pattern in local applications, no generally accepted classification of ecosystem goods and services for global accounting purposes exists (Haines-Young and Potschin, 2010; Böhnke-Henrichs et al., 2013). The complexity of such a task requires a pluralistic approach across temporal and spatial scales to make ecosystem services visible in decision-making processes and to decision-makers. Capabilities for temporal and spatial analyses are evolving rapidly (e.g. Altman et al., 2014). These now enable decision support and the use of an ecosystem services approach at local, regional, national and global scales (e.g. Zurlini et al., 2014). However, consistency across scales and across terrestrial and marine environments has not been achieved. This is often highlighted as a research, policy and management priority (Braat and de Groot, 2012). For example, the Ecosystem Service Partnership (ESP) (www.es-partnership.org) attracts scientists and practitioners working with the ecosystem services concept in a self-organizing manner. The ESP website allows the assessment of ecosystem services through the various themes, geographic locations and biomes. The themes (Table 1) provide a good overview of the variety of methods and tools and required skills through which the ecosystem services concept can be viewed. Associated with ESP, the Marine Ecosystem Services Partnership (<http://marineecosystems-services.org/>) features a library of valuation-oriented literature, organized by ecosystem, on the delivery of ecosystem services and offering interconnection with other databases (see Appendix 2 for an overview of

⁶ Non-linear behaviour refers to the characteristic of complex systems where effects are not proportional to their causes.

relevant databases). Currently organized by country, further analyses of scale addressed by the valuation studies included may help progress toward a multi-scale approach. For example, completion of Table 1 for marine ecosystem services could be very useful for a future second United Nations World Ocean Assessment.

11. Ecosystem service accounting and greening the economy		
12. Governance and institutional aspects		

The Economics of Ecosystems and Biodiversity (TEEB) started as a UNEP project (2007 – 2010) initiated by the G8. This resulted in the promotion of steps toward the management of values that people derive from ecosystems (Figure 3). In essence, the TEEB framework clusters and links the ESP themes into a process suitable for decision support for projects, governments and businesses (TEEB, 2010b). This process is then ideally implemented systemically, with appropriate feedback mechanisms for on-going assessments of all aspects involved at multiple scales.

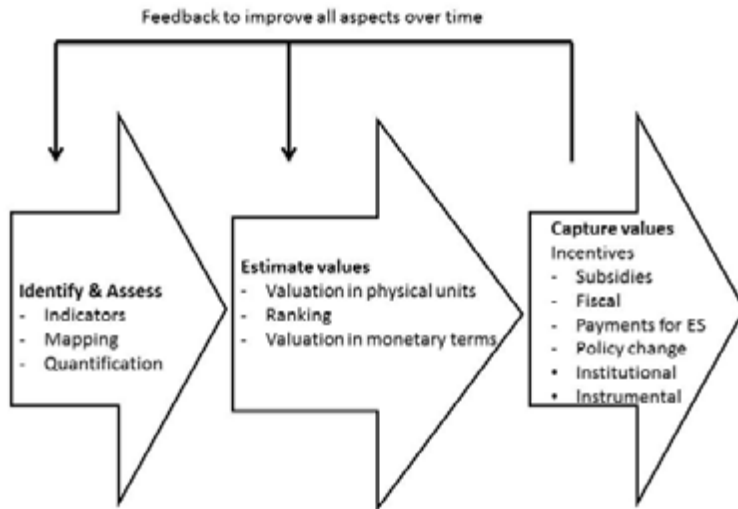

Figure 3. Process of ecosystem service assessments based on TEEB, redrawn after Hendriks et al., 2012.

2.1 *The flow of ecosystem services*

For this introductory chapter on ecosystem services, however, we elaborate on the cascading Haines-Young and Potschin (2010) framework. This framework is relevant because of its close alignment with the evolving United Nations System of Environmental-Economic Accounting (United Nations Statistics Division, 2013) and its effort to seek a consistent classification system and set of accounting principles (Boyd and Banzhaf, 2007; Landers and Nahlik, 2013).

Conceptual models, such as the Common International Classification of Ecosystem Goods and Services (CICES) (Haines-Young and Potschin, 2010), enable practitioners to differentiate between natural capital, i.e., the natural resources or ecological infrastructure, and the services that are derived from that infrastructure. This is presented in a framework cascading from biome to function/process, service, benefit and value (Figure 4). This framework is influenced by two perspectives: 1) the desire to account for ecosystem services and avoid double counting by economists and 2) an opportunity for natural scientists to rapidly communicate the value of particular ecological structures and processes. When applying this framework, supporting and cultural ecosystem services are easily ignored, as non-market⁷ values are at best considered at the end of the cascade and more often are not considered at all; and the flow of ecosystem services is portrayed as linear or unidirectional, mimicking a production chain, and implies a “trickling down” from natural capital to value for people, whose task it is to perceive this value. Appreciated for its simplicity, this framework relies, in theory, on coherent and collective policy action to correct cumulative pressures when values are perceived. This feedback requires active

⁷ In a weak application of an ecosystem services approach, cultural services are often limited to a monetary equivalent of 'recreation'. In a stronger application of this approach spiritual connections, sense of place and mental well-being are recognized. Social sciences contribute a myriad of tools to appreciate such values (e.g. (Pike et al., 2014).

management to allow natural capital to function and provide essential services and benefits, whether people perceive such values or not. This framework shows similarities to the DPSIR (Driver-Pressure-State-Impact-Response⁸) framework. In comparison, the U.S. EPA draft classification system for Final Ecosystem Goods and Services (FECS-CS) attempts to provide a categorization of beneficiaries and assist in tracking changes in ecosystem services upon those beneficiaries (Landers and Nahlik, 2013).

Economists often use the term ‘ecosystem goods and services’, in part to seek comparability and consistency with the System of National Accounting (United Nations Statistics Division, 2013). It is important to recognize that the provision of ecosystem goods and services relies on the integrity of ecosystem processes and functions, referred to as regulating and supporting ecosystem services, with characteristics that make them less than suitable for rigorous accounting (Farley, 2012). Disparate disciplinary perspectives occur in the context of applying an ecosystem services approach; e.g., economists appreciate an ability to account for outputs and optimization of the ‘production process’, whether it is human- or nature-made, whereas ecologists tend to resist such a linear accounting of ecosystems as inaccurate because ecosystems are ‘complex systems’, with highly non-linear behaviours, and simplifying these complexities can lead to misrepresentation of management needs required to maintain valued services.

Following the steps of this cascading framework, marine ecological infrastructure includes (but are not limited to) biophysical structures, e.g., the open ocean, continental shelves, coral reefs, kelp forests, seagrass beds, mangroves, salt marshes, rocky intertidal and subtidal zones, sand dunes and beaches. These are ecological systems and the associated structures created by biological and physical processes, e.g., primary production, wave generation, and decomposition of organic matter. Ecosystem functions and processes emphasize the potential capacity of natural capital to deliver an ecosystem service, which includes resource functions (e.g., mineral deposits and deep-sea fish), sink capacity (e.g., the ability to absorb, dilute or keep out of sight unwanted by-products) and service functions (e.g., habitat to support biodiversity, wave attenuation, degradation of organic matter).⁹

This flow from biophysical structures to functions and processes to ecosystem services is labelled the “supply of ecosystem services” (Figure 4). Ecosystem services also provide benefits (such as, air to breathe, water to drink, fish to eat, sustenance of marine life, energy to harness from wave/wind/tidal/thermal power, health, safety and increased human well-being). Because these benefits are essential for

⁸ DPSIR: Drivers-Pressures-State-Impact-Response generally focusses on impacts as in costs rather than on the benefits people derive from ecosystems. Another difference is that the ‘State’ in DPSIR has a biophysical focus, whereas in the ES framework, the ‘State’ of the human dimension is equally important. (Kelble et al., 2013).

⁹ Some scholars (e.g., Aronson et al., 2007) separate natural capital into renewable natural capital (living species and ecosystems); non-renewable natural capital (subsoil assets, e.g., petroleum, coal, diamonds); replenishable natural capital (e.g., the atmosphere); and cultivated natural capital (e.g., aquaculture).

human well-being, a market or non-market value¹⁰ can, in some cases, be placed on these ecosystem services. This is part of the cascade labelled ‘demand for ecosystem services’.

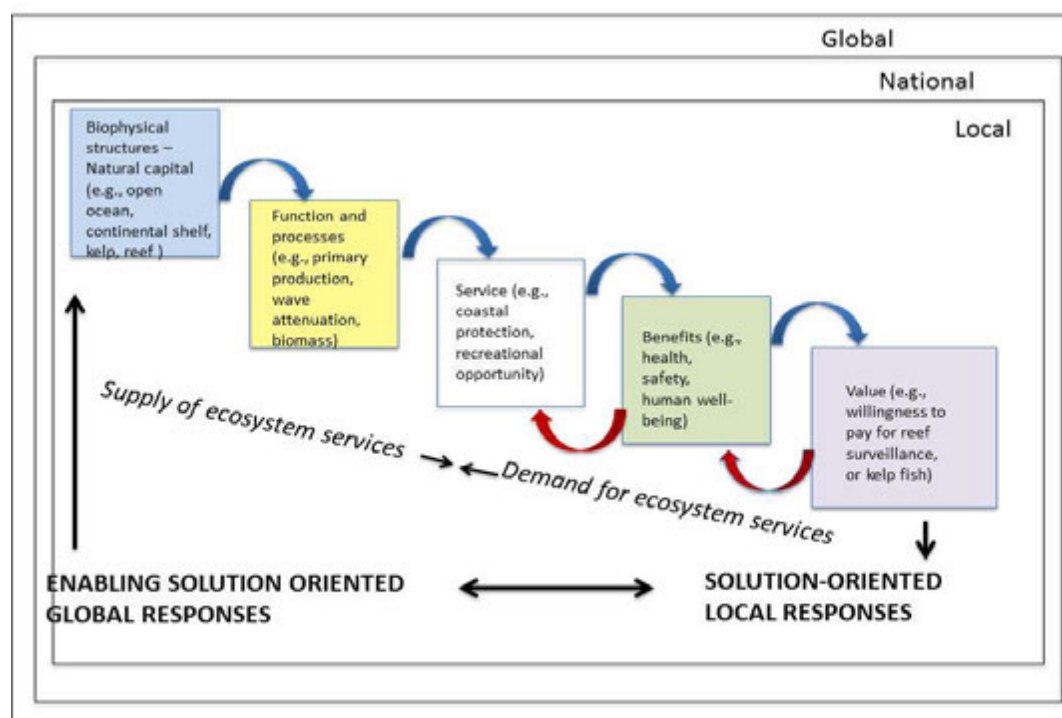

Figure 4. The flow of ecosystem services at multiple scales. Adapted from Haines-Young and Potschin (2010). While not a part of the original model, we added and highlight the ‘supply of and demand for ecosystem services’ and the gap between ‘supply and demand’, signalling a shortage or abundance of ecosystem services. This is one basis for establishing ‘value’ in a broader sense.

In essence, the flow diagram has two fundamental purposes: (1) identifying the ecological processes required to attain ecosystem services; and (2) developing the ability to account more rigorously for this natural ‘production system’, particularly at a global level. At this analytical level, the ecosystem services concept effectively reveals and communicates the ‘invisible’ biophysical processes and functions and thereby broadens, guides and informs local decision alternatives and scenarios. This is not a uni-directional flow - the ‘cascading production chain’ (as shown in Figure 4) also requires attention for reverse processes taking ‘values’ in a broad pluralistic sense, as a starting point, to collectively develop solutions (Haines-Young and Potschin, 2010; van den Belt, 2014; Maes et al., 2012; Tallis et al., 2012). Understanding this flow of ecosystem services at multiple scales, top-down and bottom-up, facilitates practical local solution-oriented responses, enabled by global guidance.

Sometimes a limited set of ecosystem services can be locally managed for short-term benefits, whereas other ecosystem services have globalized characteristics and/or

¹⁰ Market and non-market values are sometimes also referred to as use or non-use values or as instrumental and intrinsic values.

have longer-term benefits. Therefore, this approach has the potential to effectively connect mutual or competing interests at local to global scales and facilitate cohesive decision support. Given that the ecosystem services approach is an inherently anthropocentric concept and is context-dependent, any value attributed to ecosystem services is not absolute and depends on the supply of (i.e., how much of a service is available, if it is limiting) and demand for the service (i.e., how much people need or want a service). A 'gap' between supply and demand of ecosystem services indicates a shortage or abundance (Figure 4). The gap varies temporally and spatially, per societal sector, and by the political scale of the perspective (i.e., local, regional, or global). When an abundant supply of ecosystem services exists relative to demand, the governance or management requirement is primarily one of monitoring. A shortage of supply of ecosystem services, relative to demand, makes the necessity of effective governance and management more acute (see also 'time preference' below) - quality and efficiency of delivery of ecosystem service need to be considered. Supply and demand are dynamically interconnected and therefore employment of methodologies beyond market-based theories is crucial.

2.2 *Biophysical supply of ecosystem services*

Any assessment of ecosystem services must begin with natural capital. The natural system encompasses species present, the flows of matter and energy to which these species contribute, their functional attributes, and the interactions with the physical environment that serve to enhance or dampen the functional attributes and processes. This may require principles and practical guidelines codifying simplification schemes (e.g., Townsend et al., 2011), as science will not be able to provide all of the answers in the time needed to develop management responses. An assessment of natural capital in marine systems should include the distribution and level of ecosystem services in relation to space and time, so that changes in ecosystem services may be better understood following different management practices and proximity to tipping points of marine ecosystems (MacDiarmid et al, 2013; Townsend and Thrush, 2010).

Assessing the supply of ecosystem services in practice requires a process similar to the generic TEEB approach highlighted in Figure 3. First, one must define, as specifically as possible, how an ecosystem function or process of interest connects to specific human benefits of interest and exactly which aspects of a species or ecosystem structure are connected to that function. Developing such a conceptual model following ecological principles (Foley et al., 2010) is important because, for example, a single species can provide more than one function, and different attributes or processes of the species may be more or less important for (a) particular service(s) of interest. For example, mangrove forests provide coastal protection, carbon storage, nursery habitat, and wood, among other services, and these services are provided primarily by the density of above-ground biomass, below-ground biomass, submerged root structures, and the absolute amount of above-water/ground biomass, respectively. Mangroves can provide bundles of ecosystem services, which are inter-related to each other. Measurements require knowledge of such bundles and how they occur at multiple spatial scales over which their benefits are conferred (Costanza, 2008).

The second step is to develop a model describing how the biophysical system produces or inhibits production of the metric of interest, and which key drivers modify that production. This step corresponds to step 1 in Figure 3. In the mangrove example above, if we are interested in the coastal protection function of mangrove forests and thus the above-ground density of the woody biomass, we ideally would have or develop a mangrove growth model that could predict how wave height and intensity, sunlight, rainfall, sedimentation, etc., affect production, and especially the inter-plant density, of the woody biomass. In order to do this modelling, for all potential functions (and services) of interest, one can draw on or develop species-specific population models coupled with ecosystem dynamics models, although the parameters of the model may vary spatially and temporally. Once in place, these models then permit relatively simple sensitivity analyses that identify key drivers of change in the metric of interest.

Such models are always challenged by the availability of data, particularly in many developing countries. Thus, model development must proceed hand-in-hand with data discovery and, where possible, data-gap filling, so that models are tailored to the scale, resolution, and complexity of the data available for a region (Figure 5). Typically useful data include physical data on sea level, pH, temperature and wave height and intensity, and biological data on the demographics, densities, dispersal, and trophic dynamics of species. Although the data needs are similar at a global level across the major oceans, these data will vary by locale and temporally (sometimes seasonally). Availability of data and scientific understanding to properly parametrize such models in particular, depends on scale and differs between regions. Local/regional data for marine ecosystem services assessments are generally much more available for countries including, but not limited to Europe, North America, Australia/New Zealand, and Japan, and are very poor in most of Africa, Asia, and Latin America. A complete world assessment of ecosystem services is beyond the scope of this Assessment, but would ideally be undertaken for a future assessment.

The final step in the process of assessing the supply of ecosystem services is to map and monitor the modelled or empirically derived values for the metrics of interest (step 2 in Figure 3) and the communication thereof (step 3 in Figure 3). Mapping and modelling are inherently constrained by the spatial resolution of the input data for the models described above. Without such maps, one cannot say from *where* within a region of interest the supply of and demand for the service is actually coming, and thus managers are left to make decisions about how to maintain or improve the supply, in order to meet demand, at the coarsest scale of assessment (for example, for an entire country). Such coarse-scale decision-making may be appropriate, and in fact is often all that is needed for many decision contexts that occur at a scoping level. Scoping is the process used to identify the key issues of concern at an early stage in any planning process. Scoping should be carried out at an early stage to facilitate strategic planning and reporting. However, when management is using an ecosystem services framework to make smaller-scale decisions, such as designation of Marine Protected Areas, issuing permits for offshore mining, oil or wind-energy installations, and offshore aquaculture installations, then more detailed maps of service supply are critical.

Numerous examples of both types of decision-making exist. On the one hand is the more general, coarse-scale, often data-poor heuristic assessment, where decision-makers are primarily interested in whether service supply will go up, stay constant, or decline under a given management action. For example, model-building, including indigenous stakeholders, can be used to scope for changes over time in ecosystem service values in a non-spatial manner (van den Belt et al., 2012). On the other hand, more specific, finer-scale, often data-rich quantitative scenario development requires detailed assessments of who wins and loses under a given management action, and by how much, when and where. Examples include decisions on wave energy (Kim et al., 2012) and offshore aquaculture facility locations (Buck et al., 2004), considering specific tradeoffs.

At local and regional scales, often considerable but incomplete data are available, to make visible the biophysical supply of ecosystem services. Fundamental to such efforts are sufficient data to map the location and interaction of key biophysical attributes (such as wave energy, ocean temperature, species density and composition, quality and health of those species, etc.), and for some places around the world such data exist. However, for many regions of the world such data do not exist or are extremely limited, constraining the ability to produce precise global, regional and local estimates of the supply of and demand for ecosystem services. A detailed assessment of the most limiting data gaps between regions is a highly desirable study to be conducted before a second United Nations World Ocean Assessment. The ability to map and monitor key areas for ecosystem service supply is crucial for the development of scenarios and strategies to ensure future supply (Burkhard et al., 2012; Maes et al., 2012a; Maes et al., 2012b; Martinez-Harms and Balvanera, 2012). Furthermore, more complete data sets can be achieved through complementary strategies including baseline assessments in key ecosystems and/or in-depth pilot research efforts that can support model development for extrapolation to similar habitats/ecosystems.

The provisioning of ecosystem services depends not only on the presence of biophysical structure and processes, but the condition (intact vs. degraded) and, in some cases, temporal variability (e.g., seasonal variability in the density or height of seagrasses or kelps, or variability in storm-driven waves). To determine the quantity of an ecosystem service, one must identify the spatial scale (local, regional, global) and temporal scale (short- to long-term) of both supply and demand (also illustrated in Figure 4). A mismatch often exists between the data available on supply *versus* demand due to the variability in spatial provisioning and jurisdictional disconnects between supply and demand and the corresponding data available. For example, global studies often draw on low-resolution, remotely sensed data on a global scale, whereas local studies draw on higher-resolution data on a smaller spatial scale. This difference in data quality and spatial extent can lead to different conclusions on the quantity and quality of service provisioning available and the need to handle differences and uncertainty with care. Nevertheless, considering this 'mismatch' of data and information available to assess a gap between supply and demand of ecosystem services is an important move toward broadening the notion of value away from narrow commodification of ecosystem services.

Of particular importance is the multi-scale aspect of the ecosystem services approach, as it provides an invitation to consider a connection between local and global scales at different temporal/seasonal intervals (Costanza, 2008). Some ecosystem services are produced and consumed *in situ* (e.g., coastal protection), whereas others have clear global aspects (e.g., carbon sequestration, climate regulation, biodiversity, global fisheries and mineral extraction). Certain services are primarily seasonal (e.g., coastal protection), and others are provided or utilized year-round (e.g., food provision).

2.3 Demand for ecosystem services

The 'Benefits' and "Value' steps in the cascading framework (Figure 4) represent the 'demand for ecosystem services' and indicate where drivers of management and decision-making can be incorporated. The perception of values and benefits sets the context when determining the 'supply of ecosystem services'. Therefore, it is important to consider demand for ecosystem services through at least two lenses: (1) demand, as identified by market-based, economic sectors (as defined in the United Nations System of National Accounts); and (2) demand from non-market sectors or societal groups, including 'needs' and 'wants', whether perceived by people or not. Therefore, value statements, if perceived, are bi-directional and can be viewed as "trickling down" through Total Economic Values and/or "trickling up" through participatory involvement of local communities.

Although the biophysical knowledge of the *supply of ecosystems services* is progressing, the understanding and visibility of socio-cultural-health-economic benefits from ecosystems (i.e., the understanding of the *demand for ecosystem benefits*) remain fragmented and are lagging behind, especially for oceans. One difficulty in profiling demand is partly due to the vast geographic scope and overall *invisibility* of supporting and regulating ecosystem services. Demand for ecosystem services is frequently assessed based on diverse rationales, such as risk reduction, revealed preferences, direct use or consumption of goods and services (Wolff et al, 2015). Also, the relative importance of these ecosystem services is often locally perceived by non-market sectors, especially through diverse cultural perspectives. As a result, management and decision-making frequently prioritize quantifiable ecosystem services (e.g., provisioning services). This prioritization of provisioning services often occurs to the exclusion or detriment of supporting and regulating services. On the other hand, cultural services are frequently highlighted together with provisioning services, as indigenous livelihoods are often tightly coupled to provisioning services as part of cultural services.

As a consequence, in any comprehensive process of ecosystem services valuation, it will be necessary to utilize both monetary and non-monetary valuations, as befits the spatial and temporal characteristics of each ecosystem service. When classical economic theory addresses "market failures", it resorts to the following distinctions:

- A *rival good* declines in abundance as it is consumed or used, e.g., when one fishing boat catches a fish, the same fish cannot be caught by another boat.

- *Non-rival goods* can be used by many without being ‘used up’, e.g., one and the same fish can be admired by multiple divers, or clean coastal waters can be available.
- A good is *excludable* if the use of it can be prevented, e.g., one needs permission to drill for minerals in the Exclusive Economic Zone.
- A *non-excludable good* is freely accessible to all, e.g. Storm protection provided by mangroves, seagrasses and reefs and dunes.

Most provisioning goods are ‘rival and excludable’ and therefore more suitable for valuation through markets, (e.g., fisheries in an Exclusive Economic Zone). However, some provisioning services are ‘rival but non-excludable’ (e.g., fisheries outside of Exclusive Economic Zones). Depending on place, some non-rival, excludable goods can be enjoyed by those who can afford them; these include some recreational and research services. Most regulatory and cultural services are non-rival and non-excludable, such as the existence of diverse marine life or practically, whale-watching from shores. Based on these characteristics, it is generally inappropriate and unconventional to value non-rival and/or non-excludable ecosystem services using market mechanisms. Even non-market valuation approaches have severe limitations in this realm, which requires socio-political and institutional considerations. Hence, processes to support “trickling up” of local demand for ecosystem services become increasingly important, preferably supported by appropriate data and an ability to integrate and make these data visible.

Some basic global data is available that can be used for the socio-economic component of assessments based on ecosystem services, such as revenue from coastal and marine related economic sectors. Jobs related to coastal and marine related economic sectors - and cultural values related to culturally important species - may be available at regional level in some places, but are less available in other places. Until the multiple ecosystem services, their interconnections and tradeoffs between different sectors are more accurately recognized and at least semi-quantified in the decision-making sphere, full inclusion of all available global databases is beyond the scope of this first assessment. However, the distinction between markets and other interests, resolution, geographic spread and ease of access are important characteristics of any evolving framework of data sets. ‘Scale’ sets the direct context for any situation where an ecosystem services approach is envisioned, used and under improvement. The ecosystem services approach has the ability to effectively communicate land-sea connectivity and tradeoffs associated with a variety of ocean- and land-based human uses, economic sectors, stakeholders and governance (Butler et al., 2013). In such an analysis, costs (e.g., due to a loss of ecosystem services, often expressed in indirect values) and benefits (e.g., due to a monetary or non-monetary gain in direct or indirect values) are incurred by different groups over different time scales.

Data on ecosystem services and their valuation for specific case studies are often re-used for similar case studies in different locations, because local data collection and analysis are expensive and require specific skills in non-market analysis. Such ‘benefits transfer’ approaches to valuation can be controversial because they require assumptions about similarities among regions that are often inaccurate, but they remain a powerful and necessary approach to filling data gaps, when used with

caution. Table 2 provides a *sample* of references to local case studies of ecosystem services and their values associated with a *sample* of particular marine ecosystems. The development of such matrices is often referred to as a ‘rapid ecosystem service assessment (RESA)’ to identify where ecosystem services and valuation data are available and where data gaps exist. The 17 per cent of boxes that are grey and have no studies referenced represent ecosystem services provided by a particular ecosystem for which insufficient studies have been conducted.

Table 2. Each marine ecosystem provides a suite of ecosystem services, a subset of which are identified; policy and management decisions result in tradeoffs among ecosystem services. * Open ocean may include benthic and pelagic systems. Grey boxes indicate services provided by the ecosystem on the left. Numbers are examples of studies of the ecosystem service in that particular ecosystem. The numbers in table 2 correspond to the case studies listed in Appendix 1. (expanded from Granek et al. 2010).

Selected ecosystem services								
Marine ecosystems	Aquaculture production	Carbon sequestration, climate regulation	Fisheries production	Pharmaceuticals	Pollution buffering and water quality	Protection against storm surges, wind damage	Recreation and Tourism	Shoreline stabilization, Erosion control
Rocky intertidal							13,45, 50	
Salt marshes		12,36, 37						22,29,62
Mangrove forests	15,39,48	3,20,33	16,17, 41		4,23, 47	6,30, 61		10,49,61
Seagrass beds		16,17, 19, 27, 41	16,17, 41		1,34, 52	6,30		
Coral reefs		21,28, 42	9,16, 17,41	9,61		6,30, 61	9,11, 13,25	61
Kelp forests		32,54	24,43, 55,56			30	2,38, 62	
Sand dunes							13,51, 57	5,35, 40
Open ocean*	7,8,26	18,31, 59	44,53, 60				14,46, 58	

Because it is both essential and expensive to initiate studies of local ecosystem services, various databases have been developed to extract relevant information from site-specific case studies and ‘transfer’ such knowledge to similar sites. The ‘benefit transfer’ approach also comes with severe limitations and risk of propagation of errors (Liu et al., 2011). Appendix 2 provides a limited overview of

publicly searchable databases that can assist decision-makers in populating matrices suitable to their region, following the exemplified structure of Table 2. The selection of data bases in Appendix 2 was based on explicit reference to an ‘ecosystem services’ approach, and does not provide an exhaustive list of databases that could be used when applying an ecosystem services approach.

2.4 *Managing gaps, tradeoffs, and values across multiple spatial scales*

Managing tradeoffs, for example between prioritizing fish-protein production from coastal waters *versus* coastal protection (Maes et al., 2012b), recreational use (Ghermandi et al., 2011) or cultural considerations (Chan et al., 2012), can lead to difficult decisions for managers and policy-makers. Fairness of distribution and environmental justice beyond direct costs and benefits for user groups need to be considered. The supply of ecosystem services is affected by decision-making that may favour production or provisioning of one service over others. For example, if kelp harvest is a favoured service that is managed, associated “costs” may be a reduction in fish protein, as fish habitat is reduced, and/or a reduction in recreational diving, as the kelp forest is extracted from the ocean (Menzel et al., 2013). Poor decision-making often results in benefits to some users (i.e., those who harvest kelp) and costs to other users (i.e., those who fish for animals that live in kelp, recreational divers, etc.). To achieve equitable distributions via policy-making, it is necessary to consider who wins (i.e., gains, benefits) and who loses (i.e., suffers a cost or loss), directly and indirectly as well as now and in the future. In the absence of regulation or when decision-making fails to consider the suite of services provided by an ecosystem and the range of users of those services, decisions on how best to manage a marine ecosystem may lead to unintended consequences (e.g., costs to recreational divers and fishing communities).

In decision making, stakeholders or managers often choose a set of possible actions to take and then assess the tradeoffs that exist among the identified options. One strength of an inclusive ecosystem services assessment is that it allows exploration of a broader set of possible actions and outcomes and distributive impacts, often identifying and highlighting true ‘win-win’ solutions (e.g., Lester et al., 2012; White et al., 2012).

Decision-makers are faced with the challenge of considering the spatial and temporal distribution of these services, which directly affects the flow of services. Certain services may be provisioned in close proximity to local communities, but utilized by both local users and others that live far from the location of provisioning. For example, coral reefs may provide protein and coastal protection to local community members on an island, and recreational opportunities, as well as some protein, to outsiders who visit the location as tourists. Even within the local community, individuals residing along the coast may prioritize the coastal protection service of the reefs or mangroves, whereas residents who live inland or upland may prioritize the provisioning of marine protein. The ecosystem services framework, when systematically applied, allows for considerations of multiple ecosystems services over time and space and thus, in this example, highlighting regulating and

supporting services, such as habitat needed for spawning to ensure long term provisioning of protein.

Decisions on how best to manage marine resources frequently require consideration of the tradeoffs among a suite of possible scenarios. These tradeoffs generally entail values gained or lost with each scenario. Most commonly such values assigned are monetary. Historically, this has led to consideration of values that can be given a monetary worth, whereas services that are difficult to measure and value are often excluded from the decision-making process (TEEB, 2010a). Rodriguez et al. (2006) found that provisioning, regulating, cultural and supporting services are generally traded off in this respective order. This approach results in a focus on one or a few ecosystem services and in decisions that have an unequal distribution of costs and benefits across sectors of the population. Failure to include supporting and cultural services, specifically on par with provisioning services, may have unintended consequences.

In other words, understanding the flow of production (i.e., supply) and consumption (i.e., demand) of ecosystem services is complex, leaves room for cultural interpretation (Chan et al., 2012), and has distributive implications (Rodríguez et al., 2006; Halpern et al., 2011). However, tools are available - ranging from simple (for scoping purposes or in the face of poor data) to complex (for management purposes and when adequate data are available) - to assist in the development of scenarios and decision-support for this purpose.

2.5 *Time preferences*

Just as spatial analysis at multiple scales is crucial in understanding the supply of ecosystem services, the understanding of time scales and time preferences are important in assessing tradeoffs, especially with regard to the demand for ecosystem services. The perception of time is often culturally defined. Indigenous peoples often think in terms of multiple generations and time can have a spiritual element. For a market-oriented investor or government, time is captured in a 'discount rate'. In essence, a high discount rate reflects a desire to consume resources now rather than later. From an economic perspective, this choice also determines how quickly an investment returns a profit. Long-term planning to safeguard the benefits of less visible, non-provisioning ecosystem services requires low or even negative discount rates (Carpenter et al., 2007). For investments in natural capital and for people to receive ecosystem services and benefits, multiple discount rates are required. Such ecological discount rates may be place-based (e.g., when considering *in situ* ecosystem services) or universal (e.g., when ecological infrastructure is providing global ecosystem services) and should also reflect the (often slow) recovery time of ecosystems. This would apply to most supporting, regulatory and cultural services, as they are 'non-rival, non-excludable' services. In addition, certain ecosystem services may be provisioned (e.g., coastal protection when seagrass beds are dense enough to attenuate waves) or utilized (intertidal or inshore fisheries during seasons when ocean conditions do not permit offshore fishery) seasonally, highlighting the importance of managing for time frames that reflect seasonal availability of or access to a service (TEEB, 2010a).

2.6 The challenge of multi-scale integrated assessments for ecosystem services

There are indicators that allow us to reflect on the health of oceans, e.g., the Ocean Health Index (Halpern et al., 2012) and retrospectively how ocean health is changing. A general indicator for ecosystem services from oceans is not available, nor may it be desirable as one indicator. Such an indicator would require integration across biophysical and human dimensions, with relevance across multiple scales and developing a transparent ability to consider tradeoffs with a forward perspective. This requires the gathering of data at local, regional, national and global scales, and in principle with three dimensions: space, time and values. Although not unique to the ecosystem services concept, the need to connect local to global scales through bottom-up and top-down governance is paramount.

Database management and modeling capacity are increasingly important to support decision-making at multiple levels of scale. This capacity needs to be ‘fit for purpose’ (i.e., it needs to answer specific questions by decision-makers in a timely fashion), as well as contribute to the development of knowledge across scales (i.e., be relevant beyond the boundary of an individual decision-maker). Currently several tools are available, each emphasizing particular strengths, such as the ability to: (1) communicate effectively with local stakeholders (e.g., Rapid Ecosystem Service Assessments (RESA), Seasketch (McClintock et al., 2012); (2) illustrate spatial aspects (e.g., InVEST (Lester et al., 2012; White et al., 2012); and (3) consider scenarios and changes over time, e.g., Mediated Modeling at the scoping (van den Belt et al., 2012), research, and MIMES/MIDAS (Altman et al., 2014) at management levels. Table 3 illustrates some tools with differing strengths and weaknesses. A comprehensive overview of all tools is beyond the scope of this assessment.

Table 3. A subset of tools that can be included in an ecosystem services valuation ‘toolbox’. The tools range from crude conversation starters (e.g. RESA) to spatially dynamic decision support frameworks (e.g. MIMES).

	Dimension	Rapid Ecosystem Service Assessment (RESA)	SeaSketch	InVEST	Mediated Modeling	MIMES
Context	Social / values	Possible	Yes	Yes	Yes	Yes
Content	Spatial	Limited	Yes	Yes	No	Yes
	Dynamic/ changes over time	No	No	No	Yes	Yes
	Ecological	Yes	Yes	Yes	Yes	Yes
	Economic	Yes	Limited	Yes, where benefits are perceived	Yes, where benefits are not perceived	Yes, where benefits are not perceived
Process	Adaptive	Scoping	Scoping	Research	Scoping	Management

These tools draw on local ‘small data’ and global ‘big data’ to various extents. Each case study has the potential to be used in education and add to the collective building of knowledge on ecosystem services. As discussed, multiple databases on ecosystem services and their values are already available (Appendix 1), many of which feature ecosystem-based management tools (e.g., <http://ebmtoolsdatabase.org>). Newly initiated local case studies, as well as the output from modelling tools and applications of TEEB-like processes, add to this body of knowledge, and draw on ‘big data’ sets. Bringing together the various databases, tools and knowledge gained from various applications is a top priority for multiple stakeholders, such as policy makers, industry and non-governmental organizations. The iMarine infrastructure is one example of an emerging "Community Cloud" platform which offers Virtual Research Environments that integrate a broad range of data services with scientific data and advanced analysis. Such scenarios then result in new datasets. This could be expanded to include protocols for an ecosystem services approach. Figure 5 illustrates a connection between: (1) ‘big data’, primarily spatial information relevant to the supply of ecosystem service and (2) ‘small data’, the transferable insights that can be gained from local case studies. These data are brought together in (modeling) tools, evolving (1) from scoping to management level and (2) from static to dynamic tools. In the same way, but with a much more “bottom-up” and integrated emphasis, the European Marine Biodiversity Observation System (EMBOS: <http://www.embos.eu/>) offers the advantages of scale and expert identification of relevant organisms (taxonomy). This holistic approach is important since marine biodiversity provides many ecosystem services. However, biodiversity is undergoing profound changes, due to anthropogenic pressures, climatic warming and natural variation. Proper understanding of biodiversity patterns and ongoing changes is needed to assess consequences for ecosystem integrity, in order to be in a position to manage the natural resources.

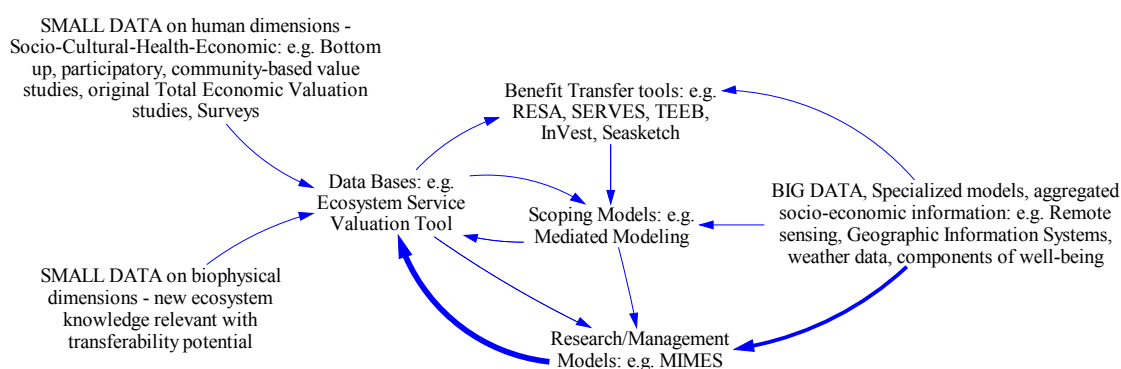

Figure 5. Evolution of ecosystem services knowledge. Adapted from van den Belt et al., 2013.

Appropriate application of an ecosystem services approach as an organizing principle in a consistent manner across multiple scales (space, time and values), requires capacity development.

3. Capacity-building and knowledge gaps

This section highlights knowledge gaps regarding the application of ecosystem services and discusses opportunities for capacity development. This concerns 'human capital', often interpreted as the 'ability to deal with complex societal challenges'. In the context of marine ecosystem services, this is reflected in the capacity to collect and use available data to make visible 'the benefits that people derive from ecosystems' relevant for effective decision-making at multiple scales. This includes effective global policies and agreements, education and awareness programmes. Assessing governance and institutional changes that are required at multiple scales is beyond the scope of this chapter, although it should be noted that a feedback to this effect is included in all of the ecosystem services frameworks.

There is a gap in social sciences and economics' ability to support ecosystem-based science. Application of an ecosystem services approach emphasizes the need for human dimensions of well-being, bridging natural and social sciences. Such integrative approach requires capability building in skills beyond existing disciplines. Generic skills that are needed to work within an ES framework, include: technical (e.g. modellers) and specialists (including scientists in specific disciplines), integrators (to make links between the parts), translators (to change policy questions into assumptions) and interpreters (who can communicate complex issues in simple terms).

The multi-scale and process-oriented aspects of an ecosystem services approach provide both a challenge and an opportunity for capacity development in understanding and capturing value regarding the supply of and demand for ecosystem services. Table 4 attempts to relate the scale of the demand for and supply of ecosystem services with data gaps and capacity to interlink/disseminate data for decision-support.

Table 4. Gaps regarding data and ability to interlink data for decision-support at multiple scales, coherent across marine and terrestrial systems.

	Local	National	Global
Supply of ecosystem services	<p>Need = high resolution data and ability to interlink data for decision-support in the short term.</p> <p>Available = Mixed data and multiple tools; sufficient for scoping purposes in developed countries. Insufficient for management in developed countries.</p> <p>Insufficient for scoping or management in developing countries.</p>	<p>Need = mixed resolution data and ability to interlink data for decision-support in the short and long term.</p> <p>Available = Multiple databases often organized per country and multiple tools.</p>	<p>Need = low resolution data and high ability to interlink and disseminate data for decision-support in the long term.</p> <p>Available = Sufficient data for scoping, insufficient ability to interlink.</p>

Demand for ecosystem services	<p>Need = high ability for recognizing market and non-market sectors in managing tradeoffs.</p> <p>Available = Market-based information often available through the system of national accounting. Non-market-based information depends on local governance and community involvement.</p>	<p>Need = ability for recognizing market and supporting non-market sectors in managing tradeoffs in the short and long term.</p> <p>Available = market-based information and some socio-cultural information depending on country.</p>	<p>Need = ability to support all sectors with understanding of global ecosystem services and humanity's long-term, collective needs.</p> <p>Available = market-based information and some socio-cultural information.</p>
Gap	Matching data between supply and demand of ecosystem services and ability to interconnect with regional/global scales.	Examples of ecosystem services supply; demand-side lagging. Interconnections among ecosystem services and between local and global scales elusive.	Shortage in some global ecosystem services. Interlinkages among global ecosystem services elusive.

The following are important capacity-development needs:

Data availability and resolution at different scales and geographic spread: Here the most important action item will be to map key areas, identify existing gaps and put in place mechanisms for filling those gaps in a coordinated and strategic way. For example, in the developing world data gaps complicate even rapid ecosystem service assessments at the scoping level. Although other areas have access to data for scoping purposes, crucial knowledge is lacking to use such data through an ecosystem services approach for management purposes.

The ability to use data in an integrated manner, both for 'trickling down' accounting, as well as for "trickling up" community empowerment and participatory purposes: This is exacerbated by the severe lack of local empowerment and understanding of the ecosystem services concept and by the fact that it is a multi-factoral and trans-regional, trans-national issue. This can be addressed by coordinated knowledge transfer and information exchange at the global level, for example, in coordination with IPBES.

Capabilities to undertake heuristic/participatory processes: Once again, this should be approached in a regional to global dimension, albeit for enhancement of specific purposes at each level. Heuristics approaches to problem solving can be used in the domains of natural science and social science and refers to 'operating under less than perfect circumstances to arrive at a way forward'. Perhaps most important will be to encourage, facilitate, collate and promote understanding of regional differences in valuation of ecosystem services according to culture and history. The first step in capacity-building and filling in knowledge gaps will be to empower local stakeholder communities and enable them to understand the impact that ecosystem services have on their lives and well-being. Empowerment and enablement are key concepts in the social sciences and if we are to improve and develop an ecosystem services approach, it will be vital to equip communities, from the bottom up, to develop a stronger sense of ownership and responsibility for the protection and

sustainability of their local and global ecosystems and resultant services. However, collectively, it is crucial for people to understand that ecosystem services do not respect national and international boundaries, necessitating an integrated approach and a trading off with adjacent regions. If not accomplished in a transparent manner, this approach is likely to exacerbate regional conflicts. A simple example is the need for an understanding of ecosystem life-processes by the community at large and the interdependence and cascading links between individual ecosystem services. Furthermore, it is vital to understand how this varies region-to-region and culture-to-culture.

Relevance and capacity for different regions, specifically for marine ecosystem services:

Human capacity-building (e.g. technology training/education) and the associated physical infrastructure (e.g., coastal marine laboratories and institutes, marine observatories/observations, oceanographic fleets, together with appropriate and robust technology/instrumentation) are important to understand marine biomes as natural capital. This is expensive infrastructure and it is often lacking or operating at a low level in developing countries. Marine research stations are scattered worldwide, are often long established, and can act as important focal points for community-wide understanding and appreciation of marine/coastal ecosystem services. However, they lack capacity to recognize and value ecosystem services or use this approach as an organizing principle. Yet, these infrastructures have the potential to underpin the ecosystem services approach and facilitate gap-filling, e.g., by collecting data relevant to different sea-users and providing avenues to educate local communities. Improvement in these domains requires appropriate national policies in science and significant institutional strengthening. Education and training are vital to share best practices, data and experience and to create a truly global approach. Good examples of the human capital that is available but is, as yet, fragmented, in terms of supporting the development and understanding of ecosystem services, are the various networks of marine infrastructures exemplified by MARS (<http://www.marsnetwork.org>) in Europe and NAML (<http://www.naml.org/>) in the USA, together with smaller Japanese and Australian counterparts. Recently a global initiative has been launched with the help of the Intergovernmental Oceanographic Commission, i.e., the World Association of Marine Stations (WAMS) (<http://www.marsnetwork.org/world-association-marine-stations-wams>), with the mission to unite and integrate their strategies from training, education, and outreach to best practice and shared research agendas. New initiatives emerging from the EMBRC consortium (<http://www.embrc.eu>) and Euromarine (www.euromarinenetwork.eu) are acting as vibrant platforms bringing together all actors in the marine sphere. An important development recently available is The European Marine Training Portal (<http://www.marinetraining.eu/>). The European Marine Training portal is a centralized access point for education and training in the field of marine sciences. It will help European scientists, technicians and other stakeholders to navigate in the jungle of courses and training opportunities. [Marinetraining.eu](http://www.marinetraining.eu) offers a variety of services to both training organizers and trainees.

Databases and tools available to Marine Stations and Meteorological Centres need to integrate and share data/tools/strategy. Time series are vital for biological/chemical/physical/geological datasets.

As original local studies of ecosystem services are expensive, guidance is needed for local stakeholders and decision-makers to progress from scoping to management tools. This includes a continuum of multiple discount rates relevant to the various ecosystem services (TEEB, 2010a). The network of existing marine research stations and institutes can play a central and coordinating role in providing relevant information and assist in preparation of options to consider bundles of ecosystem services. Many marine stations have historical data sets that, if properly digitized and shared, could help to fill gaps. Many are still locally collecting biogeochemical, biophysical and biodiversity data and recording their changes. These are powerful tools but tend to be restricted to local or regional databases. Although generally not private, they are often not widely known; this is where the United Nations Member States could come together to identify all sources and repositories of knowledge and data and bring them together to benefit the global community. Indeed this is one of the key missions of WAMS, supported by UNESCO-IOC. Whereas this is well recognized in Europe, North America and Australia, for example, an urgent need exists to embrace and empower other less well-supported regions, including but not limited to Africa, South America, the Caribbean, and the Polar regions.

4. Conclusion

Many fundamental Earth system processes are approaching or have crossed safe boundaries for their continued sustainability. Oceans play a crucial role in these Earth systems. After two decades of development, the ecosystem services approach has made good progress in making more visible the benefits people derive from ecosystems, which are often taken for granted. The ecosystem services approach outlined above provides an organizing methodology to assess and analyze the supply of and demand for ecosystem services and to connect across multiple geographic and temporal scales. However, this chapter does not fully outline the necessary steps to determine the potential supply and tradeoffs of ecosystem services for a region. The trans-disciplinary nature of an ecosystem services approach is complex and goes well beyond a mechanical application of both natural and social science, including decision making. The definitions of ecosystem services are multiple and broad and leave room for interpretation. A strong application of the ecosystem services concept can have a transformational impact, shift paradigms and provide new organizing principles advancing sustainability. A weak application of this concept may provide justification for business-as-usual. For example, a robust and strategic application has the potential to create a collaborative space to address fundamental challenges facing humanity; a weak application may address scattered local challenges at best or justify undesirable outcomes at worst.

Establishing principles, approaches and consistent terminology and guidelines for use of marine ecosystem services are needed. Linkages to people are often missing and more data and knowledge on attitudes, perceptions and beliefs of resource

users and resource dependents is key. Several networks (e.g., MEA, GEO-BON, IPBES, TEEB, Lisbon Principles) have developed and are further developing such principles and guides. A significant development in Europe is EMBOS (<http://www.embos.eu/>). This has a focus on observation systems for marine biodiversity. This represents a significant challenge since biodiversity varies over large scales of time and space, and requires research strategies beyond the tradition and capabilities of classic research. Research that covers these scales requires a permanent international network of observation stations with an optimized and standardized methodology. In this way, we recognize that it is increasingly important to develop 'frameworks of frameworks' and understand the underlying purpose and worldview of each contributing framework in order to unify instead of divide the potential support for an ecosystem services approach, especially for oceans. Developing overarching principles, creating consistency in reporting, and generating relevant shared data and information, as well as the capacity to use such information, are creating an exciting opportunity for the United Nations and its members.

The ecosystem services approach has the potential to support a variety of management frameworks, including Marine Spatial Planning and tools for coordinating national and international sustainable marine resource management. Marine laboratories and fleets provide much of the needed data and human capital to better understand the supply of ecosystem services. Opportunities to fill data gaps exist (especially in developing countries), as well as developing capability to make available data suitable for use in ecosystem services approaches. These opportunities should be identified and acted upon with some urgency.

An increasing amount of spatial data/information is readily available/accessible. However, global data are often too coarse in resolution to make accurate estimates for certain regions and the capacity to access and use global data is limited and often lacking in developing countries and even developed countries. In addition, local or fine resolution spatial data and information are often unavailable and expensive. Also, nomenclatures and protocols should be standardized to enable meaningful integration, comparison and shared analyses.

Perhaps the most important gap in knowledge is understanding and integration of an ecosystem services ethos. This can be remedied by initiating a global approach with coordinated knowledge and education transfer amongst both developed and developing nations. Marine ecosystems exist regardless of the status of development of nations, but their integrity is certainly dependent on anthropogenic effects of all kinds under the influence of cultures around the globe. Thus, the ecosystem services approach must be multi-scalar in all facets. A thematic link with IPBES for oceans could address this.

Numerous methodologies have been developed to guide the ecosystem services approach; these range from scoping to highly advanced research and management approaches. Some methodologies provide static 'snapshots,' and others provide a spatially dynamic framework highlighting inter-linkages between bundles of ecosystem services and their changes over time.

The top-down progression of the cascading model (Figure 4) reflects steps involved in scoping the provision and value of ecosystem services. Inclusive, participatory

approaches are important if we are to enhance ecosystem service models with bottom-up considerations to incorporate non-market and monetary values. The incorporation of local or bottom-up perspectives provides the opportunity to better integrate the distribution of costs and benefits and thereby enhance the fairness of decision-making.

When a participatory, bottom-up approach to ecosystem service valuation is taken, the 'gap' between 'supply of' and 'demand for' ecosystem services can more accurately define and measure 'value'; either there is an abundance, a sufficiency, or a shortage in time and space, applying both market and non-market perspectives. Mapping such gaps and how they change over time and space can be used to identify 'hotspots' for prioritization of management actions at multiple scales. Increasingly, marine ecosystem services are used in marine spatial planning (White et al., 2012; Altman et al., 2014).

It is important that the ecosystem services approach is used to influence beyond the immediate jurisdiction of those undertaking or sponsoring an ecosystem services assessment. Marine ecosystems function independently of national boundaries and Exclusive Economic Zones and so require an integrated global approach, if humanity wants to receive ecosystem services. When local biophysical data are not available, more heuristic methods can still guide conversations among multiple stakeholders to consider options to govern, manage and sustain the 'benefits people derive from ecosystems'.

At a global level, assessment of slow-moving biophysical processes (e.g., climate regulation, ocean acidification) need to be interpreted in terms of ecosystem services for their relevance to and impact on bundles of local ecosystem service in case studies.

In order to facilitate and enable the use of an ecosystem services approach, agreement on a global nomenclature and resulting classification would be useful. However, such a classification ought to be flexible enough to allow for local variability in applications. Therefore, the design of nomenclature, principles, and data management needs to be transparent and display characteristics appropriate to scale and purpose.

In addition to multiple scales, comparability between locations and case studies and over time is important. Some databases go to great lengths to encourage long-term comparability, e.g., Marine Ecosystem Service Partnership and Ecosystem Valuation Tool at Earth Economics. Comparability and transferability apply not only to data-gathering and -formatting, but also to the human component of socializing; using/interlinking such data is equally important (e.g., exchanges and collaborative opportunities).

The available ecosystem services frameworks emphasize that this is an iterative, evolving process and therefore needs an adaptive programme of strategic assessment.

Chapter 4. The Ocean's Role in the Hydrological Cycle

Contributors: Deirdre Byrne and Carlos Garcia-Soto (Convenors), Gordon Hamilton, Eric Leuliette, LisanYu, Edmo Campos, Paul J. Durack, Giuseppe M.R. Manzella, Kazuaki Tadokoro, Raymond W. Schmitt, Phillip Arkin, Harry Bryden, Leonard Nurse, John Milliman, Lorna Inniss (Lead Member), Patricio Bernal (Co-Lead Member)

1. The interactions between the seawater and freshwater segments of the hydrological cycle

The global ocean covers 71 per cent of the Earth's surface, and contains 97 per cent of all the surface water on Earth (Costello et al., 2010). Freshwater fluxes into the ocean include: direct runoff from continental rivers and lakes; seepage from groundwater; runoff, submarine melting and iceberg calving from the polar ice sheets; melting of sea ice; and direct precipitation that is mostly rainfall but also includes snowfall. Evaporation removes freshwater from the ocean. Of these processes, evaporation, precipitation and runoff are the most significant at the present time.

Using current best estimates, 85 per cent of surface evaporation and 77 per cent of surface rainfall occur over the oceans (Trenberth et al., 2007; Schanze et al., 2010). Consequently, the ocean dominates the global hydrological cycle. Water leaving the ocean by evaporation condenses in the atmosphere and falls as precipitation, completing the cycle. Hydrological processes can also vary in time, and these temporal variations can manifest themselves as changes in global sea level if the net freshwater content of the ocean is altered.

Precipitation results from the condensation of atmospheric water vapour, and is the single largest source of freshwater entering the ocean (~530,000 km³/yr). The source of water vapour is surface evaporation, which has a maximum over the subtropical oceans in the trade wind regions (Yu, 2007). The equatorward trade winds carry the water vapour evaporated in the subtropics to the Intertropical Convergence Zone (ITCZ) near the equator, where the intense surface heating by the sun causes the warm moist air to rise, producing frequent convective thunderstorms and copious rain (Xie and Arkin, 1997). The high rainfall and the high temperature support and affect life in the tropical rainforest (Malhi and Wright, 2011).

Evaporation is enhanced as global mean temperature rises (Yu, 2007). The water-holding capacity of the atmosphere increases by 7 per cent for every degree Celsius of warming, as per the Clausius-Clapeyron relationship. The increased atmospheric moisture content causes precipitation events to change in intensity, frequency, and duration (Trenberth, 1999) and causes the global precipitation to increase by 2-3 per cent for every degree Celsius of warming (Held and Soden, 2006).

Direct runoff from the continents supplies about 40,000 km³/yr of freshwater to the ocean. Runoff is the sum of all upstream sources of water, including continental precipitation, fluxes from lakes and aquifers, seasonal snow melt, and melting of mountain glaciers and ice caps. River discharge also carries a tremendous amount of solid sediments and dissolved nutrients to the continental shelves.

The polar ice sheets of Greenland and Antarctica are the largest reservoirs of freshwater on the planet, holding 7 m and 58 m of the sea-level equivalent, respectively (Vaughan et al., 2013). The net growth or shrinkage of such an ice sheet is a balance between the net accumulation of snow at the surface, the loss from meltwater runoff, and the calving of icebergs and submarine melting at tidewater margins, collectively known as marine ice loss. There is some debate about the relative importance of these in the case of Greenland. Van den Broeke et al. (2009), show the volume transport to the ocean is almost evenly split between runoff of surface meltwater and marine ice loss. In a more recent work, Box and Colgan (2013) estimate marine ice loss at about twice the volume of meltwater (see Figure 5 in that article), with both marine ice loss and particularly runoff increasing rapidly since the late 1990s. According to the Arctic Monitoring and Assessment Programme (AMAP, 2011), the annual mass of freshwater being added at the surface of the Greenland Ice Sheet (the surface mass balance) has decreased since 1990. Model reconstructions suggest a 40% decrease from 350 Gt/y (1970 - 2000) to 200 Gt/y in 2007. Accelerating ice discharge from outlet glaciers since 1995 - 2002 is widespread and has gradually moved further northward along the west coast of Greenland with global warming. According to AMAP (2011), the ice discharge has increased from the pre-1990 value of 300 Gt/y to 400 Gt/y in 2005.

Antarctica's climate is much colder, hence surface meltwater contributions are negligible and mass loss is dominated by submarine melting and ice flow across the grounding line where this ice meets the ocean floor (Rignot and Thomas, 2002). Freshwater fluxes from ice sheets differ from continental river runoff in two important respects. First, large fractions of both Antarctic ice sheets are grounded well below sea level in deep fjords or continental shelf embayments; therefore freshwater is injected not at the surface of the ocean but at several hundred meters water depth. This deep injection of freshwater enhances ocean stratification which, in turn, plays a role in ecosystem structure. Second, unlike rivers, which act as a point source for freshwater entering the ocean, icebergs calved at the grounding line constitute a distributed source of freshwater as they drift and melt in adjacent ocean basins (Bigg et al., 1997; Enderlin and Hamilton, 2014).

Sea ice is one of the smallest reservoirs of freshwater by volume, but it exhibits enormous seasonal variability in spatial extent as it waxes and wanes over the polar oceans. By acting as a rigid cap, sea ice modulates the fluxes of heat, moisture and momentum between the atmosphere and the ocean. Summertime melting of Arctic sea ice is an important source of freshwater flux into the North Atlantic, and episodes of enhanced sea ice export to warmer latitudes farther south give rise to rapid freshening episodes, such as the Great Salinity Anomaly of the late 1960s (Gelderloos et al., 2012).

The spatial distributions of these freshwater fluxes drive important patterns in regional and global ocean circulation, which are discussed in Chapter 5.

The Southern Ocean (defined as all ocean area south of 60°S) deserves special mention due to its role in the storage of heat (and carbon) for the entire planet. The Antarctic Circumpolar Current (ACC) connects the three major southern ocean basins (South Atlantic, South Pacific and Indian) and is the largest current by volume in the world. The ACC flows eastward, circling the globe in a clockwise direction as viewed from the South Pole. In addition to providing a lateral connection between the major ocean basins (Atlantic, Indian, Pacific), the Southern Ocean also connects the shallow and deep parts of the ocean through a mechanism known as the meridional overturning circulation (MOC) (Gordon, 1986; Schmitz, 1996, see Figures I-90 and I-91). Because of its capacity to bring deep water closer to the surface, and surface water to depths, the Southern Ocean forms an important pathway in the global transport of heat. Although there is no observational evidence at present, (WG II AR5, 30.3.1, Hoegh-Guldberg, 2014) model studies indicate with a high degree of confidence that the Southern Ocean will become more stratified, weakening the surface-to-bottom connection that is the hallmark of present-day Southern Ocean circulation (WG I AR5 12.7.4.3, Collins et al., 2013). A similar change is anticipated in the Arctic Ocean and subarctic seas (WG I AR5 12.7.4.3, Collins et al., 2013), another region with this type of vertical connection between ocean levels (Wüst, 1928). These changes will result in fresher, warmer surface ocean waters in the polar and subpolar regions (WGII AR5 30.3.1, Hoegh-Guldberg, 2014; WG I AR5 12.7.4.3, Collins et al., 2013), significantly altering their chemistry and ecosystems.

Imbalances in the freshwater cycle manifest themselves as changes in global sea level. Changes in global mean sea level are largely caused by a combination of changes in ocean heat content and exchanges of freshwater between the ocean and continents. When water is added to the ocean, global sea level adjusts, rapidly resulting in a relatively uniform spatial pattern for the seasonal ocean mass balance, as compared to the seasonal steric signal, which has very large regional amplitudes (Chambers, 2006). 'Steric' refers to density changes in seawater due to changes in heat content and salinity. On annual scales, the maximum exchange of freshwater from land to ocean occurs in the late Northern Hemisphere summer, and therefore the seasonal ocean mass signal is in phase with total sea level with an amplitude of about 7 mm (Chambers et al., 2004). Because most of the ocean is in the Southern Hemisphere, the seasonal maximum in the steric component occurs in the late Southern Hemisphere summer, when heat storage in the majority of the ocean peaks (Leuliette and Willis, 2011). Because globally averaged sea level variations due to heat content changes largely cancel out between the Northern and Southern Hemispheres, the size of the steric signal, globally averaged, is only 4 mm.

Globally averaged sea level has risen at 3.2 mm/yr for the past two decades (Church et al., 2011), of which about a third comes from thermal expansion. The remainder is due to fluxes of freshwater from the continents, which have increased as the melting of continental glaciers and ice sheets responds to higher temperatures. Multi-decadal fluctuations in equatorial and mid-latitude winds (Merrifield et al., 2012; Moon et al.,

2013) cause regional patterns in sea-level trends which are reflected in the El Niño/Southern Oscillation (ENSO) and the Pacific decadal oscillation (PDO) indices in the Pacific (Merrifield et al., 2012; Zhang and Church, 2012) and northern Australia (White et al., 2014). Interannual changes in global mean sea level relative to the observed trend are largely linked to exchanges of water with the continents due to changes in precipitation patterns associated largely with the ENSO; this includes a drop of 5 mm during 2010-11 and rapid rebound in 2012-13 (Boening et al., 2012; Fasullo et al., 2013).

Some key alterations are anticipated in the hydrological cycle due to global warming and climate change. Changes that have been identified include shifts in the seasonal distribution and amount of precipitation, an increase in extreme precipitation events, changes in the balance between snow and rain, accelerated melting of glacial ice, and of course sea-level rise. Although a global phenomenon, it is the impact of sea-level rise along the world's coastlines that has major societal implications. The impacts of these changes are discussed in the next Section.

Changes in the rates of freshwater exchange between the ocean, atmosphere and continents have additional significant impacts. For example, spatial variations in the distribution of evaporation and precipitation create gradients in salinity and heat that in turn drive ocean circulation; ocean freshening also affects ecosystem structure. These aspects and their impacts are discussed in Sections 3 and 4.

Another factor potentially contributing to regional changes in the hydrological cycle are changes in ocean surface currents. For example, the warm surface temperatures of the large surface currents flowing at the western boundaries of the ocean basins (the Agulhas, Brazil, East Australian, Gulf Stream, and Kuroshio Currents) provide significant amounts of heat and moisture to the atmosphere, with a profound impact on the regional hydrological cycle (e.g., Rouault et al., 2002). Ocean surface currents like these are forced by atmospheric winds and sensitive to changes in them - stronger winds can mean stronger currents and an intensification of their effects (WGII AR5 30.3.1, Hoegh-Guldberg, 2014), as well as faster evaporation rates. Shifts in the location of winds can also alter these currents, for example causing the transport of anomalously warm waters (e.g., Rouault, 2009). However, despite a well-documented increase in global wind speeds in the 1990s (Yu, 2007), the overall effect of climate change on winds is complex, and difficult to differentiate observationally from decadal-scale variability, and thus the ultimate effects of these currents on the hydrological cycle are difficult to predict with any high degree of confidence (WGII AR5 30.3.1, Hoegh-Guldberg, 2014).

2. Environmental, economic and social implications of ocean warming

As a consequence of changes in the hydrological cycle, increases in runoff, flooding, and sea-level rise are expected, and their potential impacts on society and natural environment are among the most serious issues confronting humankind, according to the Fifth Assessment Report (AR5) of the United Nations Intergovernmental Panel on

Climate Change (IPCC). This report indicates that it is very likely that extreme sea levels have increased globally since the 1970s, mainly as a result of global mean sea-level rise due in part to anthropogenic warming causing ocean thermal expansion and glacier melting (WGI AR5 3.7.5, 3.7.6; WGI AR5 10.4.3). In addition, local sea-level changes are also influenced by several natural factors, such as regional variability in oceanic and atmospheric circulation, subsidence, isostatic adjustment, and coastal erosion, among others; combined with human perturbations by land-use change and coastal development (WGI AR5 5.3.2). A 4°C warming by 2100 (Betts et al., 2011; predicted by the high-end emissions scenario RPC8.5 in WGI AR5 FAQ12.1) leads to a median sea-level rise of nearly 1 m above 1980-1999 levels (Schaeffer et al., 2012).

The vulnerability of human systems to sea-level rise is strongly influenced by economic, social, political, environmental, institutional and cultural factors; such factors in turn will vary significantly in each specific region of the world, making quantification a challenging task (Nicholls et al., 2007; 2009; Mimura, 2013). Three classes of vulnerability are identified: (i) early impacts (low-lying island states, e.g., Kiribati, Maldives, Tuvalu, etc.); (ii) physically and economically vulnerable coastal communities (e.g., Bangladesh); and (iii) physically vulnerable but economically "rich" coastal communities (e.g., Sydney, New York). Table 1 outlines the main effects of relative sea-level rise on the natural system and provides examples of socio-economic system adaptations.

It is widely accepted that relative trends in sea-level rise pose a significant threat to coastal systems and low-lying areas around the world, due to inundation and erosion of coastlines and contamination of freshwater reserves and food crops (Nicholls, 2010); it is also likely that sea-level effects will be most pronounced during extreme episodes, such as coastal flooding arising from severe storm-induced surges, wave overtopping and rainfall runoff, and increases in sea level during ENSO events. An increase in global temperature of 4°C is anticipated to have significant socio-economic effects as sea-level rise, in combination with increasingly frequent severe storms, will displace populations (Field et al., 2012). These processes will also place pressure on existing freshwater resources through saltwater contamination (Nicholls and Cazenave, 2010). Figure 1 outlines in more detail the effects of sea-level rise on water resources of low-lying coastal areas.

Small island countries, such as Kiribati, Maldives and Tuvalu, are particularly vulnerable. Beyond this, entire identifiable coherent communities also face risk (e.g., Torres Strait Islanders; Green, 2006). These populations have nowhere to retreat to within their country and thus have no alternative other than to abandon their country entirely. The low level of economic activity also makes it difficult for these communities to bear the costs of adaptation. A shortage of data and local expertise required to assess risks related to sea-level rise further complicate their situation. Indeed the response of the island structure to sea-level rise is likely to be complex (Webb and Kench, 2010). Traditional customs are likely to be at risk and poorly understood by outside agencies. Yet traditional knowledge is an additional resource that may aid adaptation in such settings and should be carefully evaluated within adaptation planning. A significant part

of the economy of many island nations is based on tourism; this too will be affected by sea-level rise through its direct effects on infrastructure and possibly also indirectly by the reduced availability of financial resources in the market (Scott et al., 2012).

Coastal regions, particularly some low-lying river deltas, have very high population densities. It is estimated that over 150 million people live within 1 metre of the high-tide level, and 250 million within 5 metres of high tide. Because of these high population densities (often combined with a lack of long-range urban planning), coastal cities in developing regions are particularly vulnerable to sea-level rise in concert with other effects of climate change (World Bank, 2012).

Table 1. The main effects of relative sea-level rise on the natural system, interacting factors, and examples of socio-economic system adaptations. Some interacting factors (for example, sediment supply) appear twice as they can be influenced both by climate and non-climate factors. Adaptation strategies: P = Protection; A = Accommodation; R = Retreat. Source: based on Nicholls and Tol, 2006.

Natural System Effects		Interacting Factors		Socio-economic System Adaptations
		Climate	Non-climate	
1. Inundation, flood and storm damage	a. Surge (sea)	– wave/storm climate – erosion – sediment supply	– sediment supply – flood management – erosion – land use	– dykes/surge barriers [P] – building codes/floodwise buildings [A] – land use planning/hazard delineation [A/R]
	b. Backwater effect (river)	– run-off	– catchment management – land use	
2. Wetland loss (and change)		– CO ₂ fertilization – sediment supply	– sediment supply – migration space – direct destruction	– land-use planning [A/R] – managed realignment/forbid hard defences [R] – nourishment/sediment management [P]
3. Erosion (direct and indirect morphological change)		– sediment supply – wave/storm climate	– sediment supply	– coast defences [P] – nourishment [P] – building setbacks [R]
4. Saltwater Intrusion	a. Surface Waters	– run-off	– catchment management – land use	– saltwater intrusion barriers [P] – change water abstraction [A/R]
	b. Ground-water	– rainfall	– land use – aquifer use	– freshwater injection [P] – change water abstraction [A/R]
5. Rising water tables/impaired drainage		– rainfall – run-off	– land use – aquifer use – catchment management	– upgrade drainage systems [P] – polders [P] – change land use [A] – land use planning/hazard delineation [A/R]

Effects of sea-level rise are projected to be asymmetrical even within regions and countries. Nicholls and Tol (2006), extending the global vulnerability analysis of Hoozemans et al. (1993) on the impacts of and responses to sea-level rise with storm surges over the 21st century, show East Africa (including small island States and countries with extensive coastal deltas) as one of the problematic regions that could experience major land loss. Dasgupta et al. (2009) undertook a comparative study on the impacts of sea-level rise with intensified storm surges on developing countries globally in terms of its impacts on land area, population, agriculture, urban extent,

major cities, wetlands, and local economies. They based their work on a 10 per cent future intensification of storm surges with respect to current 1-in-100-year storm-surge predictions. They found that Sub-Saharan African countries will suffer considerably from the impacts. The study estimated that Mozambique, along with Madagascar, Mauritania and Nigeria account for more than half (9,600 km²) of the total increase in the region's storm-surge zones.

Of the impacts projected for 31 developing countries, just ten cities account for two-thirds of the total exposure to extreme floods. Highly vulnerable cities are found in Bangladesh, India, Indonesia, Madagascar, Mexico, Mozambique, the Philippines, Venezuela and Viet Nam (Brecht et al., 2012). Because of the small population of small islands and potential problems with implementing adaptations, Nicholls et al. (2011) conclude that forced abandonment of these islands seems to be a possible outcome even for small changes in sea level. Similarly, Barnett and Adger (2003) point out that physical impact might breach a threshold that pushes social systems into complete abandonment, as institutions that could facilitate adaptation collapse.

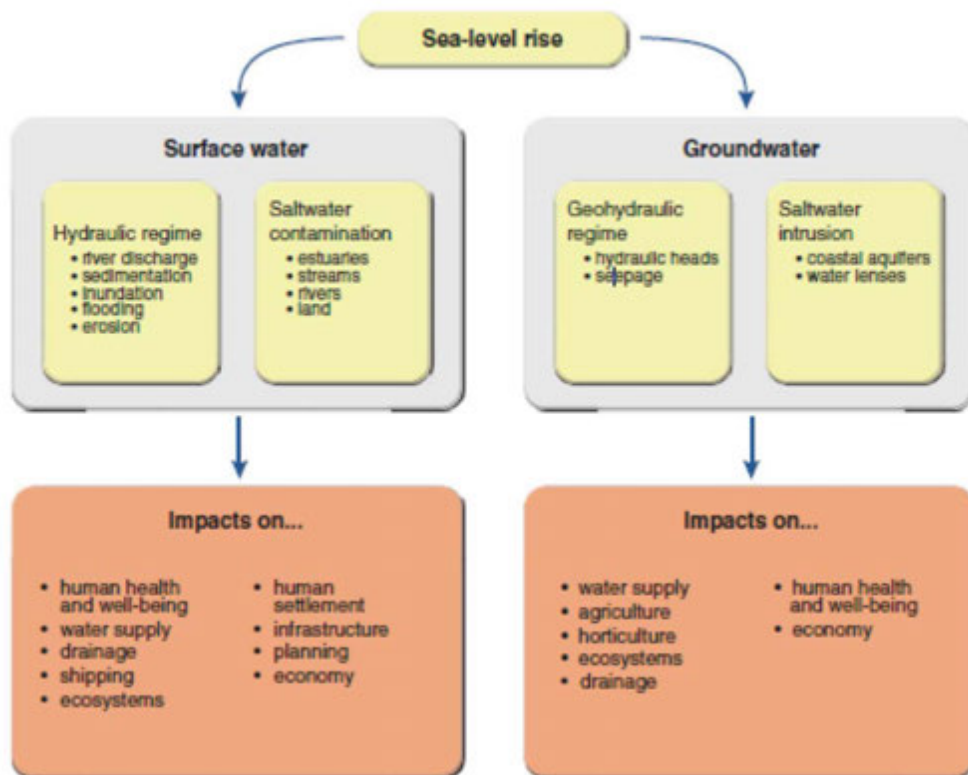

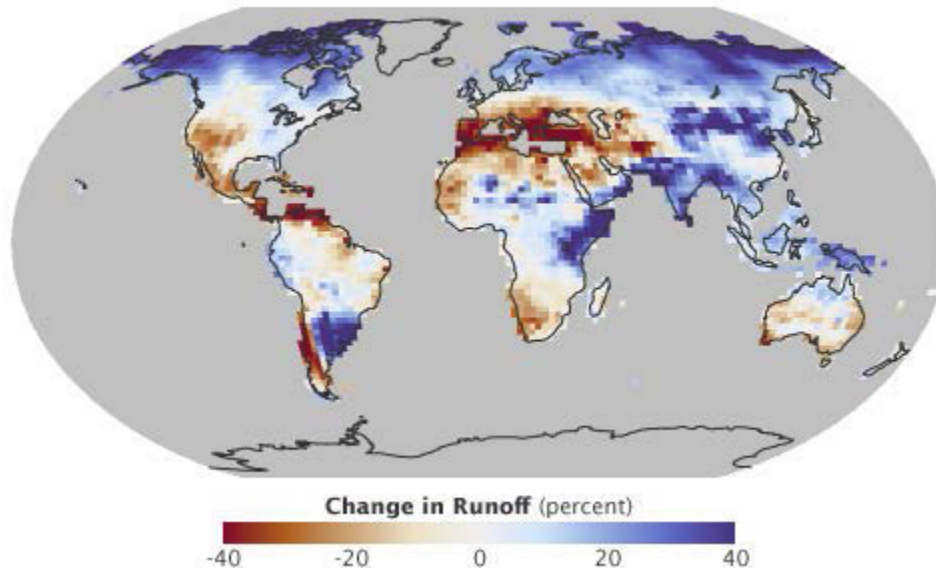

Figure 1. Effects of sea-level rise on water resources of small islands and low-lying coastal areas. Source: Based on Oude Essink et al. (1993); Hay and Mimura (2006).

Impacts of climate change on the hydrological cycle, and notably on the availability of freshwater resources, have been observed on all continents and many islands. Glaciers continue to shrink worldwide, affecting runoff and water resources downstream. Figure 2 shows the changes anticipated by the late 21st century in water runoff into rivers and streams. Climate change is the main driver of permafrost warming and thawing in both high-latitude and high-elevation mountain regions (IPCC WGII AR5 18.3.1, 18.5). This thawing has negative implications for the stability of infrastructure in areas now covered with permafrost.

Projected heat extremes and changes in the hydrological cycle will in turn affect ecosystems and agriculture (World Bank, 2012). Tropical and subtropical ecoregions in Sub-Saharan Africa are particularly vulnerable to ecosystem damage (Beaumont et al., 2011). For example, with global warming of 4°C (predicted by the high-end emissions scenario RPC8.5 in WGI AR5 FAQ 12.1), between 25 per cent and 42 per cent of 5,197 African plant species studied are projected to lose all their suitable range by 2085 (Midgley and Thuiller, 2011). Ecosystem damage would have the follow-on effect of reducing the ecosystem services available to human populations.

The Mediterranean basin is another area that has received a lot of attention in regard to the potential impacts of climate change on it. Several modelling groups are taking part in the MedCORDEX (www.medcordex.eu) international effort, in order to better simulate the Mediterranean hydrological cycle, to improve the modelling tools available, and to produce new climate impact scenarios. Hydrological model schemes must be improved to meet the specific requirements of semi-arid climates, accounting in particular for the related seasonal soil water dynamics and the complex surface-subsurface interactions in such regions (European Climate Research Alliance, 2011).

Even the most economically resilient of States will be affected by sea-level rise, as adaptation measures will need to keep pace with ongoing sea-level rise (Kates et al., 2012). As a consequence, the impacts of sea-level rise will also be redistributed through the global economic markets as insurance rates increase or become unviable and these costs are passed on to other sectors of the economy (Abel et al., 2011).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

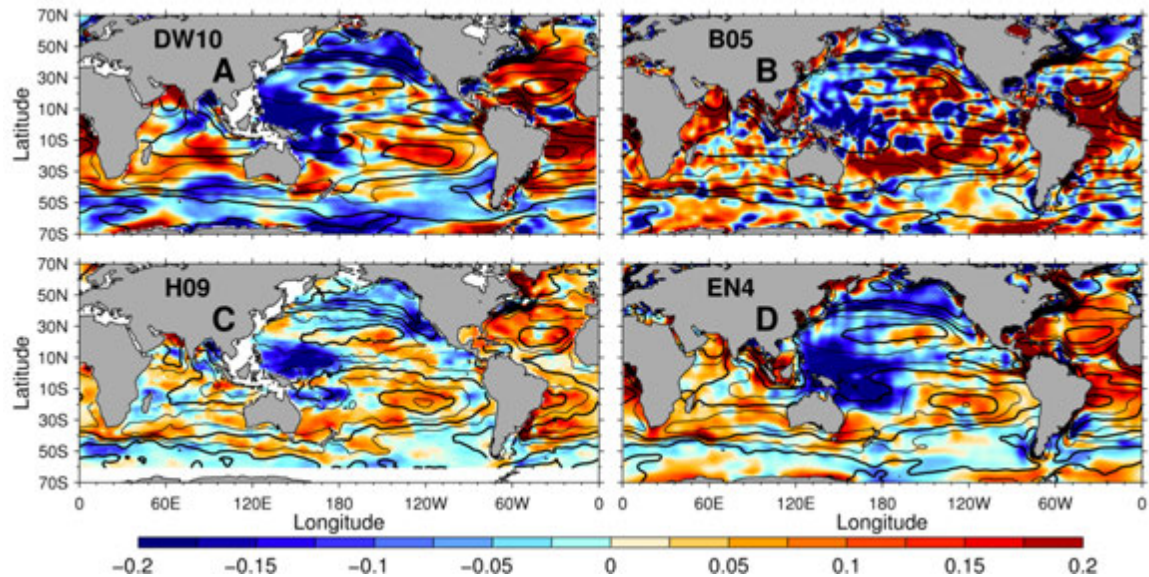

Figure 2. Changes in water runoff into rivers and streams are another anticipated consequence of climate change by the late 21st Century. This map shows predicted increases in runoff in blue, and decreases in brown and red. (Map by Robert Simmon, using data from Milly et al., 2005; Graham et al., 2010; NASA Geophysical Fluid Dynamics Laboratory.)

3. Chemical composition of seawater

3.1 Salinity

Surface salinity integrates the signals of freshwater sources and sinks for the ocean, and if long-term (decadal to centennial) changes in salinity are considered, this provides a way to investigate associated changes in the hydrological cycle. Many studies have assessed changes to ocean salinity over the long term; of these, four have considered changes on a global scale from the near-surface to the sub-surface ocean (Boyer et al., 2005; Hosoda et al., 2009; Durack and Wijffels, 2010; Good et al., 2013). These studies independently concluded that alongside broad-scale ocean warming associated with climate change, shifts in ocean salinities have also occurred. These shifts, which are calculated using methods such as objective analysis from the sparse historical observing system, suggest that at the surface, high-salinity subtropical ocean regions and the entire Atlantic basin have become more saline, and low-salinity regions, such as the western Pacific Warm Pool, and high-latitude regions have become even fresher over the period of analysis (Figure 3). Significant regional-scale differences may be ascribed to the paucity of observational data, particularly in the pre-Argo era, the difference in temporal period over which each analysis was conducted, and differences in methodology and data selection criteria.

Despite regional differences, the broad-scale patterns of change suggest that long-term, coherent changes in salinity have occurred over the observed record, and this conclusion is also supported by shifts in salinity apparent in the subsurface ocean (Figure 4). These subsurface changes also show that spatial gradients of salinity within the ocean interior have intensified, and that at depth, salinity-minimum (intermediate) waters have become fresher, and salinity-maximum waters have become saltier (Durack and Wijffels, 2010; Helm et al., 2010; Skliris et al., 2014). Taken together, this evidence suggests intensification of the global hydrological cycle; this is consistent with what is expected from global warming (see Section 1). Actual changes in the hydrological cycle may be even more intense than indicated by patterns of surface salinity anomalies, as these may be spread out and reduced in intensity by being transported (advected) by ocean currents. For example, the work of Hosoda et al. (2009) and Nagano et al. (2014) indicates that large (ENSO-scale) salinity anomalies are rapidly transported from the central Pacific to the northwestern North Pacific (the Kuroshio Extension region).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 3. Four long-term estimates of global sea-surface salinity (SSS) change according to (A) Durack and Wijffels (2010; ©American Meteorological Society. Used with permission.), analysis period 1950-2008; (B) Boyer et al. (2005), analysis period 1955-1998; (C) Hosoda et al. (2009), analysis period 1975-2005; and (D) Good et al. (2013), analysis period 1950-2012; all are scaled to represent equivalent magnitude changes over a 50-year period ($\text{PSS-78 } 50\text{-year}^{-1}$). Black contours show the associated climatological mean SSS for the analysis period. Broad-scale similarities exist between each independent analysis of long-term change, and suggest an increase in spatial gradients of salinity has occurred over the period of analysis. However, regional-scale differences are due to differences in data sources, temporal periods of analysis, and analytical methodologies.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 4. Three long-term estimates of global zonal mean subsurface salinity changes according to (A) Durack and Wijffels (2010; ©American Meteorological Society. Used with permission.), analysis period 1950-2008; (B) Boyer et al. (2005), analysis period 1955-1998; and (C) Good et al. (2013), analysis period 1950-2012; all scaled to represent equivalent magnitude changes over a 50-year period ($\text{PSS-78 } 50\text{-year}^{-1}$). Black contours show the associated climatological mean subsurface salinity for the analysis period. Broad-scale similarities also exist in the subsurface salinity changes, which suggest a decreasing salinity in ocean waters fresher than the global average, and an increasing salinity in waters saltier than the global average. However, regional differences, particularly in the high-latitude regions, are due to limited data sources, different temporal periods of analysis and different analytical methodologies.

3.2 Nutrients

Many different nutrients are required as essential chemical elements that organisms need to survive and reproduce in the ocean. Macronutrients, needed in large quantities, include calcium, carbon, nitrogen, magnesium, phosphorus, potassium, silicon and sulphur; micronutrients like iron, copper and zinc are needed in lesser quantities (Smith and Smith, 1998). Macronutrients provide the bulk energy for an organism's metabolic system to function, and micronutrients provide the necessary co-factors for metabolism to be carried out. In aquatic systems, nitrogen and phosphorus are the two nutrients that most commonly limit the maximum biomass, or growth, of algae and aquatic plants (United Nations Environment Programme (UNEP) Global Environment Monitoring System (GEMS) Water Programme, 2008). Nitrate is the most common form of nitrogen and phosphate is the most common form of phosphorus found in natural waters. On the other hand, one of arguably the most important groups of marine phytoplankton is the diatom. Recent studies, for example, Brzezinski et al., (2011), show that marine diatoms are significantly limited by iron and silicic acid.

About 40 per cent of the world's population lives within a narrow fringe of coastal land (about 7.6 per cent of the Earth's total land area; United Nations Environment Programme, 2006). Land-based activities are the dominant source of marine nutrients,

especially for fixed nitrogen, and include: agricultural runoff (fertilizer), atmospheric releases from fossil-fuel combustion, and, to a lesser extent, from agricultural fertilizers, manure, sewage and industrial discharges (Group of Experts on the Scientific Aspects of Marine Environmental Protection, 2001; Figure 5).

An imbalance in the nutrient input and uptake of an aquatic ecosystem changes its structure and functions (e.g., Arrigo, 2005). Excessive nutrient input can seriously impact the productivity and biodiversity of a marine area (e.g., Tilman et al., 2001); conversely, a large reduction in natural inputs of nutrients (caused by, e.g., damming rivers) can also adversely affect the productivity of coastal waters. Nutrient enrichment between 1960-1980 in the developed regions of Europe, North America, Asia and Oceania has resulted in major changes in adjacent coastal ecosystems.

Nitrogen flow into the ocean is a good illustration of the magnitude of changes in anthropogenic nutrient inputs since the industrial revolution. These flows have increased 15-fold in North Sea watersheds, 11-fold in the North Eastern USA, 10-fold in the Yellow River basin, 5.7-fold in the Mississippi River basin, 5-fold in the Baltic Sea watersheds, 4.1-fold in the Great Lakes/St Lawrence River basin, and 3.7-fold in South-Western Europe (Millennium Ecosystem Assessment, 2005). It is expected that global nitrogen exports by rivers to the oceans will continue to rise. Projections for 2030 show an increase of 14 per cent compared to 1995. By 2030, global nitrogen exports by rivers are projected to be 49.7 Tg/yr; natural sources will contribute 57 per cent of the total, agriculture 34 per cent, and sewage 9 per cent (Bouwman et al., 2005). An example of this is discussed in Box 1.

Box 1: Example – Nutrients in the Pacific region

The Pacific Ocean basins form the largest of the mid-latitude oceans. In addition, the subarctic North Pacific Ocean is one of the most nutrient-rich areas of the world ocean; in 2013, the most recent year for which statistics have been compiled, the North Pacific (north of 40° N) provided 30% of the world's capture, by weight, of ocean fish (FAO, 2015). Many oceanographic experiments have been carried out over the last half century in the North Pacific Ocean; studies based on these datasets reveal the decadal-scale variation of nutrient concentrations in the surface and subsurface (intermediate) layers, as seen in Figure 6.

A linearly increasing trend of nutrient concentrations (nitrate and phosphate) has been observed in the intermediate waters in a broad area of the North Pacific (Figure 6b); Ono et al., 2001; Watanabe et al., 2003; 2008; Tadokoro et al., 2009; Guo et al., 2012; Whitney et al., 2013). Conversely, the concentration of nutrients in the surface layer has decreased (Figure 6a; Freeland, 1997; Ono et al., 2002; 2008; Watanabe et al., 2005; 2008; Aoyama et al., 2008, Tadokoro et al., 2009; Whitney,

2011). Surface nutrients are primarily supplied by the subsurface ocean through a process known as "vertical mixing", an exchange between surface and subsurface waters. Vertical mixing is partly dependent on the differences in density between adjacent ocean layers: layers closer to one another in density mix more easily.

A significant increase in temperature and a corresponding decrease in salinity (see above) have been observed during the last half-century in the upper layer of the North Pacific (IPCC, 2013, WG1 AR5). These changes are in the direction of increased stratification in the upper ocean and thus it is possible that this increased stratification has caused a corresponding decrease in the vertical mixing rate.

Superimposed on the linear trends, nutrient concentrations in the ocean have also exhibited decadal-scale variability, which is evident in both surface and subsurface waters (Figure 6c). Unlike the linear trends, the decadal-scale variability appeared synchronized between the surface and subsurface layers in the western North Pacific (Tadokoro et al., 2009). These relationships suggest that the mechanisms producing the trends and more cyclical variability are different.

4. Environmental, economic and social implications of changes in salinity and nutrient content

4.1 Salinity

Although changes to ocean salinity do not directly affect humanity, changes in the hydrological cycle that are recorded in the changing patterns of ocean salinity certainly do. Due to the scarcity of hydrological cycle observations over the ocean, and the uncertainties associated with these measurements, numerous studies have linked salinity changes to the global hydrological cycle by using climate models (Durack et al., 2012; 2013; Terray et al., 2012) or reanalysis products (Skirris et al., 2014). However, these studies only considered long-term salinity changes, and not changes that occur on interannual to decadal time-scales. These latter scales are strongly affected by climatic variability (Yu, 2011; Vinogradova and Ponte, 2013). As mentioned in Section 3, these studies collectively conclude that changes to the patterns of ocean salinity are likely due to the intensification of the hydrological cycle, in particular patterns of evaporation and rainfall at the ocean surface. This result concurs well with the "rich-get-richer" mechanism proposed in earlier studies, suggesting that terrestrial "dry" zones will become dryer and terrestrial "wet" zones will become wetter due to ongoing climate change (Chou and Neelin, 2004; Held and Soden, 2006).

4.2 Nutrients

Marine environments are unsteady systems, whose response to climate-induced or anthropogenic changes is difficult to predict. As a result, no published studies quantify long-term trends in ocean nutrient concentrations. However, it is well understood that imbalances in nutrient concentration cause widespread changes in the structure and functioning of ecosystems, which, in turn, have generally negative impacts on habitats, food webs and species diversity, including economically important ones; such adverse effects include: general degradation of habitats, destruction of coral reefs and sea-grass beds; alteration of marine food-webs, including damage to larval or other life stages; mass mortality of wild and/or farmed fish and shellfish, and of mammals, seabirds and other organisms.

Among the effects of nutrient inputs into the marine environment it is important to mention the link with marine pH. The production of excess algae from increased nutrients has the effect, *inter alia*, to release CO₂ from decaying organic matter deriving from eutrophication (Hutchins et al., 2009; Sunda and Cai, 2012). The effects of these acidification processes, combined with those deriving from increasing atmospheric CO₂, can reduce the time available to coastal managers to adopt approaches to avoid or minimize harmful effects on critical ecosystem services, such as fisheries and tourism. Globally, the manufacture of nitrogen fertilizers has continued to increase (Galloway et al., 2008) accompanied by increasing eutrophication of coastal waters and degradation of coastal ecosystems (Diaz and Rosenberg, 2008; Seitzinger et al., 2010; Kim et al., 2011), and amplification of CO₂ drawdown (Borges and Gypens, 2010; Provoost et al., 2010). In addition, atmospheric deposition of anthropogenic fixed nitrogen may now account for up to about 3 per cent of oceanic new production, and this nutrient source is projected to increase (Duce et al., 2008).

Figure 5 (a)

Figure 5 (b)

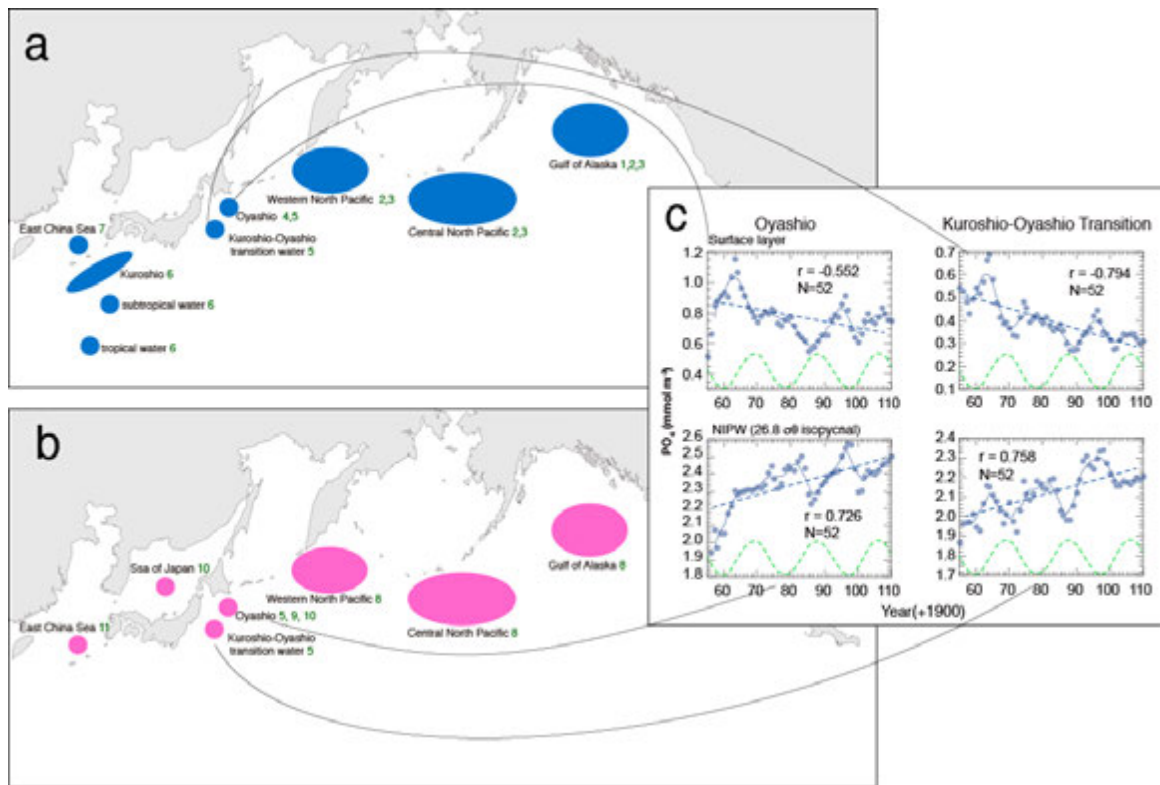

Figure 5 (a) Trends in annual rates of application of nitrogenous fertilizer (N) expressed as mass of N, and of phosphate fertilizer (P) expressed as mass of P_2O_5 , for all States of the world except for many of the countries belonging to the United Nations regional group of Eastern European States and the former USSR (scale on the left in 10^6 metric tons), and trends in global total area of irrigated crop land (H₂O) (scale on the right in 109 hectares). Source: Tilman et al., 2001. Figure 5 (b) Estimated growth in fertilizer use, 1960-2020. From GESAMP (2001). Source: Bumb and Baanante, 1996.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 6. Synthesis of the decadal-scale change in nutrient concentrations in the North Pacific Ocean in the last fifty years. (a) The blue area shows the waters for which a decreasing trend in nutrient concentrations was reported in the surface layer. (b) The pink area shows the waters for which an increasing trend in nutrient concentrations was reported in the subsurface. (c) Example of the nutrient change in the North Pacific Ocean. Five-year running mean of the annual mean concentration (mmol m⁻³) of Phosphate concentration in the surface and North Pacific Intermediate Water (NPIW) of the Oyashio and Kuroshio-Oyashio transition waters from the mid-1950s to early 2010. (Time series from Tadokoro et al., 2009). Blue broken lines indicate statistically significant trends of PO₄. Thin green broken lines represent the index of diurnal tidal strength represented by the sine curve of the 18.6-yr cycle.*The numbers following each area name indicate the referenced literature: (1) Freeland et al., (1997); (2) Ono et al., (2008); (3) Whitney (2011); (4) Ono et al., (2002); (5) Tadokoro et al., (2009); (6) Watanabe et al., (2005); (7) Aoyama et al., (2008); (8) Watanabe et al., (2008); (9) Ono et al., (2001); (10) Watanabe et al., (2003); (11) Guo et al., (2012).

Chapter 5. Sea-Air Interactions

Contributors: Jeremy T. Mathis (Convenor), Jose Santos, Renzo Mosetti, Alberto Mavume, Craig Stevens, Regina Rodrigues, Alberto Piola, Chris Reason, Patricio A. Bernal (Co-Lead member), Lorna Inniss (Co-Lead member)

1. Introduction

From the physical point of view, the interaction between these two turbulent fluids, the ocean and the atmosphere, is a complex, highly nonlinear process, fundamental to the motions of both. The winds blowing over the surface of the ocean transfer momentum and mechanical energy to the water, generating waves and currents. The ocean in turn gives off energy as heat, by the emission of electromagnetic radiation, by conduction, and, in latent form, by evaporation.

The heat flux from the ocean provides one of the main energy sources for atmospheric motions. This source of energy for the atmosphere is affected by the turbulence at the air/sea interface, and by the spatial distribution of the centres of high and low energy transfer affected by the ocean currents. This coupling takes place through processes that fundamentally occur at small scales. The strength of this coupling depends on air-sea differences in several factors and therefore has geographic and temporal scales over a broad range. At these small scales on the sea-surface interface itself, waves, winds, water temperature and salinity, bubbles, spray and variations in the amount of solar radiation that reaches the ocean surface, and other factors, affect the transfer of properties and energy.

In the long term, the convergence and divergence of oceanic heat transport provide sources and sinks of heat for the atmosphere and partly shape the mean climate of the earth. Analyzing whether these processes are changing due to anthropogenic influences and the potential impact of these changes is the subject of this chapter. Following guidance from the Ad Hoc Working Group of the Whole, much of the information presented here is based on or derives from the very thorough analysis conducted by the Intergovernmental Panel on Climate Change (IPCC) for its recent Fifth Assessment Report (AR5).

The atmosphere and the ocean form a coupled system, exchanging at the air-sea interface gases, water (and water vapour), particles, momentum and energy. These exchanges affect the biology, the chemistry and the physics of the ocean and influence its biogeochemical processes, weather and climate (exchanges affecting the water cycle are addressed in Chapter 4).

From a biogeochemical point of view, gas and chemical exchanges between the oceans and the atmosphere are important to life processes. Half of the Global Net Primary Production of the world is by phytoplankton and other marine plants, uptaking CO₂ and releasing oxygen (Field et al., 1998; Falkowski and Raven, 1997). Phytoplankton is

therefore also responsible for half of the annual production of oxygen by plants and, through the generation of organic matter, is at the basis of most marine food webs in the ocean. Oxygen production by plants is a critical ecosystem service that keeps atmospheric oxygen from otherwise declining. However, in many regions of the ocean, phytoplankton growth is limited by a deficit of iron in seawater. Most of the iron alleviating this limitation reaches the ocean through wind-borne dust from the deserts of the world.

Gas and chemical exchanges between the atmosphere and ocean are also important to climate change processes. For example, marine phytoplankton produces dimethyl sulphide (DMS), the most abundant biological sulphur compound emitted to the atmosphere (Kiene et al., 1996). DMS is oxidized in the marine atmosphere to form various sulphur-containing compounds, including sulphuric acid, which influence the formation of clouds. Through this interaction with cloud formation, the massive production of atmospheric DMS over the ocean may have an impact on the earth's climate. The absorption of CO₂ from the atmosphere at the sea surface is responsible for the fundamental role of the ocean as a carbon sink (see section 3 below).

2. Heat flux and temperature

2.1 Sea-Surface Temperature

Sea-surface temperature (SST) has been measured in surface waters by a variety of methods that have changed significantly over time. Furthermore the spatial patterns of SST change are difficult to interpret. Nevertheless a robust trend emerges from these historical series after careful inspection and analysis of the datasets. Figure 1 shows the historical SST trend instrumentally observed using the best datasets of spatially interpolated products, contrasted against the 1961 – 1990 climatology. Changes in SST are reported in this section and in Chapter 2 of the IPCC (Hartmann et al., 2013).

The IPCC in AR5 concluded that 'recent' warming (since the 1950s) is strongly evident in SST at all latitudes of each ocean. Prominent spatio-temporal structures, including the El Niño Southern Oscillation (ENSO), decadal variability patterns in the Pacific Ocean, and a hemispheric asymmetry in the Atlantic Ocean, were highlighted as contributors to the regional differences in surface warming rates, which in turn affect atmospheric circulation (Hartmann et al., 2013).

Figure 1. Global annual average sea surface temperature (SST) and Night Marine Air Temperature (NMAT) relative to a 1961–1990 climatology from state of the art data sets. Spatially interpolated products are shown by solid lines; non-interpolated products by dashed lines. From Hartmann et al. 2013, Fig. 2.18.

“It is certain that global average sea surface temperatures (SSTs) have increased since the beginning of the 20th century. (...) Intercomparisons of new SST data records obtained by different measurement methods, including satellite data, have resulted in better understanding of uncertainties and biases in the records. Although these innovations have helped highlight and quantify uncertainties and affect our understanding of the character of changes since the mid-20th century, they do not alter the conclusion that global SSTs have increased both since the 1950s and since the late 19th century.” (Hartmann et al., 2013).

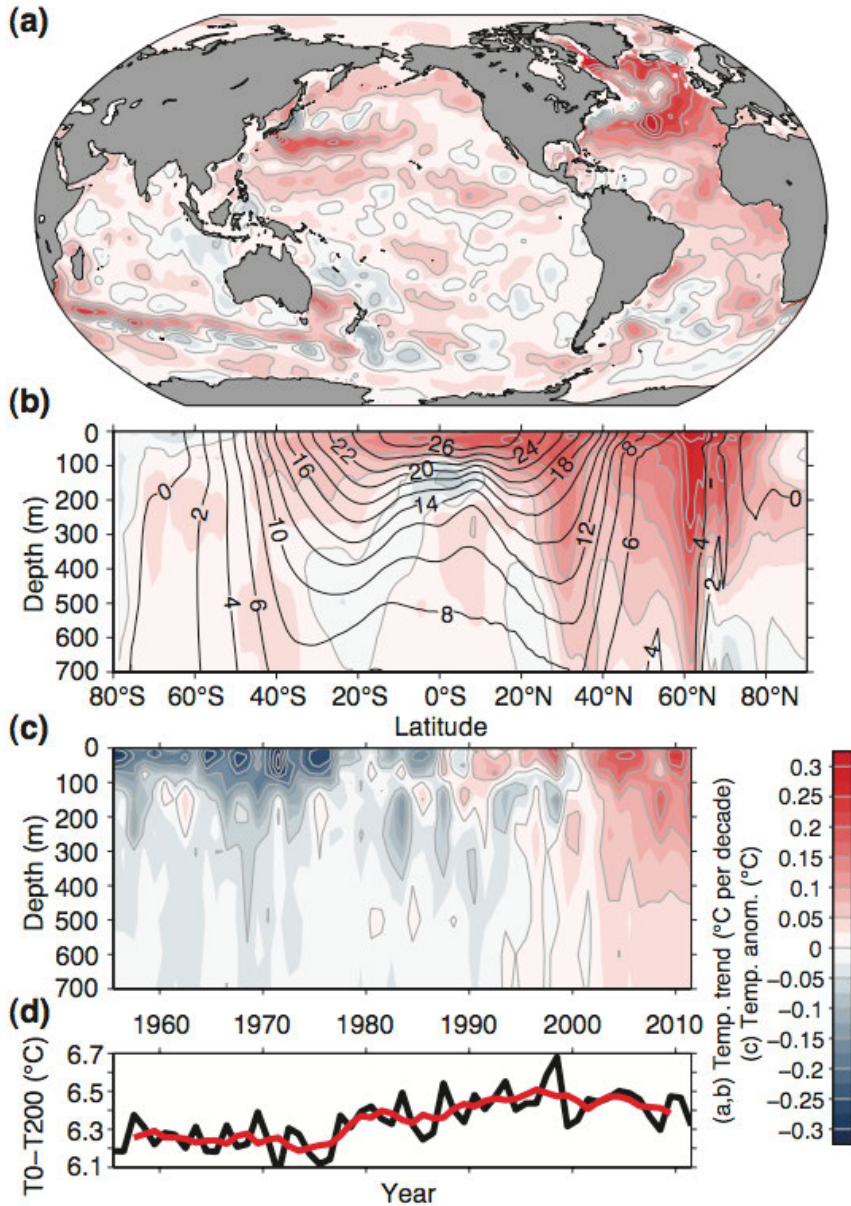

2.2 *Changes in sea-surface temperature (SST) as inferred from subsurface measurements.*

Upper ocean temperature (hence heat content) varies over multiple time scales, including seasonal, interannual (e.g., associated with El Niño), decadal and centennial (Rhein et al., 2013). Depth-averaged (0 to 700 m) ocean-temperature trends from 1971 to 2010 are positive over most of the globe. The warming is more prominent in the Northern Hemisphere, especially in the North Atlantic. This result holds true in different analyses, using different time periods, bias corrections and data sources (e.g., with or without XBT or MBT data¹) (Rhein et al. 2013). Zonally averaged upper-ocean temperature trends show warming at nearly all latitudes and depths (Figure 2a). However, the greater volume of the Southern Hemisphere ocean increases the contribution of its warming to the global heat content (Rhein et al., 2013). Strongest warming is found closest to the sea surface, and the near-surface trends are consistent

¹ XBT are expendable bathythermographs, probes that using electronic solid-state transducers register temperature and pressure while they free fall through the water column. MBT are their mechanical predecessors, that lowered on a wire suspended from a ship, used a metallic thermocouple as transducer.

with independently measured SST (Hartmann et al., 2013). The global average warming over this period is 0.11 [0.09 to 0.13] °C per decade in the upper 75 m, decreasing to 0.015°C per decade by 700 m (Figure 2c) (Rhein et al 2013).

The globally averaged temperature difference between the ocean surface and 200 m increased by about 0.25°C from 1971 to 2010. This change, which corresponds to a 4 per cent increase in density stratification, is widespread in all the oceans north of about 40°S. Increased stratification will potentially diminish the exchanges between the interior and the surface layers of the ocean; this will limit, for example, the input of nutrients from below into the illuminated surface layer and of oxygen from above into the deeper layers. These changes might in turn result in reduced productivity and increased anoxic waters in many regions of the world ocean (Capotondi et al., 2012).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. (a) Depth-averaged (0 to 700) m ocean-temperature trend for 1971-2010 (longitude vs. latitude, colours and grey contours in degrees Celsius per decade); (b) Zonally averaged temperature trends (latitude vs. depth, colours and grey contours in degree Celsius per decade) for 1971-2010 with zonally averaged mean temperature over-plotted (black contours in degrees Celsius). Both North (25-65°N) and South (south of 30°S), the zonally averaged warming signals extend to 700 m and are consistent with poleward displacement of the mean temperature field. Zonally averaged upper-ocean temperature trends show warming at nearly all latitudes and depths (Figure 2 (b)). A relative maximum in warming appears south of 30°S. (c) Globally averaged temperature anomaly (time vs. depth, colours and grey contours in degrees Celsius) relative to the 1971-2010 mean; (d) Globally averaged temperature difference between the ocean surface and 200 m depth (black: annual values, red: 5-year running mean). All panels are constructed from an update of the annual analysis of Levitus et al. (2009). From Rhein et al. (2013) Fig 3.1.

2.3 Upper Ocean Heat Content (UOHC)

The ocean's large mass and high heat capacity allow it to store huge amounts of energy: more than 1000 times that found in the atmosphere for an equivalent increase in temperature. The earth is absorbing more heat than it is emitting back into space, and nearly all this excess heat is entering the ocean and being stored there.

The upper ocean (0 to 700 m) heat content increased during the 40-year period from 1971 to 2010. Published rates range from 74 TW to 137 TW (1 TW = 10^{12} watts), while an estimate of global upper (0 to 700 m depth) ocean heat content change, using ocean statistics to extrapolate to sparsely sampled regions and estimate uncertainties (Domingues et al., 2008), gives a rate of increase of global upper ocean heat content of 137 TW (Rhein, et al. 2013). Warming of the ocean accounts for about 93 per cent of the increase in the Earth's energy inventory between 1971 and 2010 (high confidence), Melting ice (including Arctic sea ice, ice sheets and glaciers) and warming of the continents and atmosphere account for the remainder of the change in energy (Rhein et al. 2013). Global integrals of 0 to 700 m upper ocean heat content (UOHC) (Figure 3.) estimated from ocean temperature measurements all show a gain from 1971 to 2010 (Rhein et al. 2013).

Figure 3. Observation-based estimates of annual global mean upper (0 to 700 m) ocean heat content in ZJ ($1 \text{ ZJ} = 10^{21}$ Joules) updated from (see legend): Levitus et al. (2012), Ishii and Kimoto (2009), Domingues et al. (2008), Palmer et al. (2009; ©American Meteorological Society. Used with permission.) and Smith and Murphy (2007). Uncertainties are shaded and plotted as published (at the one standard error level, other than one standard deviation for Levitus, with no uncertainties provided for Smith). Estimates are shifted to align for 2006-2010, 5 years that are well measured by the ARGO Program of autonomous profiling floats, and then plotted relative to the resulting mean of all curves for 1971, the starting year for trend calculations.

2.4 *The ocean's role in heat transport*

Solar energy is unevenly distributed over the earth's surface, leading to excess heat reaching the tropics and a heat deficit in latitudes poleward of about 40° in each hemisphere. The heat balance, and therefore a relatively stable climate, is maintained through the meridional redistribution, or flux, of heat by the atmosphere and the ocean. Quantification and understanding of this heat content and its redistribution have been achieved through diverse methods, including international programmes maintaining instrumented moorings, transoceanic lines of XBTs, satellite observations, numerical modelling and, more recently, the ARGO Program of autonomous profiling instruments (Abraham et al., 2013; von Schuckmann and Le Traon, 2011).

In the latitude band between 25°N and 25°S, the atmospheric and oceanic contributions to the meridional heat fluxes are similar, and the atmosphere dominates at higher latitudes. In the ocean, the heat flux is accomplished by contributions from the wind-driven circulation in the upper ocean, by turbulent eddies, and by the Meridional Overturning Circulation (MOC). The MOC is a component of ocean circulation that is driven by density contrasts, rather than by winds or tides, and one which exhibits a pronounced vertical component, with dense water sinking at high latitudes, offset by broadly distributed upwelling at lower ones. As distinct circulation patterns characterize each of the ocean basins, their individual contributions to the meridional heat flux differ significantly. Estimates indicate that, on a yearly average, the global oceans carry 1-2 PW (1PW=10¹⁵W) of heat from the tropics to higher latitudes, with somewhat higher transports to the northern hemisphere (Fasullo and Trenberth, 2008).

Most of the heat excess due to increases in atmospheric greenhouse gases goes into the ocean (IPCC, 2013). Although all ocean basins have warmed during the last decades, the increase in heat content is not uniform; the increase in heat content in the Atlantic during the last four decades exceeds that of the Pacific and Indian Oceans combined (Levitus et al., 2009; Palmer and Haines, 2009). Enhanced northward heat flux in the subtropical South Atlantic, which includes heat driven from the subtropical Indian Ocean through the Agulhas Retroflexion, may have contributed to the larger increase in heat content in the Atlantic Ocean compared with other basins (Abraham et al., 2013; Lee et al., 2011).

Numerical simulations also indicate that changes in ocean heat fluxes are the main mechanism responsible for the observed temperature fluctuations in the subtropical and subpolar North Atlantic (Grist et al., 2010).

Meridional heat flux estimates inferred from the residual of heat content variations suggest that the heat transferred northward throughout the Atlantic is transferred to the atmosphere in the subtropical North Atlantic (Kelly et al., 2014). Observations from the Rapid/Mocha instrument array at 26°N in the North Atlantic indicate that the mean Atlantic meridional heat flux at this latitude is 1.33 PW, with substantial variability due to changes in the strength of the MOC (Cunningham et al., 2007; Kanzow et al., 2007; Johns et al., 2011; McCarthy et al., 2012). Moreover, recent studies show that interannual changes in the MOC (and the associated heat flux measured at 26°N) lead to temperature anomalies in the subtropical North Atlantic which, in turn, can have a

strong impact on the northern hemisphere climate (Cunningham et al., 2013; Buchan et al., 2014).

2.5 *Air-sea Heat fluxes*

Heat uptake by the ocean can be substantially altered by natural oscillations in the earth's ocean and atmosphere. The effects of these large-scale climate oscillations are often felt around the world, leading to the rearrangement of wind and precipitation patterns, which in turn substantially affect regional weather, sometimes with devastating consequences.

The ENSO is the most prominent of these oscillations and is characterized by an anomalous warming and cooling of the central-eastern equatorial Pacific. The warm phase is called El Niño and the cold, La Niña. During El Niño events, a weakening of the Pacific trade winds decreases the upwelling of cold waters in the eastern equatorial Pacific and allows warm surface water that generally accumulates in the western Pacific to flow east.

As a consequence, El Niños release heat into the atmosphere, causing an increase in globally averaged air temperature. However, the “recharge oscillator theory” (Ren and Jin, 2013) indicates that a buildup of upper-ocean heat content is a necessary precondition for the development of El Niño events. La Niñas are associated with a strengthening of the trade winds, which leads to a strong upwelling of cold subsurface water in the eastern Pacific. In this case, the ocean uptake of heat from the atmosphere is enhanced, causing the global average surface temperature to decrease (Roemmich and Gilson, 2011).

The cycling of ENSO between El Niño and La Niña is irregular. In some decades El Niño has dominated and in other decades La Niña has been more frequent, also seen in phase shifts of the Interdecadal Pacific Oscillation (Meehl et al., 2013), which is related to build up and release of heat. A strengthening of the Pacific trade winds in the past two decades has led to a more frequent occurrence of La Niñas (England et al., 2014). Consequently, the heat uptake by the subsurface ocean was enhanced, leading to a slowdown of the surface warming (Kosaka and Xie, 2013). This is one of the factors affecting the global mean temperature, expected to increase by 0.21°C per decade from 1998 to 2012, but which instead warmed by just 0.04°C (the so-called recent warming hiatus, IPCC, 2013). Although there are several hypotheses on the cause of the global warming hiatus, the role of ocean circulation in this negative feedback is certain. Drijfhout et al. (2014) have shown that the North Atlantic, Southern Ocean and Tropical Pacific all play significant roles in the ocean heat uptake associated with the warming hiatus.

Chen and Tung (2014) analyzed the historical and recent record of sea surface temperature and Ocean Heat Content (OHC), and found distinct patterns at the surface and in deeper layers. On the surface, the patterns conform to the El Niño/La Niña patterns, with the Pacific Ocean playing a dominant role by releasing heat during an El Niño (or capturing heat during La Niña). At depth, the dominant pattern shows heating

taking place in the Atlantic Ocean and in the Circumpolar Current region. Coinciding in time, changes in OHC could help to explain the observed slowdown in global warming. It is anticipated that the mechanisms involved may at some point reverse, releasing large amounts of heat to the atmosphere and accelerating global warming (e.g., Levermann, et al., 2012).

Many other naturally occurring ocean-atmosphere oscillations in the Pacific, Atlantic, and Indian Oceans have also been recognized and named. The ENSO as a global phenomenon, has an expression in the Atlantic basin called the Atlantic Niño. In the last six decades, this mode has weakened, leading to a warming of the equatorial eastern Atlantic of up to 1.5°C (Tokinaga and Xie, 2011). Although the role of the Atlantic Niño on the global heat budget is not significant, this Atlantic warming trend has led to an increase in precipitation over the equatorial Amazon, Northeast South America, Equatorial West Africa and the Guinea coast, and a decrease in rainfall over the Sahel (Gianinni et al., 2003; Tokinaga and Xie, 2011; Marengo et al., 2011; Rodrigues et al., 2011). Moreover, recent studies have shown that the Atlantic Niño can have an effect on ENSO (Rodríguez-Fonseca et al., 2009; Keenlyside et al., 2013).

In the Indian Ocean, the dominant basin-wide oscillation is the Indian Dipole Mode (Saji et al., 1999). A positive phase is characterized by cool surface-temperature anomalies in the eastern Indian Ocean, warm-temperature anomalies in the western Indian Ocean, and easterly wind-stress anomalies along the equator. Similarly to ENSO, meridional heat transport and the associated buildup of upper-ocean heat content are a possible precondition for the development of the Indian Ocean Dipole event (McPhaden and Nagura, 2014). The warm surface temperatures in the western Indian Ocean are associated with an increase in subsurface heat content and vice-versa for the east (Feng et al. 2001; Rao et al., 2002). This zonal contrast of ocean heat content is induced by anomalies of zonal wind along the equator and the resulting variability in zonal mass and heat transport (Nagura and McPhaden 2010). The warm surface temperatures in the western Indian Ocean are associated with an increase in subsurface heat content and *vice-versa* for the east; the positive dipole causes above-average rainfall in eastern Africa and droughts in Indonesia and Australia (Behera et al., 2005; Yamagata et al., 2004; Ummenhofer et al., 2009; Cai et al., 2011; Section 5 below). Although the phenomena discussed here are global, many of the most significant impacts are on the coastal environment (see following Section).

2.6 *Environmental, economic and social impacts of changes in ocean temperature and of major ocean temperature events*

Coastal waters are valuable both ecologically and economically because they support a high level of biodiversity. They act as nursery areas for many commercially important fish species, and are the marine areas most accessible to the public. Because inshore habitats are shallow, water temperatures in coastal areas are closely linked to the regional climate and its seasonal and long-term fluctuations. Coastal waters also host some of the most vulnerable marine habitats, because they are intensively exploited by (including, but not limited to) the fishing industry and recreational craft, and because of

their proximity to outlets of pollution, such as rivers and sewage outfalls. Coastal development and the threat of rising sea level may also impinge upon these valuable habitats (Halpern et al., 2008). Ecological degradation can lower the socio-economic value of coastal regions, with negative impacts on commercial fisheries, aquaculture facilities, damage to coastal infrastructure, problems with power-station cooling, and exert a dampening effect on coastal tourism from degraded ecological services.

It has been recently shown that when compared with estimates for the global ocean, decadal rates of SST change are higher at the coast. During the last three decades, approximately 70 per cent of the world's coastline has experienced significant increases in SST (Lima and Wethey, 2012). This has been accompanied by an increase in the number of yearly extremely hot days along 38 per cent of the world's coastline, and warming has been occurring significantly earlier in the year along approximately 36 per cent of the world's temperate coastal areas (defined as those between latitudes 30° and 60° in both hemispheres) at an average rate of 6.1 ± 3.2 days per decade (Lima and Wethey, 2012).

The warming of coastal waters can have many serious consequences for the ecological system (Harley et al., 2006). This can include changes in the distribution of important commercial fish and shellfish species, particularly the movement of species to higher latitudes due to thermal stress (Perry et al., 2005). Warming of coastal waters also can lead to more favourable conditions for many organisms, among them marine invasive species that can devastate commercial fisheries and destroy marine ecosystem dynamics (Occhipinti-Ambrogi, 2007). Water quality might also be impacted by higher temperatures that can increase the severity of local outbreaks by pathogenic bacteria or the occurrence of Harmful Algal Blooms (HABs). These in turn would cause harm to seafood, consumers and marine organisms (Bresnan et al., 2013). Increased coral reef bleaching and mortality from warming seas (combined with ocean acidification, see next sections) will lead to the loss of important marine habitats and associated biodiversity.

Changes in ocean temperatures have global impacts. As ocean temperatures warm, species that prefer specific temperature ranges may relocate – as has been observed, for instance, in copepod assemblages in the North Atlantic (Hays et al., 2005). Some organisms, like corals, are sedentary and cannot relocate with changing temperatures. If the water becomes too warm, they may experience a bleaching event. Higher sea level and warmer ocean temperatures can alter ocean circulation and current flow and increase the frequency and intensity of storms, leading to changes in the habitat of many species worldwide.

Changes in ocean temperatures affect not only marine ecosystems, but also the climate over land, with devastating economic and social implications. Many natural oceanic oscillations are known to have an impact on (terrestrial) climate, but these oscillations and the response of the climate to them are also changing during recent decades. For instance, an El Niño phase of ENSO (see previous Section for more details on ENSO) displaces great amounts of warm water from the western to the eastern Pacific, leading to more evaporation over the latter. As a consequence, western and southern South America and parts of North America experience wetter conditions. At the same time, Australia, Brazil, India, Indonesia, the Philippines, parts of Africa and the United States

of America suffer droughts. La Niña events usually cause the opposite patterns. However, in the last several decades, ENSO events have changed their spatial and temporal characteristics (Yeh et al., 2009; McPhaden, 2012).

During recent decades, the warm waters of El Niño events have been displaced to the central Pacific instead of to the eastern Pacific. It is not clear yet whether these changes are linked to anthropogenic climate change or natural variability (Yeh et al., 2011). In any case, the effects on climate of an ENSO event centred in the central Pacific (a central Pacific ENSO) are in sharp contrast to that associated with one centred in the eastern Pacific.

For instance, northeastern and southeastern Australia experience a reduction in rainfall during the eastern Pacific El Niños and there is a decrease in rainfall over northwestern and northern Australia during central Pacific events (Taschetto and England, 2009; Taschetto et al., 2009). The Indian monsoon fails during eastern Pacific El Niños, but is enhanced during central Pacific El Niños (Kumar et al., 2006). Over the semi-arid region of northeast Brazil, eastern Pacific El Niños/La Niñas cause dry/wet conditions; central Pacific El Niños have the opposite effect, with the worst drought in the last 50 years associated with the strong 2011/12 La Niña and not with El Niños as in the past (Rodrigues et al., 2011; Rodrigues and McPhaden, 2014). This drought caused the displacement of 10 million people and economic losses on the order of 3 billion United States dollars in relation to agriculture and cattle raising alone. In contrast to drought in Brazil, the 2011/12 La Niña caused floods across southeastern Australia.

In other ocean basins, changes in oceanic oscillations and temperatures have also had an impact on climate. For instance, in the Indian Ocean, a positive phase of the Indian Dipole Mode (warm/cold temperatures in the western/eastern equatorial Indian Ocean) leads to flooding in east Africa and droughts in Indonesia, Australia, and India (Saji et al., 1999; Ashok et al., 2001; Gadgil et al., 2004; Yamagata et al., 2004; Behera et al., 2005; Ummenhofer et al., 2009; Cai et al., 2011). The counterpart of ENSO in the Atlantic (Atlantic Niño) has weakened during the last six decades, leading to an increase in SST in the eastern equatorial Atlantic. As a consequence, rainfall has been enhanced over the equatorial Amazon and West Africa (Tokinaga and Xie, 2011). On the other hand, an unusual warming of the tropical North Atlantic in 2005 was responsible for one of the worst droughts in the Amazon River basin and a record Atlantic hurricane season. Hurricanes Rita and Katrina caused the loss of almost 2000 lives and an estimated economic toll of 150 billion —135 billion US dollars from Katrina and 15 billion US dollars from Rita. (<http://www.datacenterresearch.org/data-resources/katrina/facts-for-impact/>). Anomalous warm conditions also occurred in the tropical North Atlantic in 2010 leading to two once-in-a-century droughts in less than five years in the Amazon River basin (Marengo et al., 2011).

Ocean warming will stress species both through thermic changes in their environmental envelope and through increased interspecies competition. These shifts become all the more important in shelf seas once they reach terrestrial boundaries, i.e., the shifting species runs out of shelf. For example, changes in the coastal currents in south-eastern Australia cause changes to primary production through to fisheries productivity. This then feeds through to local and regional socio-economic impacts (Suthers et al., 2011).

The IPCC AR5 concluded that “it is unlikely that annual numbers of tropical storms, hurricanes and major hurricanes counts have increased over the past 100 years in the North Atlantic basin. Evidence, however, is for a virtually certain increase in the frequency and intensity of the strongest tropical cyclones since the 1970s in that region” (Hartmann et al. 2013, Section 2.6.3). Moreover, the IPCC AR5 states that “it is difficult to draw firm conclusions with respect to the confidence levels associated with observed trends prior to the satellite era and in ocean basins outside of the North Atlantic” (Hartmann et al. 2013, Section 2.6.3). Although a strong scientific consensus on the matter does not exist, there is some evidence supporting the hypothesis that global warming might lead to fewer but more intense tropical cyclones globally (Knutson et al., 2010). Evidence exists that the observed expansion of the tropics since approximately 1979 is accompanied by a pronounced poleward migration of the latitude at which the maximum intensities of storms occur at a rate of 1° of latitude per decade (Kossin et al., 2014; Hartmann et al., 2013; Seidel et al., 2008). If this trend is confirmed, it would increase the frequency of events in coastal areas that are not exposed regularly to the dangers caused by cyclones. Hurricane Sandy in 2012 may be an example of this (Woodruff et al., 2013).

3. Water flux and salinity

3.1 Regional patterns of salinity, and changes in salinity² and freshwater content

The ocean plays a pivotal role in the global water cycle: about 85 per cent of the evaporation and 77 per cent of the precipitation occur over the ocean (Schmitt, 2008). The horizontal salinity distribution of the upper ocean largely reflects this exchange of freshwater: high surface salinity is generally found in regions where evaporation exceeds precipitation, and low salinity is found in regions of excess precipitation and runoff. Ocean circulation also affects the regional distribution of surface salinity.

The Earth’s water cycle involves evaporation and precipitation of moisture at the Earth’s surface. Changes in the atmosphere’s water vapour content provide strong evidence that the water cycle is already responding to a warming climate. Further evidence comes from changes in the distribution of ocean salinity (Rhein et al. 2013; FAQ. 3.2). Diagnosis and understanding of ocean salinity trends are also important, because salinity changes, like temperature changes, affect circulation and stratification, and therefore the ocean’s capacity to store heat and carbon as well as to change biological productivity.

Seawater contains both salt and fresh water, and its salinity is a function of the weight of dissolved salts it contains. Because the total amount of salt does not change over

² ‘Salinity’ refers to the weight of dissolved salts in a kilogram of seawater. Because the total amount of salt in the ocean does not change, the salinity of seawater can be changed only by addition or removal of fresh water.

human time scales, seawater's salinity can only be altered—over days or centuries—by the addition or removal of fresh water.

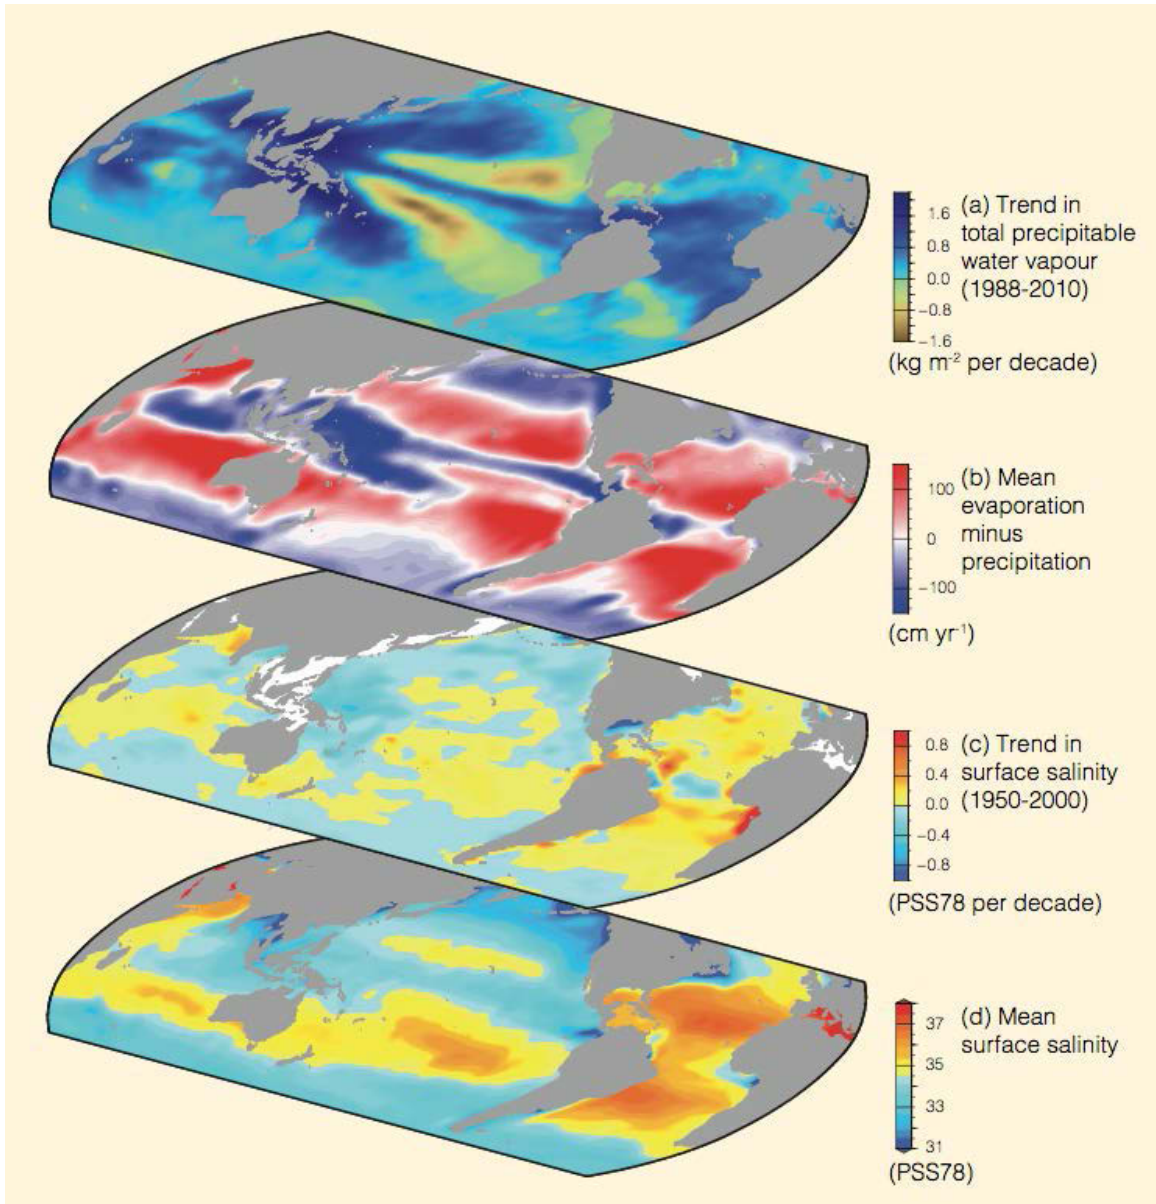

The water cycle is expected to intensify in a warmer climate. Observations since the 1970s show increases in surface and lower atmospheric water vapour (Figure 4a), at a rate consistent with observed warming. Moreover, evaporation and precipitation are projected to intensify in a warmer climate. Recorded changes in ocean salinity in the last 50 years support that projection (Rhein et al. 2013; FAQ. 3.2).

The atmosphere connects the ocean's regions of net fresh water loss to those of fresh water gain by moving evaporated water vapour from one place to another. The distribution of salinity at the ocean surface largely reflects the spatial pattern of evaporation minus precipitation (Figure 4b), runoff from land, and sea ice processes. There is some shifting of the patterns relative to each other, because of the ocean's currents. Ocean salinity acts as a sensitive and effective rain gauge over the ocean. It naturally reflects and smoothes out the difference between water gained by the ocean from precipitation, and water lost by the ocean through evaporation, both of which are very patchy and episodic (Rhein et al. 2013; FAQ. 3.2). Data from the past 50 years show widespread salinity changes in the upper ocean, which are indicative of systematic changes in precipitation and runoff minus evaporation.

(Figure 4b). Subtropical waters are highly saline, because evaporation exceeds rainfall, whereas seawater at high latitudes and in the tropics—where more rain falls than evaporates—is less so. The Atlantic, the saltiest ocean basin, loses more freshwater through evaporation than it gains from precipitation, while the Pacific is nearly neutral, i.e., precipitation gain nearly balances evaporation loss, and the Southern Ocean is dominated by precipitation. (Figure 4b; Rhein et al. 2013; FAQ. 3.2). Changes in surface salinity and in the upper ocean have reinforced the mean salinity pattern (4c). The evaporation-dominated subtropical regions have become saltier, while the precipitation-dominated subpolar and tropical regions have become fresher. When changes over the top 500 m are considered, the evaporation-dominated Atlantic has become saltier, while the nearly neutral Pacific and precipitation-dominated Southern Ocean have become fresher (Figure 4d; Rhein et al. 2013; FAQ. 3.2).

Observed surface salinity changes also suggest a change in the global water cycle has occurred (Chapter 4). The long-term trends show a strong positive correlation between the mean climate of the surface salinity and the temporal changes in surface salinity from 1950 to 2000. This correlation shows an enhancement of the climatological salinity pattern: fresh areas have become fresher and salty areas saltier.

Ocean salinity is also affected by water runoff from the continents, and by the melting and freezing of sea ice or floating glacial ice. Fresh water added by melting ice on land will change global-averaged salinity, but changes to date are too small to observe (Rhein et al. 2013; FAQ. 3.2).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 4. Changes in sea surface salinity are related to the atmospheric patterns of evaporation minus precipitation ($E - P$) and trends in total precipitable water: (a) Linear trend (1988–2010) in total precipitable water (water vapour integrated from the Earth’s surface up through the entire atmosphere) (kg m^{-2} per decade) from satellite observations (Special Sensor Microwave Imager) (after Wentz et al., 2007) (blues: wetter; yellows: drier). (b) The 1979–2005 climatological mean net $E - P$ (cm yr^{-1}) from meteorological reanalysis (National Centers for Environmental Prediction/National Center for Atmospheric Research; Kalnay et al., 1996) (reds: net evaporation; blues: net precipitation). (c) Trend (1950–2000) in surface salinity (PSS78 per 50 years) (after Durack and Wijffels, 2010) (blues freshening; yellows-reds saltier). (d) The climatological-mean surface salinity (PSS78) (blues: <35 ; yellows–reds: >35). From Rhein et al. 2013; FAQ. 3.2. Fig 1.

In conclusion, according to the last IPCC AR5, “It is very likely that regional trends have enhanced the mean geographical contrasts in sea surface salinity since the 1950s: saline

surface waters in the evaporation-dominated mid-latitudes have become more saline, while relatively fresh surface waters in rainfall-dominated tropical and polar regions have become fresher” (Stocker et al., 2013). “The mean contrast between high- and low-salinity regions increased by 0.13 [0.08 to 0.17] from 1950 to 2008. It is very likely that the inter-basin contrast in freshwater content has increased: the Atlantic has become saltier and the Pacific and Southern Oceans have freshened. Although similar conclusions were reached in AR4, recent studies based on expanded data sets and new analysis approaches provide high confidence in this assessment” (Stocker et al., 2013). “The spatial patterns of the salinity trends, mean salinity and the mean distribution of evaporation minus precipitation are all similar. These similarities provide indirect evidence that the pattern of evaporation minus precipitation over the oceans has been enhanced since the 1950s (medium confidence)” Stocker et al., (2013). “Uncertainties in currently available surface fluxes prevent the flux products from being reliably used to identify trends in the regional or global distribution of evaporation or precipitation over the oceans on the time scale of the observed salinity changes since the 1950s” (Stocker et al., 2013).

4. Carbon dioxide flux and ocean acidification

4.1 Carbon dioxide emissions from anthropogenic activities

Since the start of Industrial Revolution, human activities have been releasing large amounts of carbon dioxide into the atmosphere. As a result, atmospheric CO₂ has increased from a glacial to interglacial cycle of 180-280 ppm to about 395 ppm in 2013 (Dlugokencky and Tans, 2014). Until around 1920, the primary source of carbon dioxide to the atmosphere was from deforestation and other land-use change activities (Ciais et al., 2013). Since the end of World War II, anthropogenic emissions of CO₂ have been increasing steadily. Data from 2004 to 2013 show that human activities (fossil fuel combustion and cement production) are now responsible for about 91 per cent of the total CO₂ emissions (Le Quéré et al. 2014).

CO₂ emissions from fossil fuel consumption can be estimated from the energy data that are available from the United Nations Statistics Division and the BP Annual Energy Review. Data in 2013 suggests that about 43 per cent of the anthropogenic CO₂ emissions were produced from coal, 33 per cent from oil and 18 per cent from gas, and 6 per cent from cement production (Figure 5).

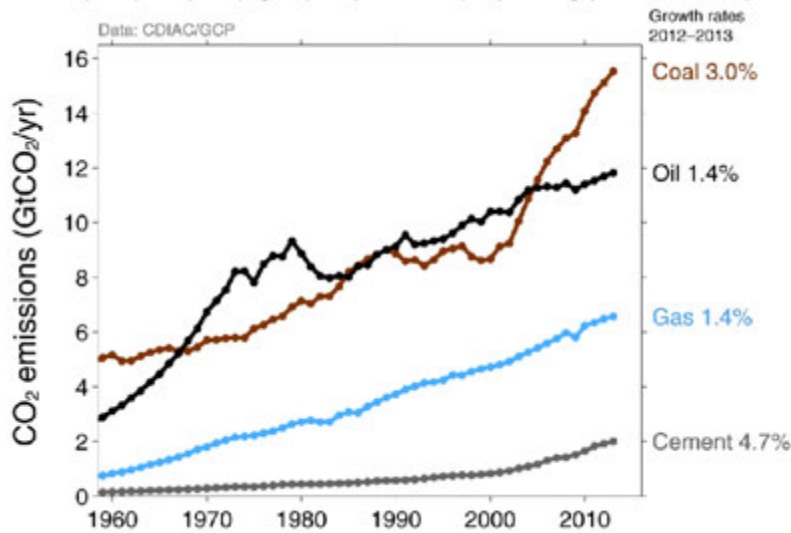

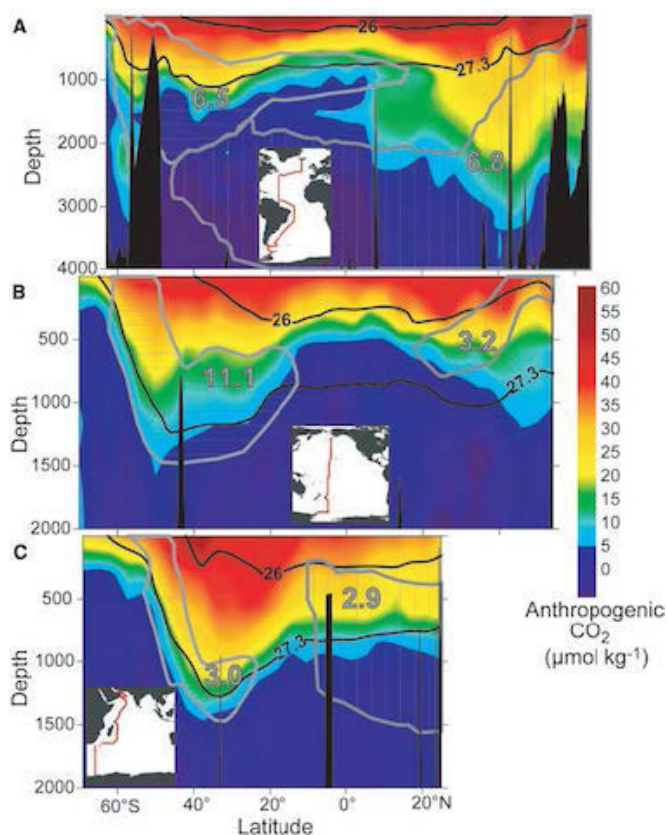

Figure 5. CO₂ emissions from different sources from 1958 to 2013 (Le Quéré et al. 2014).

Coal is an important and, recently, growing proportion of CO₂ emissions from fossil fuel combustion. From 2012 to 2013, CO₂ emissions from coal increased 3.0 per cent, compared to the increase rate of 1.4 per cent for oil and gas (Le Quéré et al. 2014). Coal accounted for about 60 per cent of the CO₂ emission growth in the same period. This is largely because many large economies of the world have recently resorted to using coal as an energy source for a wide variety of industrial processes, instead of oil, gas and other energy sources.

4.2 The ocean as a sink for atmospheric CO₂

The global oceans serve as a major sink of atmospheric CO₂. The oceans take up carbon dioxide through mainly two processes: physical air-sea flux of atmospheric CO₂ at the ocean surface, the so called "solubility pump" and through the active biological uptake of CO₂ into the biomass and skeletons of plankters the so-called "biological pump". Colder water can take up CO₂ more than warm water, and if this cold, denser water sinks to form intermediate, deep, or bottom water, there is transport of carbon away from the surface ocean and thus from the atmosphere into the ocean interior. This "solubility pump" helps to keep the surface waters of the ocean on average lower in CO₂ than the deep water, a condition that promotes the flux of the gas from the atmosphere into the ocean.

Phytoplankton take up CO₂ from the water in the process of photosynthesis, some of which sinks to the bottom in the form of particles or is mixed into the deeper waters as dissolved organic or inorganic carbon. Part of this carbon is permanently buried in the sediments and other part enters into the slower circulation of the deep ocean. This "biological pump" serves to maintain the gradient in CO₂ concentration between the surface and deep waters.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

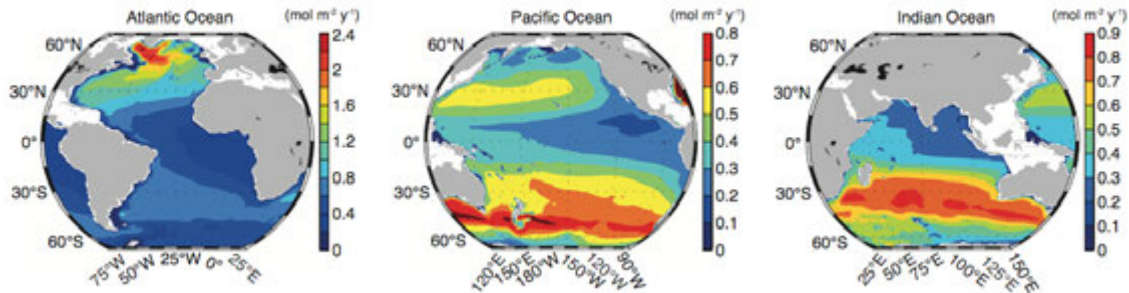

Figure 6. Anthropogenic CO₂ distributions along representative meridional sections in the Atlantic, Pacific, and Indian oceans for the mid-1990s (Sabine et al. 2004).

Because the ocean mixes slowly, about half of the anthropogenic CO₂ (C_{ant}) stored in the ocean is found in the upper 10 per cent of the ocean (Figure 6.). On average, the penetration depth is about 1000 meters and about 50 per cent of the anthropogenic CO₂ in the ocean is shallower than 400 meters.

Globally, the ocean shows large spatial variations in terms of its role as a sink of atmospheric CO₂ (Takahashi et al. 2009). Over the past 200 years the oceans have absorbed 525 billion tons of CO₂ from the atmosphere, or nearly half of the fossil fuel emissions over the period (Feely et al. 2009). The oceanic sink of atmospheric CO₂ has increased from 4.0 ± 1.8 GtCO₂ ($1 \text{ GtCO}_2 = 10^9$ tons of carbon dioxide) per year in the 1960s to 9.5 ± 1.8 GtCO₂ per year during 2004-2013. During the same period, the estimated annual atmospheric CO₂ captured by the ocean was 2.6 ± 0.5 Gt of CO₂ compared with around 1.9 Gt of CO₂ during the sixties (Le Queré et al., 2014). However, due to the decreased buffering capacity, caused by this CO₂ uptake, the proportion of anthropogenic carbon dioxide that goes into the ocean has been decreasing.

Estimates of the global inventory of anthropogenic carbon, C_{ant} (including marginal seas) have a mean value of 118 PgC and a range of 93 to 137 PgC in 1994 and a mean of 160 PgC and range of 134 to 186 PgC in 2010 (Rhein et al 2013). When combined with model results Khatiwala et al. (2013) arrive at a “best” estimate of the global ocean inventory (including marginal seas) of anthropogenic carbon from 1750 to 2010 of 155 PgC with an uncertainty of ± 20 per cent (Rhein et al 2013).

The storage rate of anthropogenic CO₂ is assessed by calculating the change in C_{ant} concentrations between two time periods. Regional observations of the storage rate are in general agreement with that expected from the increase in atmospheric CO₂ concentrations and with the tracer-based estimates. However, there are significant spatial and temporal variations in the degree to which the inventory of C_{ant} tracks changes in the atmosphere (Figure 7, Rhein et al 2013).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 7. Maps of storage rate distribution of C_{ant} in (mol m⁻² yr⁻¹) averaged over 1980-2005 for the three ocean basins (left to right: Atlantic, Pacific and Indian Ocean). From Khatiwala et al 2009, a slightly different colour scale is used for each basin.

Comprehensive evaluation of available data shows that in the context of the global carbon cycle, it is only the ocean that has acted as a net sink of carbon from the atmosphere. The land was a source early in the industrial age, and since about 1950 has trended toward a sink, but it is not yet clearly a net sink. (Ciais et al. 2013 and Khatiwala et al. 2009, Khatiwala et al. 2013). Latest data from 2004 to 2013 show that the global oceans take up about one-fourth (26 per cent, Le Quéré, 2014) of the total annual anthropogenic emissions of CO₂. This is a very important physical and ecological service that the ocean has performed in the past and performs today, that underpins all *strategies to mitigate the negative impacts of global warming*.

4.3 Ocean acidification

As already seen in the previous section, the global oceans serve as an important sink of atmospheric CO₂, effectively slowing down global climate change. However, this benefit comes with a steep bio-ecological cost. When CO₂ reacts with water, it forms carbonic acid, which then dissociates and produces hydrogen ions. The extra hydrogen ions consume carbonate ions (CO₃²⁻) to form bicarbonate (HCO₃⁻). In this process, the pH and concentrations of carbonate ions (CO₃²⁻) are decreasing. As a result, the carbonate mineral saturation states are also decreasing. Due to the increasing acidity, this process is commonly referred to as “ocean acidification (OA)”. According to the IPCC AR 4 and 5, “Ocean acidification refers to a reduction in pH of the ocean over an extended period, typically decades or longer, caused primarily by the uptake of carbon dioxide (CO₂) from the atmosphere.” (...) “Anthropogenic ocean acidification refers to the component of pH reduction that is caused by human activity” (Rhein et al. 2013).

Although the average oceanic pH can vary on interglacial time scales, the changes are usually on the order of ~ 0.002 units per 100 years; however, the current observed rate of change is ~ 0.1 units per 100 years, or roughly 50 times faster. Regional factors, such as coastal upwelling, changes in riverine and glacial discharge rates, and sea-ice loss have created “OA hotspots” where changes are occurring at even faster rates. Although OA is a global phenomenon that will likely have far-reaching implications for many marine organisms, some areas will be affected sooner and to a greater degree.

Recent observations show that one such area in particular is the cold, highly productive region of the sub-arctic Pacific and western Arctic Ocean, where unique biogeochemical processes create an environment that is both sensitive and particularly susceptible to accelerated reductions in pH and carbonate mineral concentrations. The OA phenomenon can cause waters to become undersaturated in carbonate minerals and thereby affect extensive and diverse populations of marine calcifiers.

4.4 *The CO₂ problem*

Based on the most recent data of 2004 to 2013, 35.7 GtCO₂ (1 GtCO₂ = 10⁹ tons of carbon dioxide) of anthropogenic CO₂ are released into the atmosphere every year (Le Quéré et al. 2014). Of this, approximately 32.4 GtCO₂ come directly from the burning of fossil fuels and other industrial processes that emit CO₂. The remaining 3.3 GtCO₂ are due to changes in land-use practices, such as deforestation and urbanization. Of this 35.7 GtCO₂ of anthropogenically produced CO₂ emitted annually, approximately 10.6 GtCO₂ (or 29 per cent) are incorporated into terrestrial plant matter. Another 15.8 GtCO₂ (or 46 per cent) are retained in the atmosphere, which has led to some planetary warming. The remaining 9.5 GtCO₂ (or 26 per cent) are absorbed by the world’s oceans (Le Quéré et al. 2014).

As the hydrogen ions produced by the increased CO₂ dissolution take carbonate ions out of seawater, the rate of calcification of shell-building organisms is affected; they are confronted with additional physiological challenges to maintain their shells. Although alteration of the carbonate equilibrium system in the ocean reducing carbonate ion concentration, and saturation states of calcium carbonate minerals will play a role imposing an additional energy cost to calcifier organisms, such as corals and shellbearing plankton, this is by no means the sole impact of OA.

4.5 *What are the impacts of a more acidic ocean?*

Throughout the last 25 million years, the average pH of the ocean has remained fairly constant between 8.0 and 8.2. However, in the last three decades, a fast drop has begun to occur, and if CO₂ emissions are left unchecked, the average pH could fall below 7.8 by the end of this century (Rhein, et al. 2013).

This is well outside the range of pH change of any other time in recent geological history. Calcifying organisms in particular, such as corals, crabs, clams, oysters and the tiny free-swimming pteropods that form calcium carbonate shells, could be particularly vulnerable, especially during the larval stage. Many of the processes that cause OA have

long been recognized, but the ecological implications of the associated chemical changes have only recently been investigated. OA may have important ecological and socioeconomic consequences by impacting directly the physiology of all organisms in the ocean.

The altered environment is imposing an extra energy cost for the acid-base regulation of their internal body milieu. Through biological and evolutionary adaptation this process might have a huge variation of expression among different types of organisms, a subject that only recently has become the focus of intense scientific research.

Calcification is an internal process that in its vast majority does not depend directly on seawater carbonate content, since most organisms use bicarbonate, that is increasing under acidification scenarios, or CO₂ originating in their internal metabolism. It has been demonstrated in the laboratory and in the field that some calcifiers can compensate and thrive in acidification conditions.

OA is not a simple phenomenon nor will it have a simple unidirectional effect on organisms. The abundance and composition of species may be changed, due to OA with the potential to affect ecosystem function at all trophic levels, and consequential changes in ocean chemistry could occur as well. Some species may also be better able than others to adapt to changing pH levels due to their exposure to environments where pH naturally varies over a wide range. However, at this point, it is still very uncertain what the ecological and societal consequences will be from any potential losses of keystone species.

4.6 Socioeconomic impacts of ocean acidification

Some examples of economic disruptions due to OA have been reported. The most visible case is the harvest failure in the oyster hatcheries along the Pacific Northwest coast of the USA. Hatcheries that supply the majority of the oyster spat to farms nearly went out of business as they unknowingly pumped low pH water, apparently corrosive to oyster larvae, into their operation. Although intense upwelling that could have brought low oxygen water to hatcheries might also be a factor in these massive mortalities, low pH, “corrosive water” tends to recur seasonally in this region. Innovations and interactions with scientists allowed these hatcheries to monitor the presence of corrosive incoming waters and adopt preventive measures.

Economic studies have shown that potential losses at local and regional scales may have negative impacts for communities and national economies that depend on fisheries. For example, Cooley and Doney (2009) using data from 2007, found that of the 4 billion dollars in annual domestic sales, Alaska and the New England states likely to be affected by hotspots of OA, contributed the most at 1.5 billion dollars and 750 million dollars, respectively. These numbers clearly show that any disruption in the commercial fisheries in these regions due to OA could have a cascading effect on the local as well as on the national economy.

Chapter 6. Primary Production, Cycling of Nutrients, Surface Layer and Plankton

Writing team: Thomas Malone (Convenor), Maurizio Azzaro, Antonio Bode, Euan Brown, Robert Duce, Dan Kamykowski, Sung Ho Kang, Yin Kedong, Michael Thorndyke, and Jinhui Wang, Chul Park (Lead member); Hilconida Calumpong and Peyman Eghtesadi (Co-Lead members)

1. Primary Production¹

1.1 Definition and ecological significance

Gross primary production (GPP) is the rate at which photosynthetic plants and bacteria use sunlight to convert carbon dioxide (CO₂) and water to the high-energy organic carbon compounds used to fuel growth. Free oxygen (O₂) is released during the process. Net primary production (NPP) is GPP less the respiratory release of CO₂ by photosynthetic organisms, i.e., the net photosynthetic fixation of inorganic carbon into autotrophic biomass. NPP supports most life on Earth; it fuels global cycles of carbon, nitrogen, phosphorus and other nutrients and is an important parameter of atmospheric CO₂ and O₂ levels (and, therefore, of anthropogenic climate change).

Global NPP is estimated to be ~105 Pg C yr⁻¹, about half of which is by marine plants (Field et al., 1998; Falkowski and Raven, 1997; Westberry et al., 2008).² Within the euphotic zone of the upper ocean,³ phytoplankton and macrophytes⁴ respectively account for ~94 per cent (~50 ± 28 Pg C yr⁻¹) and ~6 per cent (~3.0 Pg C yr⁻¹) of NPP (Falkowski et al., 2004; Duarte et al., 2005; Carr et al., 2006; Schneider et al., 2008; Chavez et al., 2011; Ma et al., 2014; Rousseaux and Gregg, 2014). All NPP is not equal in terms of its fate. Marine macrophytes play an important role as carbon sinks in the global carbon cycle, provide habitat for a diversity of animal species, and food for marine and terrestrial consumers (Smith, 1981; Twilley et al., 1992; Duarte et al., 2005; Duarte et al., 2010; Heck et al., 2008; Nellemann et al., 2009; McLeod et al., 2011, Fourqurean et al., 2012). Phytoplankton NPP fuels the marine food webs upon which marine fisheries depend (Pauly and Christensen, 1995; Chassot et al., 2010) and the

¹ Microbenthic, epiphytic and symbiotic algae can be locally important in shallow waters and corals, but are not addressed here. Chemosynthetic primary production is addressed elsewhere.

² 1 Pg = 10¹⁵ g

³ Defined here to include the epipelagic (0-200 m) and mesopelagic (200 – -1000 m) zones. The euphotic zone lies within the epipelagic zone.

⁴ Macrophytes include sea grasses, macroalgae, salt marsh plants and mangroves. Phytoplankton are single-celled, photosynthetic prokaryotic and eukaryotic microorganisms growing in the euphotic zone (the layer between the ocean's surface and the depth at which photosynthetically active radiation [PAR] is 1 per cent of surface intensity). Most phytoplankton species are > 1 µm and < 1 mm in equivalent spherical diameter (cf. Ward et al., 2012).

“biological pump” which transports 2-12 Pg C yr⁻¹ of organic carbon to the deep sea (Falkowski et al., 1998; Muller-Karger et al., 2005; Emerson and Hedges, 2008; Doney, 2010; Passow and Carlson, 2012), where it is sequestered from the atmospheric pool of carbon for 200-1500 years (Craig, 1957; Schlitzer et al., 2003; Primeau and Holzer, 2006; Buesseler, et al., 2007).

Changes in the size structure of phytoplankton communities influence the fate of NPP (Malone, 1980; Legendre and Rassoulzadegan, 1996; Pomeroy et al., 2007; Marañón, 2009). In general, small cells (picophytoplankton with equivalent spherical diameters < 2 µm) account for most NPP in subtropical, oligotrophic (< 0.3 mg chlorophyll-a m⁻³), nutrient-poor (nitrate + nitrite < 1 µM), warm (> 20°C) waters. Under these conditions, the flow of organic carbon to harvestable fisheries and the biological pump are relatively small. In contrast, larger cells (microphytoplankton > 20 µm) account for > 90 per cent of NPP in more eutrophic (> 5 mg chlorophyll-a m⁻³), nutrient-rich (nitrate + nitrite >10 µM), cold (< 15°C) waters (Kamykowski, 1987; Agawin et al., 2000; Buitenhuis et al., 2012). Under these conditions, diatoms⁵ account for most NPP during spring blooms at high latitudes and periods of coastal upwelling when NPP is high and nutrients are not limiting (Malone, 1980). The flow of organic carbon to fisheries and the biological pump is higher when larger cells account for most NPP (Laws et al., 2000; Finkel et al., 2010).

1.2 *Methods of measuring net primary production (NPP)*

1.2.1 *Phytoplankton Net Primary Production*

Phytoplankton (NPP) has been estimated using a variety of *in situ* and remote sensing methods (Platt and Sathyendranath, 1993; Geider et al., 2001; Marra, 2002; Carr et al., 2006; Vernet and Smith, 2007; Cullen, 2008a; Cloern et al., 2013). Multiplatform (e.g., ships, moorings, drifters, gliders, aircraft, and satellites) sampling strategies that utilize both approaches are needed to effectively detect changes in NPP on ecosystem to global scales (UNESCO-IOC, 2012).

On small spatial and temporal scales (meters-kilometres, hours-days), several techniques have been used including oxygen production and the incorporation of ¹³C and ¹⁴C labelled bicarbonate (Cullen, 2008a). The most widely used and standard method against which other methods are compared or calibrated is based on the incorporation of ¹⁴C-bicarbonate into phytoplankton biomass (Steeman-Nielsen, 1963; Marra, 1995; Marra, 2002; Vernet and Smith, 2007; Cullen, 2008a). On large spatial scales (Large Marine Ecosystems⁶ to the global ocean), the most effective way to detect space-time variability is via satellite-based measurements of water-leaving radiance combined with diagnostic models of depth-integrated NPP as a function of depth-

⁵ Diatom growth accounts for roughly half of marine NPP and therefore for about a quarter of global photosynthetic production (Smetacek, 1999).

⁶ Large marine ecosystems (200,000 km² or larger) are coastal ecosystems characterized by their distinct bathymetry, hydrography, productivity and food webs (Sherman et al., 1993).

integrated chlorophyll-a concentration (Ψ Chl), photosynthetically active solar radiation, and temperature (Antoine and Morel, 1996; Perry, 1986; Morel and Berthon, 1989; Platt and Sathyendranath, 1993; Behrenfeld and Falkowski, 1997; Sathyendranath, 2000; Gregg et al., 2003; Behrenfeld et al., 2006; Carr et al., 2006; Arrigo et al., 2008; Bissinger et al., 2008; McClain, 2009; Westberry et al., 2008; Cullen et al., 2012; Siegel et al., 2013).

An overview of the latest satellite based models may be found at the Ocean Productivity website.⁷ Satellite ocean-colour radiometry (OCR) data have been used to estimate surface chlorophyll-a fields and NPP since the Coastal Zone Color Scanner (CZCS) mission (1978-1986). Uninterrupted OCR measurements began with the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) mission (1997-2010) (Hu et al., 2012). A full accounting of current polar orbiting and geostationary ocean-colour sensors with their capabilities (swath width, spatial resolution, spectral coverage) can be found on the web site of the International Ocean-Colour Coordinating Group.⁸

The skill of model-based estimates of NPP has been improving (O'Reilly et al., 1998; Lee, 2006; Friedrichs et al., 2009; Saba et al., 2010; Saba et al., 2011; Mustapha et al., 2012), but further improvements are needed through more accurate estimates of Ψ Chl. Chlorophyll-a fields can be estimated more accurately by blending data from remote sensing and *in situ* measurements, especially in regions where *in situ* measurements are sparse and in turbid, coastal ecosystems (Conkright and Gregg, 2003; Gregg et al., 2003; Onabid, 2011). An empirical approach has been developed for ocean-colour remote sensing called Empirical Satellite Radiance-In situ Data (ESRID) algorithm (Gregg et al., 2009).

1.2.2 *Macrophyte Net Primary Production*

The NPP of macroalgae, sea grasses, salt marsh plants and mangroves can be estimated by sequentially (e.g., monthly during the growing season) measuring increases in biomass (including leaf litter in salt marshes and mangrove forests) using a combination of *in situ* techniques (e.g., Mann, 1972; Cousens, 1984; Dame and Kenny, 1986; Amarasinghe and Balasubramaniam, 1992; Long et al., 1992; Day et al., 1996; Ross et al., 2001; Curco et al., 2002; Morris, 2007) and satellite-based multispectral imagery (e.g., Gross et al., 1990; Zhang et al., 1997; Kovacs et al., 2001; Gitelson, 2004; Liu et al., 2008; Kovacs et al., 2009; Heumann, 2011; Mishra et al., 2012; Son and Chen, 2013). For remote sensing, accurate *in situ* measurements are critical for validating models used to map these habitats and estimate NPP (Gross et al., 1990; Kovacs et al., 2009; Roelfsema et al., 2009; Mishra et al., 2012; Jia et al., 2013; Trilla et al., 2013). These include shoot- or leaf-tagging techniques, measurements of ¹⁴C incorporation into leaves, and measurements of dissolved O₂ production during the growing season (Bittaker and

Iverson, 1976; Kemp et al., 1986; Duarte, 1989; Kaldy and Dunton, 2000; Duarte and Kirkman, 2001; Plus et al., 2001, Silva et al., 2009).

1.2.3 *The Phenology⁹ of Phytoplankton Annual Cycles*

The timing of seasonal increases in phytoplankton NPP is determined by environmental parameters, including day length, temperature, changes in vertical stratification, and the timing of seasonal sea-ice retreat in polar waters. All but day length are affected by climate change. Thus, phytoplankton phenology provides an important tool for detecting climate-driven decadal variability and secular trends. Phenological metrics to be monitored are the time of bloom initiation, bloom duration and time of maximum amplitude (Siegel et al., 2002; Platt et al., 2009).

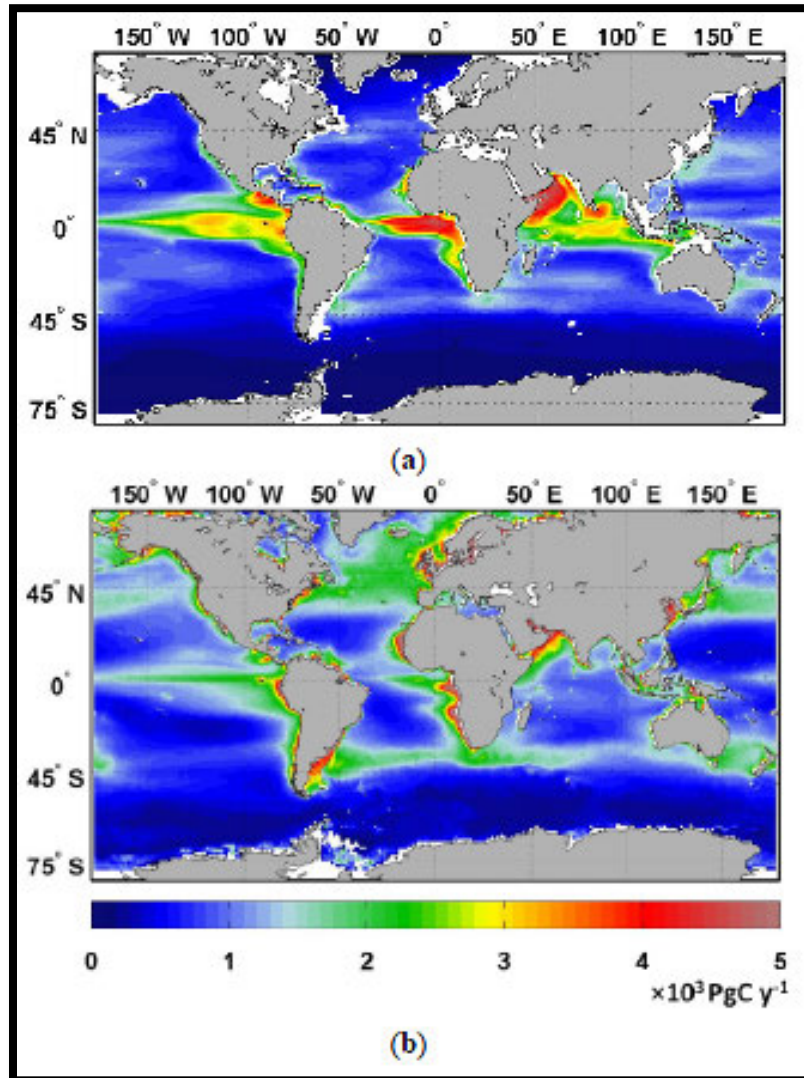

1.3 *Spatial patterns and temporal trends*

Marine NPP varies over a broad spectrum of time scales from tidal, daily and seasonal cycles to low-frequency basin-scale oscillations and multi-decade secular trends (Malone, 1971; Pingree et al., 1975; Steele, 1985; Cloern, 1987; Cloern, 2001; Cloern et al., 2013; Duarte, 1989; Powell, 1989; Malone et al., 1996; Henson and Thomas, 2007; Vantrepotte and Mélin, 2009; Cloern and Jassby, 2010; Bode et al., 2011; Chavez et al., 2011). Our focus here is on low-frequency cycles and multi-decade trends.

1.3.1 *Phytoplankton NPP*

For the most part, the global pattern of phytoplankton NPP (Figure 1) reflects the pattern of deep-water nutrient inputs to the euphotic zone associated with winter mixing and thermocline erosion at higher latitudes, thermocline shoaling at lower latitudes, and upwelling along the eastern boundaries of the ocean basins and the equator (Wollast, 1998; Pennington et al., 2006; Chavez et al., 2011; Ward et al., 2012). The global distribution of phytoplankton NPP is also influenced by iron limitation and grazing by microzooplankton in so-called High Nutrient Low Chlorophyll (HNLC) zones which account for ~20 per cent of the global ocean, e.g., oceanic waters of the subarctic north Pacific, subtropical equatorial Pacific, and Southern Ocean (Martin et al., 1994; Landry et al., 1997; Edwards et al., 2004). Nutrient inputs associated with river runoff enhance NPP in coastal waters during the growing season (Seitzinger et al., 2005; Seitzinger et al., 2010). Annual cycles of NPP associated with patterns of nutrient supply and seasonal variations in sunlight tend to increase in amplitude and decrease in duration with increasing latitude. Seasonal increases in NPP generally follow winter mixing when nutrient concentrations are high, the seasonal thermocline sets up, and day length increases. Annual cycles are also more pronounced in coastal waters subject to seasonal upwelling.

⁹ Phenology is the study of the timing and duration of cyclic and seasonal natural phenomena (e.g., spring phytoplankton blooms, seasonal cycles of zooplankton reproduction), especially in relation to climate and plant and animal life cycles.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Climatological map Distribution of annual marine NPP for (a) NASA Ocean Biogeochemical Model and (b) Vertically-Integrated Production Model (VGPM) for the period from September 1998 to 2011 (Rousseaux – August 1999 (Blue < 100 g C m⁻², Green > 110 g C m⁻² and < 400 g C m⁻², Red > 400 g C m⁻²) (Rutgers Institute of Marine and Gregg, 2014). Globally, diatoms accounted for about 50 per cent of NPP while coccolithophores, chlorophytes and cyanobacteria accounted for about 20 per cent, 20 per cent and 10 per cent, respectively. Diatom NPP was highest at high latitudes and in equatorial and eastern boundary upwelling systems. Coastal Sciences, <http://marine.rutgers.edu/opp/>). Coastal ecosystems (red – green) and the permanently stratified subtropical waters of the central gyres (blue) each account for ~30 per cent of the ocean’s NPP, whereas the former accounts for only ~8 per cent of the ocean’s surface area compared to ~60 per cent for the open ocean waters of the subtropics (Geider et al., 2001; Marañón et al., 2003; Muller-Karger et al., 2005).

The global distribution of annual NPP in the ocean can be partitioned into broad provinces with eastern boundary upwelling systems and estuaries exhibiting the highest rates and subtropical central gyres the lowest rates (Figure 1, Table 1).

Table 1. Ranges of phytoplankton mean daily NPP and annual NPP reported for different marine provinces. Estimates are based on *in situ* measurements and models using satellite-based observations of chlorophyll-a fields. Western boundaries of the ocean basins generally feature broad continental shelves and eastern boundaries tend to have narrow shelves with coastal upwelling. (Data sources: Malone et al., 1983; O'Reilly and Busch, 1983; Pennock and Sharp, 1986; Cloern, 1987; Malone, 1991; Barber et al., 1996; Karl et al., 1996; Malone et al., 1996; Pilska et al., 1996; Smith and DeMaster, 1996; Lohrenz et al., 1997; Cloern, 2001; Smith et al., 2001; Steinberg et al., 2001; Marañón et al., 2003; Sakshaug, 2004; PICES, 2004; Teira et al., 2005; Tian et al., 2005; Pennington et al., 2006; Subramanian et al., 2008; Vernet et al., 2008; Bidigare et al., 2009; Sherman and Hempel, 2009; Chavez et al., 2010; 176 Saba et al., 2011; Brown and Arrigo, 2012; Cloern et al., 2013; Lomas et al., 2013).

Province	mg C m ⁻² d ⁻¹	g C m ⁻² yr ⁻¹
Subtropical Central Gyres	20 – 1,040	150 – 170
Western Boundaries	10 – 3,500	200 – 470
Eastern Boundaries	30 – 7,300	460 – 1,250
Equatorial Upwelling	640 – 900	240
Arctic Ocean	3 – 1,100	5 – 400
Southern Ocean	290 – 370	50 – 450
Coastal Seas	100 – 1,400	40 – 600
Estuaries & Coastal Plumes	100 – 8,000	70 – 1,890

Interannual variability and multi-decadal trends in phytoplankton NPP on regional to global scales are primarily driven by: (1) climate change (e.g., basin-scale oscillations and decadal trends, including loss of polar ice cover, upper ocean warming, and changes in the hydrological cycle); (2) land-based, anthropogenic nutrient loading; and (3) pelagic and benthic primary consumers. Global-scale trends in phytoplankton NPP remain controversial (Boyce et al., 2010; Boyce et al., 2014; Mackas, 2011; Rykaczewski and Dunne, 2011; McQuatters-Gollop et al., 2011; Dave and Lozier, 2013; Wernand et al., 2013). Remote sensing (sea-surface temperature and chlorophyll fields), model simulations and marine sediment records suggest that global phytoplankton NPP may have increased over the last century as a consequence of basin-scale climate forcing that promotes episodic and seasonal nutrient enrichment of the euphotic zone through vertical mixing and upwelling (McGregor et al., 2007; Bidigare et al., 2009; Chavez et al., 2011; Zhai et al., 2013). In contrast, global analyses of changes in chlorophyll distribution over time suggest that annual NPP in the global ocean has declined over the

last 100 years (Gregg et al., 2003; Boyce et al., 2014). A decadal scale decline is consistent with model simulations indicating that both NPP and the biological pump have decreased by ~7 per cent and 8 per cent, respectively, over the last five decades (Laufkötter et al., 2013), trends that are likely to continue through the end of this century (Steinacher et al., 2010).

Given uncertainties concerning global trends, long-term impacts of secular changes in phytoplankton NPP on food security and climate change cannot be assessed at this time with any certainty. Resolving this controversy and predicting future trends will require sustained, multi-decadal observations and modelling of phytoplankton NPP and key environmental parameters (e.g., upper ocean temperature, pCO₂, pH, depth of the aragonite saturation horizon, vertical stratification and nutrient concentrations) on regional and global scales – observations that may have to be sustained for at least another 40-50 years (Henson et al., 2010).

1.3.2 *Macrophyte NPP*

Marine macrophyte NPP, which is limited to tidal and relatively shallow waters in coastal ecosystems, varies from 30-1,200 g C m⁻² yr⁻¹ (Smith, 1981; Charpy-Roubaoud and Sournia, 1990; Geider et al., 2001; Duarte et al., 2005; Duarte et al., 2010; Fourqurean et al., 2012; Ducklow et al., 2013). In contrast to the uncertainty of decadal trends in phytoplankton NPP, decadal declines in the spatial extent and biomass of macrophytes (a proxy for NPP) over the last 50-100 years are relatively well documented. Macrophyte habitats are being lost and modified (e.g., fragmented) at alarming rates (Duke et al., 2007; Valiela et al., 2009; Waycott et al., 2009; Wernberg et al., 2011), i.e., 2 per cent for macrophytes as a group, with total areal losses to date of 29 per cent for seagrasses, 50 per cent for salt marshes and 35 per cent for mangrove forests (Valiela et al., 2001; Hassan et al., 2005; Orth et al., 2006; Waycott et al., 2009; Fourqurean et al., 2012). As a whole, the world is losing its macrophyte ecosystems in coastal waters four times faster than its rain forests (Duarte et al., 2008), and the rate of loss is accelerating (Waycott et al., 2009).

2. Nutrient Cycles

Nitrogen (N) and phosphorus (P) are major nutrients required for the growth of all organisms, and NPP is the primary engine that drives the cycles of N and P in the oceans. The cycles of C, N, P and O₂ are coupled in the marine environment (Gruber, 2008). As discussed in section 6.1.3, the global pattern of phytoplankton NPP reflects the pattern of dissolved inorganic N and P inputs to the euphotic zone from the deep ocean (Figure 1). Superimposed on this pattern are nutrient inputs associated with N fixation, atmospheric deposition, river discharge and submarine ground water discharge. In regard to the latter, ground water discharge may be a significant source of N locally in some parts of Southeast Asia, North and Central America, and Europe, but on the scale of ocean basins and the global ocean, ground water discharge of N has been estimated

to be on the order of 2-4 per cent of river discharge (Beusen et al., 2013). Given this, and challenges of quantifying ground water inputs on ocean basin to global scales (NRC, 2004), this source is not considered herein.

2.1 Nitrogen

The ocean's nitrogen cycle is driven by complex microbial transformations, including N fixation, assimilation, nitrification, anammox and denitrification (Voss et al., 2013) (Figure 2). NPP depends on the supply of reactive N (N_r)¹⁰ to the euphotic zone. Although most dissolved chemical forms of N_r can be assimilated by primary producers, the most abundant chemical form, dissolved dinitrogen gas (N_2), can only be assimilated by marine diazotrophs.¹¹ N_r inputs to the euphotic zone occur via fluxes of nitrate from deep water (vertical mixing and upwelling), marine N_2 fixation, river discharge, and atmospheric deposition.¹² N_r is removed from the marine N inventory through denitrification and anammox¹³ with subsequent efflux of N_2 and N_2O to the atmosphere (Thamdrup et al., 2006; Capone, 2008; Naqvi et al., 2008; Ward et al., 2009; Ward, 2013). Although there is no agreement concerning the oxygen threshold that defines the geographic extent of denitrification and anammox (Paulmier and Ruiz-Pino, 2009), these processes are limited to suboxic waters with very low oxygen concentrations (< 22 μM).

¹⁰ Reactive or fixed N forms include dissolved inorganic nitrate, nitrite, ammonium and organic N compounds, such as urea and free amino acids.

¹¹ Prokaryotic, free-living and symbiotic bacteria, cyanobacteria and archaea.

¹² River discharge and atmospheric deposition include nitrate from fossil fuel burning and fixed N in synthetic fertilizer produced by the Haber-Bosch process for industrial nitrogen fixation.

¹³ Anaerobic ammonium oxidation.

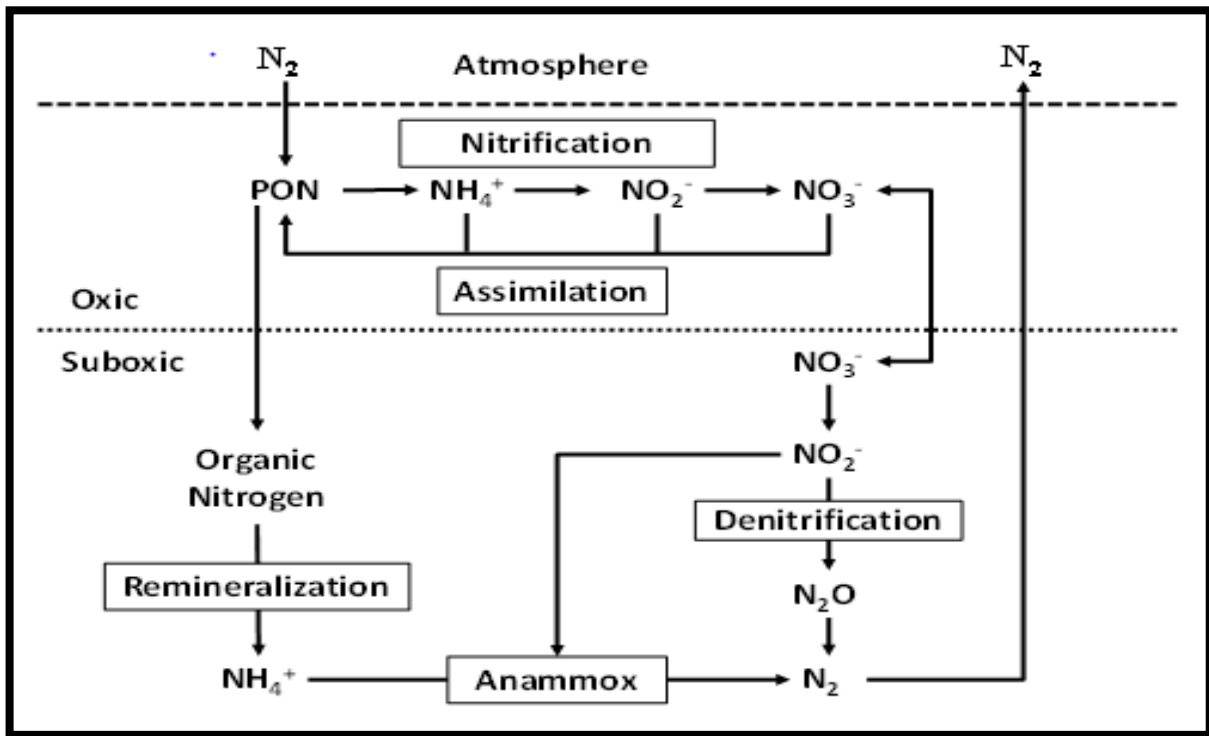

Figure 2. The biological nitrogen cycle showing the main inorganic forms in which nitrogen occurs in the ocean (PON-pariculate organic nitrogen) (adapted from Ward, 2012).

Variations in the ocean's inventory of N_r have driven changes in marine NPP and atmospheric CO_2 throughout the Earth's geological history (Falkowski, 1997; Gruber, 2004; Arrigo, 2005). Marine N_2 fixation provides a source of "new" N and NPP that fuel marine food webs and the biological pump. Thus, the rate of N_2 fixation can affect atmospheric levels of CO_2 on time-scales of decades (variability in upper ocean nutrient cycles) to millennia (changes in the N_r inventory of the deep sea). This makes the balance between the conversion of N_2 to biomass (N_2 fixation) and the production of N_2 (reduction of nitrate and nitrite by denitrification and anammox) particularly important processes in the N cycle that govern the marine inventory of N_r and sustain life in the oceans (Karl et al., 2002; Ward et al., 2007; Gruber, 2008; Ward, 2012).

2.1.1 The Marine Nitrogen Budget

Estimates of global sources and sinks of N_r vary widely (Table 2). Marine biological N_2 fixation accounts for ~50 per cent of N_2 fixation globally (Ward, 2012). Most marine N_2 fixation occurs in the euphotic zone of warm ($> 20^\circ C$), oligotrophic waters between $30^\circ N$ and $30^\circ S$ (Karl et al., 2002; Mahaffey et al., 2005; Stal, 2009; Sohm et al., 2011). Denitrification and anammox in benthic sediments and mid-water oxygen minimum

zones (OMZs) account for most losses of N from the marine N_r inventory (Ulloa et al., 2012; Ward, 2013).

Table 2. Summary of estimated sources and sinks ($Tg\ N\ yr^{-1}$) in the global marine nitrogen budget. (Data sources: Codispoti et al., 2001; Gruber and Sarmiento, 2002; Karl et al., 2002; Galloway et al., 2004; Mahaffey et al., 2005; Seitzinger et al., 2005; Boyer et al., 2006; Moore et al., 2006; Deutsch et al., 2007; Duce et al., 2008; DeVries et al., 2012; Grosskopf et al., 2012; Luo et al., 2012; Naqvi, 2012.)

Sources	N fixation	60-200
	Rivers	35-80
	Atmosphere	38-96
	TOTAL	133-376
Sinks	Denitrification & anammox	120-450
	Sedimentation	25
	N_2O loss	4-7
	TOTAL	149-482

Assuming a C:N:P ratio of 106:16:1 (the Redfield Ratio, Redfield et al., 1963), the quantity of N_r needed to support NPP globally is $\sim 8800\ Tg\ N\ yr^{-1}$. Given current estimates, inputs of N_r from river discharge and atmospheric deposition support 2-4 per cent of NPP annually, i.e., most NPP is supported by recycled nitrate from deep waters (cf. Okin et al., 2011).

Although the N_2O flux is a small term in the marine N budget (Table 2), it is a significant input to the global atmospheric N_2O pool. Given a total input of $17.7\ Tg\ N\ yr^{-1}$ (Freing et al., 2012), marine sources may account for 20-40 per cent of N_2O inputs to the atmosphere. As N_2O is 200-300 times more effective than CO_2 as a greenhouse gas, increases in N_2O from the ocean may contribute to both global warming and the destruction of stratospheric ozone. We note that although global estimates for anammox have yet to be made, this anaerobic process may be responsible for most N_2 production in some oxygen minimum zones (OMZs) (Strous et al., 2006; Hamersley et al., 2007; Lama et al., 2009; Koeve and Kähler, 2010; Ulloa et al., 2012).

The accounting in Table 2 suggests that total sinks may exceed total sources, but the difference is not significant. Many scientists believe that biological N_2 fixation is underestimated or the combined rates of denitrification and anammox are overestimated (Capone, 2008). On average, the Redfield Ratio approximates the C:N:P ratio of phytoplankton biomass, and the distribution of deviations from the Redfield Ratio (Martiny et al., 2013) suggests that: sources exceed sinks in the subtropical gyres; sources and sinks are roughly equal in upwelling systems (including their OMZs); and sources tend to be less than sinks at high latitudes. This pattern is consistent with the

known distribution of marine diazotrophs and the observation that most marine N_2 fixation occurs in warm, oligotrophic waters between 30° N and 30° S (Mahaffey et al., 2005; Stal, 2009; Sohm et al., 2011). However, given the wide and overlapping ranges of current estimates of N_r sources and sinks (Table 2), the extent to which the two are in steady state remains controversial.

Atmospheric deposition of iron to the oceans via airborne dust may ultimately control the rate of N_2 fixation in the global ocean and may account for the relatively high rate of N_2 fixation in the subtropical central gyres (Karl et al., 2002). Fe II is required for photosynthetic and respiratory electron transport, nitrate and nitrite reduction, and N_2 fixation. The large dust plume that extends from North Africa over the subtropical North Atlantic Ocean dominates the global dust field (Stier et al., 2005). Consequently, iron deposition is particularly high in this region (Mahowald et al., 2005) where it may increase phytoplankton NPP by stimulating N_2 fixation (Mahowald et al., 2005; Krishnamurthy et al., 2009; Okin et al., 2011). Model simulations indicate that the distribution and rate of N_2 fixation may also be influenced by non-Redfield uptake of N and P by non- N_2 fixing phytoplankton (Mills and Arrigo, 2010). In these simulations, N_2 fixation in ecosystems dominated by phytoplankton with N:P ratios < Redfield is lower than expected when estimated rates are based on Redfield stoichiometry. In contrast, in systems dominated by phytoplankton with N:P ratios > Redfield, N_2 fixation is higher than expected based on Redfield stoichiometry.

2.1.2 Time-Space Coupling of N_2 Fixation and Denitrification/Anammox

Early measurements of N_2 fixation and the geographic distribution of *in situ* deviations from the Redfield Ratio suggest that the dominant sites of N_2 fixation and denitrification are geographically separated and coupled on the time scales of ocean circulation (Capone et al., 2008 and references therein). In this scenario, the ocean oscillates between being a net source and a net sink of N_r on time scales of hundreds to thousands of years (Naqvi, 2012). However, there is also evidence that N_2 fixation is closely coupled with denitrification/anammox in upwelling-OMZ systems¹⁴, i.e., rates of N_2 fixation are high downstream from OMZs where denitrification/anammox is high (Deutsch et al., 2007). Their findings indicate that N_2 fixation and denitrification are in steady state on a global scale. Results from 3-D inverse modelling (DeVries et al., 2013) and observations that the marine N_r inventory has been relatively stable over the last several thousand years (Gruber, 2004; Altabet, 2007) support the hypothesis that rates of N_2 fixation and denitrification/anammox are closely coupled in time and space.

At the same time, global biogeochemical modelling suggests that the negative feedbacks stabilizing the N_r inventory cannot persist in an ocean where N_2 fixation and denitrification/anammox are closely coupled, i.e., spatial separation, rather than spatial proximity, promoted negative feedbacks that stabilized the marine N inventory and

¹⁴ Oxygen minimum zones (OMZs) are oxygen-deficient layers in the ocean's water column (Paulmier and Ruiz-Pino, 2009).

sustained a balanced N budget (Landolfi et al., 2013). If the coupling is close as argued above, the budget may not be in steady state. In this scenario, increases in vertical stratification of the upper ocean and expansion of OMZs associated with ocean warming (Keeling et al., 2010) could lead to closer spatial coupling of N₂ fixation and denitrification, a net loss of N from the marine N_r inventory, and declines in NPP and CO₂ sequestration during this century.

2.2 Phosphorus

Phosphorus (P) is an essential nutrient utilized by all organisms for energy transport and growth. The primary inputs of P occur via river discharge and atmospheric deposition (Table 3). Biologically active P (BAP) in natural waters usually occurs as phosphate (PO₄⁻³), which may be in dissolved inorganic forms (including orthophosphates and polyphosphates) or organic forms (organically bound phosphates). Natural inputs of BAP begin with chemical weathering of rocks followed by complex biogeochemical interactions, whose time scales are much longer than anthropogenic P inputs (Benitez-Nelson, 2000). Primary anthropogenic sources of BAP are industrial fertilizer, sewage and animal wastes.

The Marine Phosphorus Budget: River discharge of P into the coastal ocean accounts for most P input to the ocean (Table 3). However, most riverine P is sequestered in continental shelf sediments (Paytan and McLaughlin, 2007) so that only ~25 per cent of the riverine input enters the NPP-driven marine P cycle. Estimates of BAP reaching the open ocean from rivers range from a few tenths to perhaps 1 Tg P yr⁻¹ (Seitzinger et al., 2005; Meybeck, 1982; Sharpies et al., 2013). Mahowald et al., (2008) estimated that atmospheric inputs of BAP are ~0.1 Tg P yr⁻¹. Together these inputs would support ~0.1 per cent of NPP annually. Thus, like N_r, virtually all NPP is supported by BAP recycled within the ocean on a global scale.

Table 3. Summary of estimated sources and sinks (Tg P yr⁻¹) in the global marine phosphorus budget. (Data sources: Filippelli and Delaney, 1996; Howarth et al., 1996; Benitez-Nelson, 2000; Compton et al., 2000; Ruttenberg, 2004; Seitzinger et al., 2005; Paytan and McLaughlin, 2007; Mahowald et al., 2008; Harrison et al., 2010; Krishnamurthy et al., 2010.)

Sources	River discharge	10.79 – 31.00
	Atmospheric deposition	0.54 – 1.05
	TOTAL	11.33 – 32.05
Sinks	Open ocean sedimentation	1.30 – 10.57

The primary source of P in the atmosphere is mineral dust, accounting for approximately 80 per cent of atmospheric P. Other important sources include biogenic particles, biomass burning, fossil-fuel combustion, and biofuels. The P in mineral particles is not

very soluble, and most of it is found downwind of desert and arid regions. Only $\sim 0.1 \text{ Tg P yr}^{-1}$ of BAP appears to enter the oceans via atmospheric deposition (Mahowald et al., 2008). Although a small term in the P budget (Table 3), atmospheric deposition appears to be the main external source of BAP in the oligotrophic waters of the subtropical gyres and the Mediterranean Sea (Paytan and McLaughlin, 2007; Krishnamurthy et al., 2010).

Burial in continental shelf and deep-sea sediments is the primary sink, with most riverine input being removed from the marine P cycle by rapid sedimentation of particulate inorganic (non-reactive mineral lattices) P in coastal waters (Paytan and McLaughlin, 2007). Burial in deep-sea sediments occurs after transformations from dissolved to particulate forms in the water column. Of the riverine input, 60-85 per cent is buried in continental shelf sediments (Slomp, 2011). Assuming that inputs from river discharge and atmospheric deposition are, respectively, $\sim 15 \text{ Tg P yr}^{-1}$ and 1 Tg P yr^{-1} , and that 11 Tg P yr^{-1} and 5 Tg P yr^{-1} , respectively, are buried in shelf and open-ocean sediments, the P budget appears to be roughly balanced on the scale of P turnover times in the ocean (~ 1500 years, Paytan and McLaughlin, 2007).

3. Variability and Resilience of Marine Ecosystems

3.1 *Phytoplankton species diversity and resilience*

Biodiversity enhances resilience by increasing the range of possible responses to perturbations and the likelihood that species will functionally compensate for one another following disturbance (functional redundancy) (McCann, 2000; Walker et al., 2004; Hooper et al., 2005; Haddad et al., 2011; Appeltans et al., 2012; Cleland, 2011). Annually averaged phytoplankton species diversity of the upper ocean tends to be lowest in polar and subpolar waters, where fast-growing (opportunistic) species account for most NPP, and highest in tropical and subtropical waters, where small phytoplankton ($< 10 \mu\text{m}$) account for most NPP (Barton et al., 2010). Phytoplankton species diversity is also a unimodal function of phytoplankton NPP, with maximum diversity at intermediate levels of NPP and minimum diversity associated with blooms of diatoms, dinoflagellates, *Phaeocystis* sp., and coccolithophores (Irigoien et al., 2004). This suggests that pelagic marine food webs may be most resilient to climate and anthropogenic forcings at intermediate levels of annual phytoplankton NPP.

3.2 *Events, phenomena and processes of special interest*

Zooplankton grazing: Zooplankton populations play key roles in both microbial food webs¹⁵ supported by small phytoplankton ($< 10 \mu\text{m}$) and metazoan food webs¹⁶

¹⁵ The microbial food web (or microbial loop) consists of small phytoplankton (mean spherical diameter $< 10 \mu\text{m}$), heterotrophic bacteria, archaea and protozoa (flagellates and ciliates).

supported by large phytoplankton (> 20 µm). As such, they are critical links in nutrient cycles and the transfer of NPP to higher trophic levels of metazoan consumers. They fuel the biological pump and they limit excessive increases in NPP (e.g., Corten and Linley, 2003; Greene and Pershing, 2004; Steinberg et al., 2012). Microbial food webs dominate the biological cycles of C, N and P in the upper ocean and feed into metazoan food webs involving zooplankton, planktivorous fish, and their predators (Pomeroy et al., 2007; Moloney et al., 2011; Ward et al., 2012). Zooplankton in microbial food webs are typically dominated by heterotrophic and mixotrophic flagellates and ciliates. Metazoan food webs dominate the flow of energy and nutrients to harvestable fish stocks and to the deep sea (carbon sequestration). Zooplankton in metazoan food webs are typically dominated by crustaceans (e.g., copepods, krill and shrimp) and are part of relatively short, efficient, and nutritionally rich food webs supporting large numbers of planktivorous and piscivorous fish, seabirds, and marine mammals (Richardson, 2008; Barnes et al., 2010; Barnes et al., 2011).

Microbial food webs support less zooplankton biomass than do metazoan food webs, and a recent analysis suggests that zooplankton/phytoplankton ratios range from a low of ~0.1 in the oligotrophic subtropical gyres to a high of ~10 in upwelling systems and subpolar regions (Ward et al., 2012). Such a gradient is consistent with a shift from “bottom-up”, nutrient-limited NPP in the oligotrophic gyres, where microflagellates are the primary consumers of NPP (Calbet, 2008), to “top-down”, grazing control of NPP by zooplankton in more productive high-latitude and upwelling ecosystems, where planktonic crustaceans are the primary grazers of NPP (Ward et al., 2012). Thus, zooplankton grazing on phytoplankton is an important parameter of spatial patterns and temporal trends in NPP, particularly at high latitudes and in coastal upwelling systems (section 6.1.4).

3.2.1 NPP and Fisheries

Fish production depends to a large extent on NPP but the relationship between NPP and fish landings is complex. For instance, Large Marine Ecosystems (LMEs) of the coastal ocean account for ~30 per cent of marine phytoplankton NPP and ~80 per cent of marine fish landings globally (Sherman and Hempel, 2009). They are also “proving grounds” for the development of ecosystem-based approaches (EBAs) to fisheries management (McLeod and Leslie, 2009; Sherman and Hempel, 2009; Malone et al., 2014b). EBAs are guided in part by the recognition that the flow of energy and nutrients from NPP through marine food webs ultimately limits annual fish landings (Pauly and Christensen, 1995; Pikitch et al., 2004).

Both mean annual and maximum fish landings have been shown to be related to NPP on regional scales, with increases in potential landings at high latitudes (> 30 per cent) and decreases at low latitudes (up to 40 per cent) (Pauly and Christensen, 1995; Ware, 2000;

¹⁶ The so-called “classical” food web is dominated by larger phytoplankton, metazoan zooplankton and nekton.

Ware and Thomson, 2005; Frank et al., 2006; Chassot et al., 2007; Sherman and Hempel, 2009; Blanchard et al., 2012). However, the NPP required to support annual fish landings (PPR) varies among LMEs, e.g., fisheries relying on NPP at the Eastern Boundary Upwelling Systems require substantially higher levels of NPP than elsewhere (Chassot et al., 2010). Variations in PPR/NPP are related to a number of factors, including the relative importance of microbial and metazoan food webs and differences in the efficiencies of growth and transfer efficiencies among trophic levels. The level of exploitation (PPR/NPP) increased by over 10 per cent from 2000 to 2004, and the NPP appropriated by current global fisheries is 17-112 per cent higher than that appropriated by sustainable fisheries. Temporal and spatial variations in PPR/NPP call into question the usefulness of global NPP *per se* as a predictor of global fish landings (Friedland et al., 2012). Friedland et al. (2012) found that NPP is a poor predictor of fish landings across 52 LMEs, with most variability in fish landings across LMEs accounted for by chlorophyll-a concentration, the fraction of NPP exported to deep water, and the ratio of secondary production to NPP. Given these considerations and uncertainties concerning the effects of climate change on fluxes of nutrients to the euphotic zone, it is not surprising that there is considerable uncertainty associated with projections of how changes in NPP will affect fish landings over the next few decades.

3.2.2 NPP Fisheries and zooplankton

Zooplankton is a critical link between NPP and fish production (Cushing, 1990; Richardson, 2008). Efficient transfer of phytoplankton NPP to higher trophic levels ultimately depends on the relative importance of microbial and metazoan food webs and the coherence between the timing of phytoplankton blooms (initiation, amplitude, duration) and the reproductive cycles of zooplankton and planktivorous fish (Cushing, 1990; Platt et al., 2003; Koeller et al., 2009; Jansen et al., 2012). Energy transfer to higher trophic levels via microbial food webs is less efficient than for metazoan food webs (e.g., Barnes et al., 2010; Barnes et al., 2011; Suikkanen et al., 2013). Coherence in time and space is especially important in higher-latitude ecosystems (Sherman et al., 1984; Edwards and Richardson, 2004; Richardson, 2008; Ohashia et al., 2013), where seasonal variations in NPP are most pronounced and successful fish recruitment is most dependent on synchronized production across trophic levels (Cushing, 1990; Beaugrand et al., 2003). The phenological response to ocean warming differs among functional groups of plankton, resulting in predator-prey mismatches that may influence PPR/NPP in marine ecosystems. For example, phytoplankton blooms in the North Atlantic begin earlier south of 40°N (autumn – winter) and in spring north of 40°N (Siegel et al., 2002; Ueyama and Monger, 2005; Vargas et al., 2009). Likewise, a 44-year time series (1958-2002) revealed progressively earlier peaks in abundance of dinoflagellates (23 days), diatoms (22 days) and copepods (10 days) under stratified summer conditions in the North Sea (Edwards and Richardson, 2004). Such differential responses in phytoplankton and zooplankton phenology lead to mismatches between successive trophic levels and, therefore, a decline in PPR/NPP, i.e., a decrease in carrying capacity for harvestable fish stocks.

3.2.3 Coastal Eutrophication and “Dead Zones”

Excess phytoplankton NPP in coastal ecosystems can lead to accumulations of phytoplankton biomass and eutrophication. Anthropogenic N and P loading to estuarine and coastal marine ecosystems has more than doubled in the last 100 years (Seitzinger et al., 2010; Howarth et al., 2012),¹⁷ leading to a global spread of coastal eutrophication and associated increases in the number of oxygen-depleted “dead zones” (Duarte, 1995; Malone et al., 1999; Diaz and Rosenberg, 2008; Kemp et al., 2009), loss of sea grass beds (Dennison et al., 1993; Kemp et al., 2004; Schmidt et al., 2012), and increases in the occurrence of toxic phytoplankton blooms (see below). Current global trends in coastal eutrophication and the occurrence of “dead zones” and toxic algal events indicate that phytoplankton NPP is increasing in many coastal ecosystems, a trend that is also likely to exacerbate future impacts of over-fishing, sea-level rise, and coastal development on ecosystem services (Dayton et al., 2005; Koch et al., 2009; Waycott et al., 2009).

3.2.4 Oxygen minimum zones (OMZs)

OMZs, which occur at midwater depths (200-1000 m) in association with eastern boundary upwelling systems, are expanding globally as the solubility of dissolved O₂ decreases and vertical stratification increases due to upper ocean warming (Chan et al., 2008; Capotondi et al., 2012; Bijma et al., 2013). Currently, the total surface area of OMZs is estimated to be $\sim 30 \times 10^6$ km² (~ 8 per cent of the ocean’s surface area) with a volume of $\sim 10 \times 10^6$ km³ (~ 0.1 per cent of the ocean’s volume). It is expected that the spatial extent of OMZs will continue to increase (Oschlies et al., 2008), a trend that is likely to affect nutrient cycles and fisheries – especially when combined with the spread of coastal dead zones associated with coastal eutrophication.

3.2.5 Toxic Algal Blooms

Toxin-producing algae are a diverse group of phytoplankton species with only two characteristics in common: (1) they harm people and ecosystems; and (2) their initiation, development and dissipation are governed by species-specific population dynamics and oceanographic conditions (Cullen, 2008b). Negative impacts of algal toxins include illness and death in humans who consume contaminated fish and shellfish or are exposed to toxins via direct contact (swimming, inhaling noxious aerosols); mass mortalities of wild and farmed fish, marine mammals and birds; and declines in the capacity of ecosystems to support goods and services (Cullen, 2008b; Walsh et al., 2008). Impacts associated with toxic algal blooms are global and appear to be increasing in severity and extent in coastal ecosystems as a consequence of anthropogenic nutrients, introductions of non-native toxic species with ballast water from ships, and climate-driven increases in water temperature and vertical stratification of the upper ocean (Glibert et al., 2005; Glibert and Bouwman, 2012; Cullen, 2008b; Franks, 2008; Malone, 2008; Hallegraeff, 2010; Moore et al., 2008; Babin et al., 2008).

¹⁷ Primarily due to the rapid rise in fertilizer use in agriculture, production of manure from farm animals, domestic sewage, and atmospheric deposition associated with fossil-fuel combustion.

3.2.6 Nanoparticles

Nanoparticles have dimensions of 1-100 nm and are produced both naturally and anthropogenically. Of concern here are anthropogenic nanoparticles, such as titanium dioxide (TiO₂)¹⁸ and nanoplastics¹⁹. Nanoparticulate TiO₂ is highly photoactive and generates reactive oxygen species (ROS) when exposed to ultraviolet radiation (UV). Consequently, TiO₂ has been used for antibacterial applications, such as wastewater treatment. It also has the potential to affect NPP. For example, it has been found that ambient levels of UV from the sun can cause TiO₂ nanoparticles suspended in seawater to kill phytoplankton, perhaps through the generation of ROS (Miller et al., 2012). Recent work has also highlighted the potential environmental impacts of microplastics (cf. Depledge et al., 2013; Wright et al., 2013). Experimental evidence suggests that nanoplastics may reduce grazing pressure on phytoplankton and perturb nutrient cycles. For example, Wegner et al., (2012) found that mussels (*Mytilus edulis*) exposed to nanoplastics consume less phytoplankton and grow slower than mussels that have not been exposed. In addition, microplastics contain persistent organic pollutants, and both mathematical models and experimental data have demonstrated the transfer of pollutants from plastic to organisms (Teuten et al., 2009).

Understanding the ecotoxicology of anthropogenic nanoparticles in the marine environment is an important challenge, but as of this writing there is no clear consensus on environmental impacts *in situ* (cf. Handy et al., 2008). We know so little about the persistence and physical behaviour of anthropogenic nanoparticles *in situ* that extrapolating experimental results, such as those given above, to the natural marine environment would be premature. We urgently need to develop the means to reliably and routinely monitor nanoparticles of anthropogenic origin and their impacts on production and fate of phytoplankton biomass. A first step towards risk assessment would be to establish and set limits based on their intrinsic toxicity to phytoplankton and the consumers of plankton biomass. The provision of such information is part of the mission of Working Group 40 of the Joint Group of Experts on the Scientific Aspects of Marine Environmental Protection (GESAMP). WG 40 was established to assess the sources, fate and effects of micro-plastics in the marine environment globally.²⁰

3.2.7 Ultraviolet Radiation and the Ozone Layer

The Sun emits ultraviolet radiation (UV, 400-700 nanometers), with UV-B (280-315 nm) having a wide range of potentially harmful effects, including inhibition of primary

¹⁸ The world production of nanoparticulate TiO₂ is an order of magnitude greater than the next most widely produced nanomaterial, ZnO. About 70 per cent of all pigments use TiO₂, and it is a common ingredient in products such as sunscreen and food colouring. Titanium dioxide is therefore likely to enter estuaries and oceans, for example, from industrial discharge.

¹⁹ Plastic nanoparticles are released when plastic debris decomposes in seawater. Nanoparticles are also released from cosmetics and from clothes in the wash, and enter sewage systems where they are discharged into the sea.

²⁰ <http://www.gesamp.org/work-programme/workgroups/working-group-40>.

production by phytoplankton and cyanobacteria (Häder et al., 2007; Villar-Argaiz et al., 2009; Ha et al., 2012), changes in the structure and function of plankton communities (Ferreyra et al., 2006; Häder et al., 2007; Fricke et al., 2011; Guidi et al., 2011; Santos et al., 2012a; Ha et al., 2014), and alterations of the N cycle (Goes et al., 1995; Jiang and Qiu, 2011). The ozone layer in the Earth's stratosphere blocks most UV-B from reaching the ocean's surface. Consequently, stratospheric ozone depletion since the 1970s has been a concern, especially over the South Pole, where a so-called ozone hole has developed.²¹ However, the average size of the ozone hole declined by ~2 per cent between 2006 and 2013 and appears to have stabilized, with variation from year to year driven by changing meteorological conditions.²² It has even been predicted that there will be a gradual recovery of ozone concentrations by ~2050 (Taalas et al., 2000). Given these observations and variations in the depths to which UV-B penetrates in the ocean (~1-10 m), a consensus on the magnitude of the ozone-depletion effect on NPP and nutrient cycling has yet to be reached.

4. Socioeconomic importance

Marine NPP supports a broad range of ecosystem services valued by society and required for sustainable development (Millennium Ecosystem Assessment, 2005; Worm et al., 2006; Conservation International, 2008; Perrings et al., 2010; Schlitzer et al., 2012; Malone et al., 2014b; Chapter 3 in this assessment). These include:

- (1) food security through the production of harvestable fish, shellfish and macroalgae (Sherman and Hempel, 2009; Chassot et al., 2010; Barbier et al., 2011);
- (2) climate regulation through carbon sequestration (Twilley et al., 1992; Cebrian, 2002; Schlitzer et al., 2003; Duarte et al., 2005; Bouillon et al., 2008; Mitsch and Gosselink, 2008; Schneider et al., 2008; Subramaniam et al., 2008; Laffoley and Grimsditch, 2009; Nellemann et al., 2009; Chavez et al., 2011; Crooks et al., 2011; Henson et al., 2012);
- (3) maintenance of water quality through nutrient recycling and water filtration (Falkowski et al., 1998; Geider et al., 2001; Dayton et al., 2005; Howarth et al., 2011);
- (4) protection from coastal erosion and flooding through the growth of macrophyte habitats (Danielsen et al., 2005; UNEP-WCMC, 2006; Davidson and Malone,

²¹ Ozone can be destroyed by reactions with by-products of man-made chemicals, such as chlorine from chlorofluorocarbons (CFCs). Increases in the concentrations of these chemicals have led to ozone depletion.

²² <http://www.nasa.gov/content/>.

2006/2007; Braatz et al., 2007; Koch et al., 2009; Titus et al., 2009; Barbier et al., 2011), and

- (5) development of biofuels and discovery of pharmaceuticals through the maintenance of biodiversity (Chynoweth et al., 2001; Orhan et al., 2006; Han et al., 2006; Yusuf, 2007; Negreanu-Pîrjol et al., 2011; Vonthron-Sénécheau et al., 2011; Pereira et al., 2012; Sharma et al., 2012).

On a global scale, the value of these services in coastal marine and estuarine ecosystems has been estimated to be > 25 trillion United States dollars annually, making the coastal zone among the most economically valuable regions on Earth (Costanza et al., 1997; Martínez et al., 2007). The global loss of macrophyte ecosystems threatens the ocean's capacity to sequester carbon from the atmosphere (climate control), support biodiversity (Part V of this Assessment) and living marine resources (Part IV of this Assessment), maintain water quality, and protect against coastal erosion and flooding (Boesch and Turner, 1984; Dennison et al., 1993; Duarte, 1995; CENR, 2003; Scavia and Bricker, 2006; Davidson and Malone, 2006/07; Diaz and Rosenberg, 2008; MacKenzie and Dionne, 2008; Nellemann et al., 2009). Estimates of the value of these services by Koch et al., (2009) and Barbier et al., (2011) suggest that the socioeconomic impact of the degradation of marine macrophyte ecosystems is on the order of billions of US dollars per year.

5. Anthropogenic Impacts on Upper Ocean Plankton and Nutrient Cycles

5.1 Nitrogen loading

The rate of industrial Nitrogen gas (N₂) fixation increased rapidly during the 20th century and is now about equal to the rate of biological N₂ fixation, resulting in a two- to threefold increase in the global inventory of Reactive nitrogen (N_r) (Galloway et al., 2004; Howarth, 2008), a trend that has accelerated the global N cycle (Gruber and Galloway 2008). Today, anthropogenic N_r inputs to surface waters via atmospheric deposition and river discharge are now roughly equivalent to marine N₂ fixation (Table 2) and are expected to exceed marine N₂ fixation in the near future as a result of increases in emissions from combustion of fossil fuels and use of synthetic fertilizers. This trend is expected to continue (Duce et al., 2008; Seitzinger et al., 2010).

Atmospheric deposition of anthropogenic N_r increased by an order of magnitude during the 20th century to ~54 Tg N y⁻¹ (80 per cent of total deposition), an amount that could increase NPP by ~0.06 per cent. Estimates of anthropogenic emissions for 2030 indicate a 4-fold increase in total atmospheric N_r deposition to the ocean and an 11-fold increase in AAN deposition (Duce et al., 2008). However, Lamarque et al., (2013) suggest that oxidized N_r may decrease later this century because of increased control of the emission of oxidized N compounds. At the same time, the geographic distribution of atmospheric deposition has also changed (Suntharalingam et al., 2012). In the late 1800s,

atmospheric deposition over most of the ocean is estimated to have been $< 50 \text{ mg N m}^{-2} \text{ y}^{-1}$. By 2000, deposition over large ocean areas exceeded $200 \text{ mg N m}^{-2} \text{ y}^{-1}$ with intense deposition plumes ($> 700 \text{ mg N m}^{-2} \text{ y}^{-1}$) extending downwind from Asia, India, North and South America, Europe and West Africa. Predictions for 2030 indicate similar patterns, but with higher deposition rates extending farther offshore into the oligotrophic, subtropical central gyres. Likewise, marine N_2O production has increased compared to pre-industrial times downwind of continental population centres (in coastal and inland seas by 15-30 per cent, in oligotrophic regions of the North Atlantic and Pacific by 5-20 per cent, and in the northern Indian Ocean by up to 50 per cent). These regional patterns reflect a combination of high N_r deposition and enhanced N_2O production in suboxic zones.

The major pathway of anthropogenic N_r loading to the oceans is river runoff. Anthropogenic N_r input to the coastal ocean via river discharge more than doubled during the 20th century due to increases in fossil-fuel combustion, discharges of human and animal wastes, and the use of industrial fertilizers in coastal watersheds (Peierls et al., 1991; Galloway et al., 2004; Seitzinger et al., 2010). Riverine input of N_r to the coastal ocean is correlated with human population density in and net anthropogenic inputs (NANI)²³ to coastal watersheds (Howarth et al., 2012). NPP in coastal marine and estuarine ecosystems increases with increasing riverine inputs of N_r (Nixon, 1992). Given predicted increases in population density in coastal watersheds and climate-driven changes in the hydrological cycle, global nutrient-export models predict that riverine inputs of N_r to coastal waters will double again by 2050 (Seitzinger et al., 2010). In this context, it is noteworthy that anthropogenic perturbations of the N-cycle caused by NANI already exceed the estimated “planetary boundary” ($35 \times 10^3 \text{ kg yr}^{-1}$) within which sustainable development is possible (Rockstram et al., 2009).

Ocean warming and associated increases in vertical stratification are likely to exacerbate the effects of increases in NANI on phytoplankton NPP in coastal waters (Rabalais et al., 2009). As a consequence, excess NPP and the global extent of coastal eutrophication are likely to continue increasing, especially in coastal waters near large watersheds, population centres and areas of industrial agriculture (Kroeze and Seitzinger, 1998; Dayton et al., 2005; Seitzinger et al., 2005; UNESCO, 2008; Kemp et al., 2009; Rabalais et al., 2009; Sherman and Hempel, 2009).

5.2 *Ocean warming*

5.2.1 *Global impacts on NPP*

Henson et al., (2013) used the results of six global biogeochemical models to project the effects of upper ocean warming on the amplitude and timing of seasonal peaks in

²³ Net anthropogenic nitrogen input (NANI) is the sum of synthetic N fertilizer used, N fixation associated with agricultural crops, atmospheric deposition of oxidized N, and the net movement of N into or out of the region in human food and animal feed.

phytoplankton NPP. Amplitude decreased by 1-2 per cent over most of the ocean, except in the Arctic, where an increase of 1 per cent by 2100 is projected. These results are supported by the response of phytoplankton and zooplankton to global climate-change projections carried out with the IPSL Earth System Model (Chust et al., 2014). Projected upper ocean warming by the turn of the century led to reductions in phytoplankton and zooplankton biomass of 6 per cent and 11 per cent, respectively. Simulations suggest such declines are the predominant response over nearly 50 per cent of the ocean and prevail in the tropical and subtropical oceans while increasing trends prevail in the Arctic and Antarctic oceans. These results suggest that the capacity of the oceans to regulate climate through the biological carbon pump may decrease over the course of this century. The model runs also indicate that, on average, a 30-40 year time series of observations will be needed to validate model results.

Regardless of the direction of global trends in NPP, climate change may be causing shifts in phytoplankton community size spectra toward smaller cells which, if confirmed, will have profound effects on the fate of NPP and nutrient cycling during this century (Polovina and Woodworth, 2012). The size spectrum of phytoplankton communities in the upper ocean's euphotic zone largely determines the trophic organization of pelagic ecosystems and, therefore, the efficiency with which NPP is channelled to higher trophic levels, is exported to the deep ocean, or is metabolized in the upper ocean (Malone, 1980; Azam et al., 1983; Cushing, 1990; Kiørboe, 1993; Legendre and Rassoulzadegan, 1996; Shurin et al., 2006; Pomeroy et al., 2007; Marañón, 2009; Barnes et al., 2010; Finkel et al., 2010; Suikkanen et al., 2013; and section 6.3.2).

In today's ocean, the proportion of NPP accounted for by small phytoplankton (cells with an equivalent spherical diameter $< 10 \mu\text{m}$) generally increases with increasing water temperature in the ocean (Atkinson et al., 2003; Daufresne et al., 2009; Marañón, 2009; Huete-Ortega et al., 2010; Morán et al., 2010; Hilligsøe et al., 2011) and with increasing vertical stratification of the euphotic zone (Margalef, 1978; Malone, 1980; Kiørboe, 1993). Small cells also have a competitive advantage over large cells in nutrient-poor environments (Malone, 1980a; Chisholm, 1992; Kiørboe, 1993; Raven, 1998; Marañón, 2009). Thus, as the upper ocean warms and becomes more stratified, it is likely that the small phytoplankton species will account for an increasingly large fraction of NPP (Morán et al., 2010) resulting in increases in energy flow through microbial food webs and decreases in fish stocks and organic carbon export to the deep sea (see section 6.1.1 and references therein).

This trend may be exacerbated by increases in temperature that are likely to stimulate plankton metabolism, enhancing both NPP and microbial respiration. Recent studies (Montoya and Raffaelli, 2010; Sarmiento et al., 2010; Behrenfeld, 2011; Taucher and Oschlies, 2011; Taucher et al., 2012) suggest that predicted climate-driven increases in the temperature of the upper ocean will stimulate the NPP of smaller picophytoplankton cells (equivalent spherical diameter $< 2\mu\text{m}$), despite predicted decreases in nutrient inputs to the euphotic zone from the deep sea in permanently stratified regions of the ocean (e.g., the oligotrophic, subtropical central gyres).

However, if this does occur, it will not result in an increase in fishery production or in the ocean's uptake of atmospheric CO₂, because increases in picophytoplankton NPP will be accompanied by equivalent increases in the respiratory release of CO₂ by bacterioplankton and other heterotrophic microbial consumers in the upper ocean (Sarmiento et al., 2010; Behrenfeld, 2011).

5.2.2 Regional impacts on NPP

Regional trends in phytoplankton NPP are less controversial. The area of low NPP in the subtropical central gyres increased by 1-4 per cent yr⁻¹ from 1998 through 2006 (Polovina et al., 2008; Vantrepotte and Mélin, 2009), a trend that is likely to continue through this century (Polovina et al., 2011). Decreasing NPP has been attributed to climate-driven (ocean warming) increases in vertical stratification and associated decreases in nutrient fluxes from deep water to the euphotic zone in the permanently stratified subtropical gyres (Rost et al., 2008; Jang et al., 2011; Polovina et al., 2011; Capotondi et al., 2012; Moore et al., 2013). In the North Atlantic, upper ocean warming and increases in stratification have been accompanied by decreasing NPP in waters south of ~50°N, whereas warming and increases in stratification to the north have been accompanied by increasing NPP (Richardson and Shoeman, 2004; Bode et al., 2011). These divergent responses to stratification reflect increases in the availability of sunlight in nutrient-rich, well-mixed subpolar waters and increases in nutrient limitation in nutrient-poor, permanently stratified²⁴ subtropical waters (Richardson and Shoeman, 2004; Steinacher et al., 2010; Bode et al., 2011; Capotondi et al., 2012).

Polar ecosystems are particularly sensitive to climate change (Smith et al., 2001; Anisimov et al., 2007; Bode et al., 2011; Doney et al., 2012; Engel et al., 2013), and the impacts of shrinking ice cover on NPP are expected to be especially significant in the Arctic Ocean (Wang and Overland, 2009). Loss of Arctic sea ice has accelerated in recent years (with a record low in 2012),²⁵ a trend that is correlated with an increase in annual NPP by an average of 27.5 Tg C yr⁻¹ since 2003, with an overall increase of 20 per cent from 1998 to 2010 (Arrigo et al., 2008; Arrigo and van Dijken, 2011; Brown and Arrigo, 2012). Of this increase, 30 per cent has been attributed to a decrease in the spatial extent of summer ice and 70 per cent to a longer growing season (the spring bloom is occurring earlier). The change in NPP is not spatially homogeneous. Positive trends are most pronounced in seasonally ice-free regions, including the eastern Barents shelf, Siberian shelves (Kara and east Siberian seas), western Mackenzie shelf, and the Bering Strait. NPP is expected to continue increasing during this century due to continued sea-ice retreat and the associated increase in available sunlight. However, this trend may be short-lived if nitrate supplies from deep water are insufficient (Tremblay and Gagnon, 2009). Neglecting the latter, Arrigo and van Dijken (2011) project a > 60 per cent increase in NPP for a summer ice-free Arctic using a linear extrapolation of the historical

²⁴ The permanent or main thermocline extends from ~50° N to ~50° S. North Atlantic Deep Water and Antarctic Bottom Water formation take place at higher latitudes.

²⁵ <http://nsidc.org/arcticseaicenews//>.

trend. Should these trends continue, additional loss of ice during Arctic spring could boost NPP more than three-fold above 1998-2002 levels and alter marine ecosystem structure and the degree of pelagic-benthic coupling. However, predictions of future trends in Arctic NPP are uncertain, given the possibility of nitrate limitation (Vancoppenolle et al., 2013). Reducing uncertainty for both nitrate fields and rates of biogeochemical processes in the sea-ice zone should improve the skill of projected changes in NPP needed to anticipate the impact of climate change on Arctic food webs and the carbon cycle.

The coastal marine ecosystem of the West Antarctic Peninsula supports massive spring-summer phytoplankton blooms upon which the production of Antarctic krill depends. NPP associated with these blooms is correlated with the spatial and temporal extent of ice cover during the previous winter. Air temperatures over the West Antarctic Peninsula have warmed by 7°C since the 1970s, resulting in a 40 per cent decline in winter sea-ice cover and a decrease in phytoplankton NPP (Flores et al., 2012; Ducklow et al., 2013; Henley, 2013). Continued declines in the extent of winter sea-ice cover is likely to drive decadal-scale reductions in NPP and the production of krill, reducing the food supply for their predators (marine mammals, seabirds and people).

5.2.3 *Distribution and abundance of toxic phytoplankton species*

The socioeconomic impacts of toxic dinoflagellate species are increasing globally (Van Dolah, 2000; Glibert et al., 2005; Hoagland and Scatista, 2006; Babin et al., 2008; UNESCO, 2012), and their distribution and abundance are sensitive indicators of the impacts of anthropogenic nutrient inputs and climate-driven increases in water temperature and vertical stratification on ecosystem services (see section 6.3.2).

Alexandrium tamarense represents a group of species that cause paralytic shellfish poisoning (PSP) (*Alexandrium catenella*, *A. fundyense*, *Pyrodinium bahamense* and *Gymnodinium catenatum*) globally (Boesch et al., 1997). Since the 1970s, PSP episodes have spread from coastal waters of Europe, North America and Japan to coastal waters of South America, South Africa, Australia, the Pacific Islands, India, all of Asia and the Mediterranean (Lilly et al., 2007). Climate-driven shifts in the geographic ranges of *Ceratium furca* and *Dinophysis spp.* in the NE Atlantic have also occurred (Edwards et al., 2006), and the abundance of dinoflagellates in the North Sea have been positively correlated with the North Atlantic Oscillation (NAO) and sea surface temperature (Edwards et al., 2001).

5.2.4 *Distribution and abundance of indicator zooplankton species*

The distribution and abundance of calanoid copepods are also sensitive indicators of climate-driven increases in upper ocean temperature and basin-scale oscillations (Hays et al., 2005; Burkill and Reid, 2010; Edwards et al., 2010) including poleward shifts in species distributions (Beaugrand et al., 2002; Beaugrand et al., 2003; Cheung et al., 2010; Chust et al., 2014), decreases in size, and higher growth rates (e.g., Beaugrand et al., 2002; Richardson, 2008; Mackas and Beaugrand, 2010). There have also been phenological changes, with the seasonal peak in abundance advancing to earlier in the

year for some species and being delayed for others (Edwards and Richardson, 2004, section 6.3.2). In the North Pacific, there is a strong correlation between sea-surface temperature in the spring and the latitude at which subtropical species reach their seasonal peak in abundance.²⁶ Water temperature also influences the annual cycle of *Neocalanus plumchrus* biomass in the Northeast Pacific, where decadal-scale variations include a shift to an earlier occurrence of the seasonal biomass peak, as well as a decrease in the duration of the bloom under warm ocean conditions (Mackas et al., 2007; Batten and Mackas, 2009).

The frequency and magnitude of gelatinous zooplankton blooms may be important indicators of the status and performance of marine ecosystems (Hay, 2006; Graham et al., 2014). Both predators (medusa and ctenophores) and herbivores (tunicates) can affect the fate of NPP (Pitt et al., 2009; Lebrato and Jones, 2011). Predators disrupt metazoan food webs by consuming copepods and small fish (Richardson et al., 2009). Tunicates reduce the transfer of NPP to upper trophic levels and to the deep sea as their gelatinous remains are degraded via microbial food webs (Lebrato and Jones, 2011).

Although, there is no evidence for an increase in the frequency and magnitude of gelatinous zooplankton on a global scale (Condon et al., 2012), decadal scale increases have been reported in several coastal marine ecosystems (Brodeur et al., 2002; Kideys, 2002; Lynam et al., 2006; Uye, 2008; Licandro et al., 2010). A rigorous analysis of multi-decadal (using a 1950 baseline) abundance data for 45 Large Marine Ecosystems, Brotz et al., 2012 found that 28 (62 per cent) exhibited increasing trends while 3 (7 per cent) exhibited decreasing trends. Thus, while increases of jellyfish populations may not be globally universal, they are both numerous and widespread. The most likely causes of these trends include ocean warming, overfishing, coastal eutrophication, habitat modification, aquaculture, and introductions of non-indigenous gelatinous species (Brotz et al., 2012; Purcell, 2012). While direct evidence is lacking for most of these pressures, jellyfish tend to be most abundant in warm waters with low forage fish populations, and it is likely that ocean warming will provide a rising baseline of abundance leading to increases in the magnitude of jellyfish blooms and associated impacts on ecosystem services (Graham et al., 2014).

5.3 *Ocean acidification*

The oceans are becoming more acidic due to increases in uptake of atmospheric CO₂ (Calderia and Wickett, 2003; Calderia and Wickett, 2005; Doney et al., 2009; Beardall et al., 2009), and most of the upper ocean is projected to be undersaturated with respect to aragonite within 4-7 decades (Orr et al., 2005) with undersaturation expected to occur earliest at high latitudes (> 40°) and in upwelling systems where the aragonite saturation horizon is expected to shoal most rapidly (Feely et al., 2009, Gruber et al., 2009). These chemical changes in turn affect marine plankton via several mechanisms

²⁶ http://www.pices.int/publications/pices_press/volume16/v16_n2/pp_19-21_CPR_f.pdf.

including the following: (1) decreases in the degree of aragonite saturation makes it harder for calcifying organisms (e.g., coccolithophores, foraminifera, and pteropods) to precipitate their mineral structures; (2) decreases in pH alters the bioavailability of essential algal nutrients such as iron and zinc; and (3) increases in CO₂ decrease the energy requirements for photosynthetic organisms to synthesize biomass. Such biological effects are likely to perturb marine biogeochemical cycles including carbon export to the deep sea via the biological pump which may have a positive feedback on the buildup of CO₂ in the upper ocean and atmosphere. However, assessments of the impacts of ocean acidification on NPP and nutrient cycling remain controversial and are a subject of much research (cf., Delille et al., 2005; Doney et al., 2009; Shi et al., 2009; Shi et al., 2010; Shi et al., 2012; Moy et al., 2009; Kristy et al., 2010). For example, increases in CO₂ may stimulate N₂ and carbon fixation by colonial cyanobacterial diazotrophs (Barcelos e Ramos et al., 2007). In addition, as the upper ocean warms, the geographic range of diazotrophs will expand. These effects may combine to enhance N₂ fixation by as much as 35-65 per cent by the end of this century (Hutchins et al., 2009). It is noteworthy interesting that projected increases in N₂ fixation are about the same magnitude as increases in denitrification projected by Oschlies et al., (2008). Although both of these estimates have large uncertainties, if input and output fluxes accelerate at about the same rate, the ocean's global inventory of N_r would not change, whereas NPP could increase (Sarmiento et al., 2010; Behrenfeld, 2011).

In regard to macrophytes, photosynthetic rates of calcifying macroalgae do not appear to be stimulated by elevated CO₂ conditions, i.e., the majority of studies to date have shown a decrease or no change in photosynthetic rates under elevated CO₂ conditions (Hofmann and Bischof, 2014). On the other hand, there is clear evidence that ocean acidification (higher pCO₂) stimulates seagrass NPP resulting in increases in above- and below-ground biomass suggesting that the capacity of seagrasses to sequester carbon may be significantly increased (Garrard and Beaumont, 2014).

5.4 *Sea-level rise, coastal development and macrophyte NPP*

Sea levels have increased globally since the 1970s, mainly as a result of global mean sea-level rise due in part to anthropogenic warming causing ocean thermal expansion and glacier melting (Chapter 4 of this Assessment). Sea-level rise will not be uniform globally. Regional differences in sea-level trends will be related to changes in prevailing winds, ocean circulation, gravitational pull of polar ice sheets, and subsidence, so that sea-level rise will exceed the global mean in some regions and will actually fall in others.²⁷

To date, the global decline in macrophyte habitats has been primarily due to coastal development, artificially hardened shorelines, aquaculture operations, dredging and eutrophication. This will change with sea-level rise (Short and Neckles, 1999; Nicholls

²⁷ <http://tidesandcurrents.noaa.gov/sltrends/>.

and Cazenave, 2010). Macrophyte habitats are projected to be negatively affected by sea-level rise and subsidence, especially where distributions are constrained on their landward side by geomorphology and human activities along the shoreline (Pernetta, 1993; Short and Neckles, 1999; Orth et al., 2006; Alongi, 2008; Gilman et al., 2008; Silliman et al., 2009; Waycott et al., 2009; Donato et al., 2011). Together, sea-level rise, subsidence, coastal development and aquaculture operations are destroying mangrove forests, tidal marshes and seagrass beds at an alarming rate. The combination of sea-level rise and the loss of these coastal habitats will decrease the capacity of coastal ecosystems to provide services, including climate regulation (carbon sequestration), protection against coastal flooding and erosion, and the capacity to support biodiversity and living marine resources.

5.5 *Regions of special interest*

5.5.1 *Coastal river plumes*

Increases in land-based anthropogenic inputs of N and P to coastal waters is driving increases in annual phytoplankton NPP in estuaries and coastal marine ecosystems near population centres and areas of industrial agriculture in large river basins (sections 6.2.1 and 6.2.2). This may lead to further increases in the spatial extent and/or number of coastal ecosystems experiencing eutrophication and oxygen-depleted dead zones associated with the coastal plumes of major river-coastal systems, including the Yangtze (E. China Sea), Mekong (S. China Sea), Niger (Gulf of Guinea), Nile (Mediterranean Sea), Parana (Atlantic Ocean), Mississippi (Gulf of Mexico), and Rhine (North Sea) (UNESCO, 2012).

5.5.2 *Polar waters and subtropical gyres*

Ocean warming appears to be driving opposing trends in phytoplankton NPP in polar waters (interannual increases in NPP) and subtropical gyres (interannual decreases in NPP) and a global expansion of oxygen minimum zones associated with upwelling systems. Regions of special interest include the Arctic Ocean, coastal waters of the western Antarctic Peninsula, permanently stratified subtropical gyres of the North Pacific and North Atlantic, and major coastal upwelling centers (Cariaco Basin and California, Humboldt, Canary, Benguela and Somali Currents).

5.5.3 *Subpolar waters*

Early expressions of the impacts of ocean acidification on upper ocean plankton are most likely to occur at high latitudes. Pteropods and foraminifera (dominated by *Globigerina bulloides*) are most abundant at high latitudes (> 40°N) in surface waters of the North Atlantic (Barnard et al., 2004; Fraile et al., 2008; Bednaršek et al., 2012), whereas the coccolithophore *E. huxleyi* is most abundant in the

“Great Southern Coccolithophore Belt” of the Southern Ocean²⁸ and at high latitudes in the NE Atlantic (Barnard et al., 2004; Balch et al., 2011; Sadeghi et al., 2012). If the abundance of these functional groups declines in these regions, likely impacts will be to reduce the capacity of the oceans to take up CO₂, export carbon to the deep sea, and support fisheries (Cooley et al., 2009).

6. Information needs

As shown above, anthropogenic nutrient-loading of coastal waters and climate-change pressures on marine ecosystems (ocean warming and acidification, sea-level rise) are driving changes in NPP and nutrient cycles that are affecting the provision of ecosystem services and, therefore, sustainable development. However, although changes in macrophyte NPP and their impacts are relatively well documented (and must continue to be), a consensus on the magnitude of changes and even the direction of change in phytoplankton NPP and upper ocean nutrient cycles has yet to be reached.

Documenting spatial patterns and temporal trends in NPP and nutrient cycles (and their causes and socioeconomic consequences) will rely heavily on the accuracy and frequency with which changes in NPP and nutrient cycling can be detected over a broad range of scales (cf. deYoung et al., 2004; UNESCO, 2012; Mathis and Feeley, 2013). Given the importance of marine NPP and the species diversity of primary producers to sustaining ecosystem services, rapid detection of changes in time-space patterns of marine NPP and in the diversity of primary producers that contribute to NPP is an important dimension of the Regular Process²⁹ for global reporting and assessment of the state of the marine environment, including socioeconomic aspects.

Data requirements for the Regular Process have been used to help guide the development of the Global Ocean Observing System and an implementation strategy for its coastal module (UNESCO, 2012; Malone et al., 2014a; Malone et al., 2014b). The essential variables required to compute key indicators of ecosystem health include species richness, chlorophyll-*a*, dissolved N_r, and dissolved BAP (UNESCO, 2012). Routine and sustained measurements of these variables over a range of temporal and spatial scales are required for rapid and timely detection of changes in NPP and nutrient cycles and the impacts of these changes on ecosystem services on regional (e.g., Large Marine Ecosystems) to global scales. Although satellite imagery, limited *in situ* measurements and numerical models are making it possible to detect interannual and decadal changes in NPP on these scales, the same cannot be said for observations of species richness and nutrient distributions (UNESCO, 2012).

²⁸ The belt is centered around the sub-Antarctic front and has a spatial extent of 88 x 106 km² (~25 per cent of the global ocean).

²⁹ http://www.un.org/Depts/los/global_reporting/global_reporting.htm.

6.1 Net primary production

Sustained observations of chlorophyll, irradiance and temperature fields are required for model-based estimates of phytoplankton NPP (see section 6.1.2). An integrated approach using long term data streams from both remote sensing and frequent *in situ* observations is needed to capture the dynamics of marine phytoplankton NPP and to detect decadal trends. Remote sensing provides a cost-effective means to observe physical and biological variables synoptically in time and space with sufficient resolution to elucidate linkages between climate-driven changes in the NPP of ecosystems and the dynamic relationship between phytoplankton NPP and the provision of ecosystem services (Platt et al., 2008; Forget et al., 2009). For details on requirements, advantages and limitations of satellite-based remote sensing of ocean colour, see IOCCG (1998), Sathyendranath (2000), and UNESCO (2006, 2012).

Two related activities, both contributions to the Global Ocean Observing System, provide the core of an integrated observing system needed to provide data required to assess the state of the marine environment in terms of both time-space variations in phytoplankton NPP and the impacts of these variations on ecosystem services: the Chlorophyll Global Integrated Network (ChloroGIN)³⁰ (Sathyendranath et al., 2010) and Societal Applications in Fisheries and Aquaculture using Remotely-Sensed Imagery (SAFARI) (Forget et al., 2010). FARO (Fisheries Applications of Remotely Sensed Ocean Colour) has recently been initiated to coordinate the development of ChloroGIN and SAFARI for the provision of ocean-colour data and data products for use in fisheries research and ecosystem-based management of living marine resources.³¹ Likewise, the GEO Biodiversity Observation Network, the Global Biodiversity Information Facility (GBIF), and the Ocean Biogeographical Information System (UNESCO, 2012) provide data and information on the species richness of marine primary producers.

6.2 Nitrogen and phosphorus cycles

The N cycle is more dynamic³² and less well understood than previously thought (Codispoti et al., 2001; Capone and Knapp, 2007; Zehr and Kudela, 2011; Landolfi et al., 2013; Voss et al., 2013). Major impediments to detecting and understanding decadal changes in the marine N cycle are: current uncertainties about the rates (undersampling); distribution and coupling of sources and sinks; sensitivity of N₂ fixation, denitrification, and anammox to anthropogenic inputs of N_r; and changes in the marine environment associated with climate change (warming and increases in stratification of the upper ocean, ocean acidification, oxygen depletion, and sea-level rise).

³⁰ <http://www.chlorogin.org/>.

³¹ <http://www.faro-project.org/index.html>.

³² Estimates of turnover times of N_r have decreased from 10,000 years to 1,500 years (Codispoti et al., 2001).

Quantifying inputs of N and P to coastal ecosystems and the open ocean requires a network of coordinated and sustained observations on local to global scales. For atmospheric deposition, monitoring should focus on regions that have intense deposition plumes downwind of major population centres in West Africa, East Asia, Europe, India, North and South America (section 6.2.1 and Schulz et al., 2012). This is a major goal of the SOLAS programme³³. Shipboard time-series observations of biogeochemical variables that are being established globally³⁴ should provide deposition data for these plumes. For riverine inputs, rivers that are part of the Global Terrestrial Network for River Discharge (GTN-R)³⁵ and that represent a broad range of volume discharges and catchment-basin population densities are high priorities for monitoring land-based inputs and associated land-cover/land-use practices in their watersheds (UNESCO, 2012).

All global ocean biogeochemistry models require oceanographic data on physical and chemical variables, including temperature, salinity, mixed-layer depth, and the concentration of macro-nutrients (N, P, Si) (Le Quéré et al., 2010). Over the last decade, autonomous technologies for measuring essential physical variables (including temperature, salinity and mixed-layer depth) have revolutionized our ability to observe the sea surface and the ocean's interior. By integrating data from both remote sensing (satellite-based sensors and land-based HF radar) and *in situ* measurements (from ships of opportunity, research vessels and automated moorings, profiling floats, gliders, surface drifters and large pelagic predators), observations of atmospheric and upper ocean geophysics are now made continuously in four dimensions; data are transmitted to data assembly centers in near-real time via satellites, fiber-optic cables, and the internet; and predictions (nowcasts and forecasts) of atmospheric and upper ocean "weather" are made routinely using data assimilation techniques and coupled atmospheric-hydrodynamic models (Hall et al., 2010).

Over the last decade, autonomous technologies have revolutionized our ability to measure nitrate, nitrite, ammonium and reactive phosphate *in situ* (Johnson and Coletti, 2002; ACT, 2003; Sakamoto et al., 2004; Adornato et al., 2010). Efforts are also underway to expand sampling programmes such Repeat Hydrography (Hood 2009), Argo (Rudnick et al., 2004; Testor et al., 2010), and OceanSites³⁶ to incorporate *in situ* nutrient sensors.

6.3 Plankton species diversity

Sustaining marine species richness³⁷ is the single most important indicator of the capacity of ecosystems to support services valued by society (Worm et al., 2006). A biodiversity observation network (GEO BON)³⁸ has been established to document changes in species biodiversity, and the Ocean Biogeographic Information System (OBIS)³⁹ documents the species diversity, distribution and abundance of life in the oceans. Both are contributions to GEOSS.⁴⁰ A set of sentinel sites should be targeted for sustained observations of species richness including Large Marine Ecosystems and the emerging network of marine protected areas that is nested within them (Malone et al., 2014a). As a group, these sites represent a broad range of species diversity, climate-related changes in the marine environment, and anthropogenic nutrient inputs. Here we underscore the importance of rapid detection of changes in plankton diversity and early warnings of impacts on marine ecosystem services.

Chapter 7. Calcium Carbonate Production and Contribution to Coastal Sediments

Contributors: Colin D. Woodroffe, Frank R. Hall, John W. Farrell and Peter T. Harris (Lead member)

1. Calcium carbonate production in coastal environments

Biological production of calcium carbonate in the oceans is an important process. Although carbonate is produced in the open ocean (pelagic, see Chapter 5), this chapter concentrates on production in coastal waters (neritic) because this contributes sediment to the coast through skeletal breakdown producing sand and gravel deposits on beaches, across continental shelves, and within reefs. Marine organisms with hard body parts precipitate calcium carbonate as the minerals calcite or aragonite. Corals, molluscs, foraminifera, bryozoans, red algae (for example the algal rims that characterize reef crests on Indo-Pacific reefs) are particularly productive, as well as some species of green algae (especially *Halimeda*). Upon death, these calcareous organisms break down by physical, chemical, and biological erosion processes through a series of discrete sediment sizes (Perry et al., 2011). Neritic carbonate production has been estimated to be approximately 2.5 Gt year⁻¹ (Milliman and Droxler, 1995; Heap et al., 2009). The greatest contributors are coral reefs that form complex structures covering a total area of more than 250,000 km² (Spalding and Grenfell, 1997; Vecsei, 2004), but other organisms, such as oysters, may also form smaller reef structures.

Global climate change will affect carbonate production and breakdown in the ocean, which will have implications for coastal sediment budgets. Rising sea level will displace many beaches landwards (Nicholls et al., 2007). Low-lying reef islands called sand cays, formed over the past few millennia on the rim of atolls, are particularly vulnerable, together with the communities that live on them. Rising sea level can also result in further reef growth and sediment production where there are healthy coral reefs (Buddemeier and Hopley, 1988). In areas where corals have already been killed or damaged by human activities, however, reefs may not be able to keep pace with the rising sea level in which case wave energy will be able to propagate more freely across the reef crest thereby exposing shorelines to higher levels of wave energy (Storlazzi et al., 2011; see also Chapter 43).

Reefs have experienced episodes of coral bleaching and mortality in recent years caused by unusually warm waters. Increased carbon dioxide concentrations are also causing ocean waters to become more acidic, which may affect the biological production and supply of carbonate sand. Bleaching and acidification can reduce coral growth and limit the ability of reef-building corals and other organisms to produce calcium carbonate (Kroeker et al., 2010). In some cases, ocean acidification may lead to a reduced supply of carbonate sand to beaches, increasing the potential for erosion (Hamilton, 2014).

1.1 *Global distribution of carbonate beaches*

Beaches are accumulations of sediment on the shoreline. Carbonate organisms, particularly shells that lived in the sand, together with dead shells reworked from shallow marine or adjacent rocky shores, can contribute to beach sediments. Dissolution and re-precipitation of carbonate can cement sediments forming beachrock, or shelly deposits called coquina. On many arid coasts and islands lacking river input of sediment to the coast, biological production of carbonate is the dominant source of sand and gravel. Over geological time (thousands of years) this biological source of carbonate sediment may have formed beaches that are composed entirely, or nearly entirely, of calcium carbonate. Where large rivers discharge sediment to the coast, or along coasts covered in deposits of glacial till deposited during the last ice age, beaches are dominated by sediment derived from terrigenous (derived from continental rocks) sources. Carbonate sediments comprise a smaller proportion of these beach sediments (Pilkey et al., 2011).

Sand blown inland from carbonate beaches forms dunes and these may be extensive and can become lithified into substantial deposits of carbonate eolianite (wind-blown) deposits. Significant deposits of eolianite are found in the Mediterranean, Africa, Australia, and some parts of the Caribbean (for example most of the islands of the Bahamas). The occurrence of carbonate eolianites is therefore a useful proxy for mapping the occurrence of carbonate beaches (Brooke, 2001).

Carbonate beaches may be composed of shells produced by tropical to sub-polar species, so their occurrence is not limited by latitude, although carbonate production on polar shelves has received little attention (Frank et al., 2014). For example, Ritchie and Mather (1984) reported that over 50 beaches in Scotland are composed almost entirely of shelly carbonate sand. There is an increase in carbonate content towards the south along the east coast of Florida (Houston and Dean, 2014). Carbonate beaches, comprising 60-80 per cent carbonate on average, extend for over 6000 km along the temperate southern coast of Australia, derived from organisms that lived in adjacent shallow-marine environments (James et al., 1999; Short, 2006). Calcareous biota have also contributed along much of the western coast of Australia; carbonate contents average 50-70 per cent, backed by substantial eolianite cliffs composed of similar sediments along this arid coast (Short, 2010). Similar non-tropical carbonate production occurs off the northern coast of New Zealand (Nelson, 1988) and eastern Brazil (Carannante et al., 1988), as well as around the Mediterranean Sea, Gulf of California, North-West Europe, Canada, Japan and around the northern South China Sea (James and Bone, 2011).

On large carbonate banks, biogenic carbonate is supplemented by precipitation of inorganic carbonate, including pellets and grapestone deposits (Scoffin, 1987). Ball (1967) identified marine sand belts, tidal bars, eolian ridges, and platform interior sand blankets comprising carbonate sand bodies present in Florida and the Bahamas. This is also one of the locations where ooids (oolites) form through the concentric precipitation of carbonate on spherical grains. Inorganic precipitation in the Persian Gulf, including the shallow waters of the Trucial Coast, reflects higher water temperature and salinity (Purser, 1973; Brewer and Dyrssen, 1985).

1.2 Global distribution of atolls

The most significant social and economic impact of a possible reduction in carbonate sand production is the potential decrease in supply of sand to currently inhabited, low-lying sand islands on remote reefs, particularly atolls. Atolls occur in the warm waters of the tropics and subtropics. These low-lying and vulnerable landforms owe their origin to reef-building corals (see Chapter 43 which discusses warm-water corals in contrast to cold-water corals dealt with in Chapter 42). The origin of atolls was explained by Charles Darwin as the result of subsidence (sinking) of a volcanic island. Following an initial eruptive phase, volcanic islands are eroded by waves and by slumping, and gradually subside, as the underlying lithosphere cools and contracts. In tropical waters, fringing coral reefs grow around the volcanic peak. As the volcano subsides the reef grows vertically upwards until eventually the summit of the volcano becomes submerged and only the ring of coral reef (i.e., an atoll) is left behind. The gradual subsidence can be understood in the context of plate tectonics and mantle “hot spots”. Many oceanic volcanoes occur in linear chains (such as the Hawaiian Islands and Society Islands) with successive islands being older along the chain and moving into deeper water as the plate cools and contracts (Ramalho et al., 2013).

Most atolls are in the Pacific Ocean (in archipelagoes in the Tuamotu Islands, Caroline Islands, Marshall Islands, and the island groups of Kiribati, Tuvalu and Tokelau) and Indian Ocean (the Maldives, the Laccadive Islands, the Chagos Archipelago and the Outer Islands of the Seychelles). The Atlantic Ocean has fewer atolls than either the Pacific or Indian Oceans, with several in the Caribbean (Vecsei, 2003; 2004). The northernmost atoll in the world is Kure Atoll at 28°24' N, along with other atolls of the northwestern Hawaiian Islands in the North Pacific Ocean. The southernmost are the atoll-like Elizabeth (29°58' S) and Middleton (29°29' S) Reefs in the Tasman Sea, South Pacific Ocean (Woodroffe et al., 2004). The occurrence of seamounts (submarine volcanoes) is two times higher in the Pacific than in the Atlantic or Indian Oceans, explaining the greater frequency of atolls.

Corals, which produce aragonite, are the principal reef-builders that shape and vertically raise the reef deposit, and there are secondary contributions from other aragonitic organisms, particularly molluscs, as well as coralline algae, bryozoans and foraminifera which are predominantly made of calcite. Carbonate sand and gravel is derived from the breakdown of the reef. Bioerosion is an important process in reefs, with bioeroders, such as algae, sponges, polychaete worms, crustaceans, sea urchins, and boring molluscs (e.g., *Lithophaga*) reducing the strength of the framework and producing sediment that infiltrates and accumulates in the porous reef limestone (Perry et al., 2012). Erosion rates by sea urchins have been reported to exceed 20 kg CaCO₃ m⁻² year⁻¹ in some reefs, and parrotfish may produce 9 kg CaCO₃ m⁻² year⁻¹ (Glynn, 1996). Over time, cementation lithifies the reef. Whereas the reef itself is the main feature produced by these calcifying reef organisms, loose carbonate sediment is also transported from its site of production. Transported sediment can be deposited, building sand cays. Broken coral or larger boulders eroded from the reef by storms form coarser islands (termed *motu* in the Pacific). Sand and gravel can be carried across the reef and deposited together with finer mud filling in the lagoon (Purdy and Gischler, 2005).

Carbonate production on reefs has been measured by at least three different approaches; hydrochemical analysis of changes in alkalinity of water moving across a section of reef, radiometric dating of accretion rates in reef cores, and census-based approaches that quantify relative contributions made by different biota (including destruction by bioeroders). These approaches indicate relatively consistent rates of $\sim 10 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$ on flourishing reef fronts, $\sim 4 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$ on reef crests, and $< 1 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$ in lagoonal areas (Hopley et al., 2007; Montaggioni and Braithwaite, 2009; Perry et al., 2012; Leon and Woodroffe, 2013). These rates have been described in greater detail in specific studies (Harney and Fletcher, 2003; Hart and Kench, 2007), and have been used to produce regional extrapolations of net production (Vecsei, 2001, 2004).

2. Changes known and foreseen –sea-level rise and ocean acidification.

Several climate change and oceanographic drivers threaten the integrity of fragile carbonate coastal ecosystems. Anticipated sea-level rise will have an impact on the majority of coasts around the world. In addition, carbonate production is likely to be affected by changes in other climate drivers, including warming and acidification. Tropical and subtropical reefs would appear to be some of the worst affected systems. However, it is also apparent that already many degraded systems can be attributed to impacts from social and economic drivers of change; pollution, overfishing and coastal development have deteriorated reef systems and many severely eroded beaches can be attributed to poor coastal management practices.

2.1 Potential impacts of sea-level rise on beaches

Sea-level rise poses threats to many coasts. Between 1950 and 2010, global sea level has risen at an average rate of $1.8 \pm 0.3 \text{ mm year}^{-1}$; approximately 10 cm of anthropogenic global sea-level rise is therefore inferred since 1950. Over the next century, the mean projected sea-level rise for 2081-2100 is in the range 0.26-0.54 m relative to 1986-2005, for the low-emission scenario (RCP 2.6). The rate of rise is anticipated to increase from $\sim 3.1 \text{ mm year}^{-1}$ indicated by satellite altimetry to 7-15 mm year^{-1} by the end of the century (Church et al., 2013). The rate experienced on any particular coast is likely to differ from the global mean trend as a result of local and regional factors, such as rates of vertical land movement or subsidence. Beach systems can be expected to respond to this gradual change in sea level, and the low-lying reef islands on atolls appear to be some of the most vulnerable coastal systems (Nicholls et al., 2007).

Based on predictions from the Bruun Rule, a simple heuristic that uses slope of the foreshore and conservation of mass, sea-level rise will cause erosion and net recession landwards for many beaches (Bruun, 1962). Although this approach has been widely applied, it has been criticized as unrealistic for many reasons, including that it does not adequately incorporate consideration of site-specific sediment

budgets (Cooper and Pilkey, 2004). Few analyses consider the contribution of biogenic carbonate and none foreshadow the consequences of any reduction in supply of carbonate sand. This is partly because of time lags between production of carbonate and its incorporation into beach deposits, which is poorly constrained in process studies and which is subject to great variability between different coastal settings, ranging from years to centuries (Anderson et al., 2015). In view of uncertainties in rates of sediment supply and transport, probabilistic modeling of shoreline behavior may be a more effective way of simulating possible responses, including potential accretion where sediment supply is sufficient (Cowell et al., 2006).

2.2 *Potential impacts of sea-level rise on reef islands*

Small reef islands on the rim of atolls appear to be some of the most vulnerable of coastal environments; they are threatened by exacerbated coastal erosion, inundation of low-lying island interiors, and saline intrusion into freshwater lenses upon which production of crops, such as taro, depends (Mimura, 1999). Sand cays, on atolls as well as on other reefs, have accumulated incrementally over recent millennia because reefs attenuate wave energy sufficiently to create physically favourable conditions for deposition of sand islands (Woodroffe et al., 2007), as well as enabling growth of sediment-stabilizing seagrasses and mangrove ecosystems (Birkeland, 1996). Sand cays are particularly low-lying, rarely rising more than a few metres above sea level; for example, <8 per cent of the land area of Tuvalu and Kiribati is above 3 m above mean sea level, and in the Maldives only around 1 per cent, reaches this elevation (Woodroffe, 2008). This has led to dramatic warnings in popular media and inferences in the scientific literature that anthropogenic climate change may lead to reef islands on atolls submerging beneath the rising ocean, with catastrophic social and economic implications for populations of these atoll nations (Barnett and Adger, 2003; Farbotko and Lazrus, 2012).

However, reef islands may be more resilient than implied in these dire warnings (Webb and Kench, 2010). Unlike the majority of temperate beaches that have a finite volume of sediment available, biogenic production of carbonate sediments means that there may be an ongoing supply of sediment to these islands. Although coral is a major contributor, it is not necessarily the principal constituent of beaches; large benthic foraminifera (particularly *Calcarina*, *Amphistegina* and *Baculogypsina*) contribute more than 50 per cent of sediment volume on many islands on Pacific atolls (Woodroffe and Morrison, 2001; Fujita et al., 2009). One survey of Pacific coral islands (Webb and Kench, 2010) reported that 86 per cent of islands had remained stable or increased in area over recent decades, and only 14 per cent of islands exhibited a net reduction in area; however, the greatest increases in area resulted from artificial reclamation (Biribo and Woodroffe, 2013). Further studies of shoreline changes on atoll reef islands using multi-temporal aerial photography and satellite imagery indicate accretion on some shorelines and erosion on others, but with the most pronounced changes associated with human occupation and impacts (Rankey, 2011; Ford, 2012; Ford 2013; Hamylton and East, 2012; Yates et al., 2013).

The impacts of future sea-level rise on individual atolls remain unclear (Donner, 2012). Healthy reef systems may be capable of keeping pace with rates of sea-level rise. There is evidence that reefs have coped with much more rapid rates of rise during postglacial melt of major ice sheets than are occurring now or anticipated in this century. Reefs have responded by keeping up, catching up, or in cases of very rapid rise giving up, often to backstep and occupy more landward locations (Neumann and Macintyre, 1985; Woodroffe and Webster, 2014). Geological evidence suggests that healthy coral reefs have exhibited accretion rates in the Holocene of 3 to 9 mm year⁻¹ (e.g., Perry and Smithers, 2011), comparable to projected rates of sea-level rise for the 21st century. However, reef growth is likely to lag behind sea-level rise in many cases resulting in larger waves occurring over the reef flat and affecting the shoreline (Storlazzi et al., 2011; Grady et al., 2013). It is unclear whether these larger waves, and the increased wave run-up that is likely, will erode reef-island beaches, overtopping some and inundating island interiors, or whether they will more effectively move sediments shoreward and build ridge crests higher (Gourlay and Hacker, 1991; Smithers et al., 2007). Dickinson (2009) inferred that reef islands on atolls will ultimately be unable to survive because once sea level rises above their solid reef-limestone foundations, which formed during the mid-Holocene sea-level highstand 4,000 to 2,000 years ago, formerly stable reef islands will be subject to erosion by waves.

2.3 *Impact of climate change and ocean acidification on production*

The impact of climate change on the rate of biogenic production of carbonate sediment is also little understood, but it seems likely to have negative consequences. Although increased temperatures may lead to greater productivity in some cases, for example by extending the latitudinal limit to coral-reef formation, ocean warming has already been recognised to have caused widespread bleaching and death of corals (Hoegh-Guldberg, 1999; Hoegh-Guldberg, 2004; Hoegh-Guldberg et al., 2007). Ocean acidification will have further impacts, and may inhibit some organisms from secreting carbonate shells; for example reduction in production of the Pacific oyster has been linked to acidification (Barton et al., 2012). Decreased seawater pH increases the sensitivity of reef calcifiers to thermal stress and bleaching (Anthony et al., 2008). Based on the density of coral skeleton in >300 long-lived *Porites* corals from across the Great Barrier Reef, De'ath et al. (2009) inferred that a decline in calcification of ~14 per cent had occurred since 1990 manifested as a reduction in the extension rate at which coral grows, which they attributed to temperature stress and declining saturation state of seawater aragonite (which is related to a decrease in pH). However, this extent of the apparent decline has been questioned because of inclusion of many young corals (Ridd et al., 2013); it is not observed in corals collected more recently from inshore (D'Olivo et al., 2013).

There has been some debate about the role of carbonate sediments acting as a chemical buffer against ocean acidification; in this scenario, dissolution of metastable carbonate mineral phases produces sufficient alkalinity to buffer pH and carbonate saturation state of shallow-water environments. However, it is apparent that dissolution rates are slow compared with shelf water-mass mixing processes, such that carbonate dissolution has no discernable impact on pH in shallow waters

that are connected to deep-water, oceanic environments (Andersson and McKenzie, 2012). The seawater chemistry within a reef system can be significantly different from that in the open ocean, perhaps partially offsetting the more extreme effects (Andersson et al., 2013; Andersson and Gledhill, 2013). Corals have the ability to modulate pH at the site of calcification (Trotter et al. 2011; Venn et al. 2011; Falter et al., 2013). Internal pH in both tropical and temperate coral is generally 0.4 to 1.0 units higher than in the ambient seawater, whereas foraminifera exhibit no elevation in internal pH (McCulloch et al., 2012).

Changes in the severity of storms will affect coral reefs; storms erode some island shorelines, but also provide inputs of broken coral to extend other islands (Maragos et al., 1973; Woodroffe, 2008). Alterations in ultra-violet radiation may also have an impact, as UV has been linked to coral bleaching. Furthermore, if reefs are not in a healthy condition due to thermal stress (bleaching) coupled with acidification and other anthropogenic stresses (pollution, overfishing, etc.), then reef growth and carbonate production may not keep pace with sea-level rise. This could, in the long-term, reduce carbonate sand supply to reef islands causing further erosion, although ongoing erosion of cemented reef substrate is also a source of sediment on reefs, indicating that supply of carbonate sand to beaches is dependent upon several interrelated environmental processes. Disruption of any one (or combination) of the controlling processes (carbonate production, reef growth, biological stabilization, bioerosion, physical erosion and transport) may result in reduction of carbonate sand supply to beaches.

3. Economic and social implications of carbonate sand production.

More than 90 per cent of the population of atolls in the Maldives, Marshall Islands, and Tuvalu, as well many in the Cayman Islands and Turks and Caicos (which all have populations of less than 100,000), live at an elevation <10 m above sea level and appear vulnerable to rising sea level, coastal erosion and inundation (McGranahan et al., 2007). The social disruption caused by relocating displaced people to different islands or even to other countries is a problem of major concern to many countries (Farbotko and Lazrus, 2012, see also Chapter 26). Beach aggregate mining is a small-scale industry on many Pacific and Caribbean islands employing local peoples (McKenzie et al., 2006), but mining causes environmental damage when practised on an industrial scale (Charlier, 2002; Pilkey et al., 2011, see also Chapter 23). In the Caribbean, illegal beach mining is widespread but there is little information on what proportion is carbonate (Cambers, 2009). Beach erosion reduces the potential opportunities associated with tourism (see Chapter 27), and decreases habitat for shorebirds and turtles (Fish et al., 2005; Mazaris et al., 2009).

Without coral reefs producing sand and gravel for beach nourishment and protecting the shoreline from currents, waves, and storms, erosion and loss of land are more likely (see also Chapter 39). In Indonesia, Cesar (1996) estimated that the loss due to decreased coastal protection was between 820 United States dollars (for remote areas) and 1,000,000 dollars per kilometre of coastline (in areas of major tourist infrastructure) as a consequence of coral destruction (based on lateral erosion rates

of 0.2 m year⁻¹, and a 10 per cent discount rate [similar to an interest rate] over a 25-year period). In the Maldives, mining of coral for construction has had severe impacts (Brown and Dunne, 1988), resulting in the need for an artificial substitute breakwater around Malé at a construction cost of around 12,000,000 dollars (Moberg and Folke, 1999).

4. Conclusions, Synthesis and Knowledge Gaps

There has been relatively little study of rates of carbonate production, and further research is needed on the supply of biogenic sand and gravel to coastal ecosystems. Most beaches have some calcareous biogenic material within them; carbonate is an important component of the shoreline behind coral-reef systems, with reef islands on atolls entirely composed of skeletal carbonate.

The sediment budgets of these systems need to be better understood; direct observations and monitoring of key variables, such as rates of calcification, would be very useful. Not only is little known about the variability in carbonate production in shallow-marine systems, but their response to changing climate and oceanographic drivers is also poorly understood. In the case of reef systems, bleaching as a result of elevated sea temperatures and reduced calcification as a consequence of ocean acidification seem likely to reduce coral cover and production of skeletal material. Longer-term implications for the sustainability of reefs and supply of sediment to reef islands would appear to decrease resilience of these shorelines, although alternative interpretations suggest an increased supply of sediment, either because reef flats that are currently exposed at low tide and therefore devoid of coral, may be re-colonized by coral under higher sea level, or because the disintegration of dead stands of coral may augment the supply of sediment.

Determining the trend in shoreline change, on beaches in temperate settings and on reef islands on atolls or other reef systems, requires monitoring of beach volumes at representative sites. This has rarely been undertaken over long enough time periods, or with sufficient attention to other relevant environmental factors, to discern a pattern or assign causes to inferred trends. Although climate and oceanographic drivers threaten such systems, the most drastic erosion appears to be the result of more direct anthropogenic stressors, such as beach mining, or the construction of infrastructure or coastal protection works that interrupt sediment pathways and disrupt natural patterns of erosion and deposition.

Chapter 8. Aesthetic, Cultural, Religious and Spiritual Ecosystem Services Derived from the Marine Environment

Contributor: Alan Simcock (Lead Member)

1. Introduction

At least since the ancestors of the Australian aboriginal people crossed what are now the Timor and Arafura Seas to reach Australia about 40,000 years ago (Lourandos, 1997), the ocean has been part of the development of human society. It is not surprising that human interaction with the ocean over this long period profoundly influenced the development of culture. Within “culture” it is convenient to include the other elements – aesthetic, religious and spiritual – that are regarded as aspects of the non-physical ecosystem services that humans derive from the environment around them. This is not to decry the difference between all these aspects, but rather to define a convenient umbrella term to encompass them all. On this basis, this chapter looks at the present-day implications of the interactions between human culture and the ocean under the headings of cultural products, cultural practices and cultural influences.

2. Cultural products

No clear-cut distinction exists between objects which have a utilitarian value (because they are put to a use) and objects which have a cultural value (because they are seen as beautiful or sacred or prized for some other non-utilitarian reason). The two categories can easily overlap. Furthermore, the value assigned to an object may change: something produced primarily for the use to which it can be put may become prized, either by the society that produces it or by some other society, for other reasons (Hawkes, 1955). In looking at products from the ocean as cultural ecosystem services, the focus is upon objects valued for non-utilitarian reasons. The value assigned to them will be affected by many factors: primarily their aesthetic or religious significance, their rarity and the difficulty of obtaining them from the ocean. The example of large numbers of beads made from marine shells found in the burial mounds dating from the first half of the first millennium CE of the Mound People in Iowa, United States of America, 1,650 kilometres from the sea, shows how exotic marine products can be given a cultural value (Alex, 2010).

Another good – albeit now purely historical – example is the purple dye derived from marine shellfish of the family *Muricidae*, often known as Tyrian purple. In the Mediterranean area, this purple dye was very highly valued, and from an early date (around 1800-1500 BCE) it was produced in semi-industrial fashion in Crete and later elsewhere. Its cost was high because large numbers of shellfish were required to produce small amounts of the dye. Because of this, its use became restricted to the elite. Under the Roman republic, the togas of members of the Senate were

distinguished by a border of this colour, and under the Roman empire it became the mark of the emperors (Stieglitz, 1994). This usage has produced a whole cultural structure revolving around the colour purple and spreading out into a range of metaphors and ideas: for example, the concept of the “purple patch,” an elaborate passage in writing, first used by the Roman poet Horace (Horatius).

Goods derived from marine ecosystems that are given a cultural value because of their appearance and/or rarity include pearls, mother-of-pearl, coral and tortoiseshell. In the case of coral, as well as its long-standing uses as a semi-precious item of jewellery and inlay on other items, a more recent use in aquariums has developed.

2.1 Pearls and mother-of-pearl

Pearls and mother-of-pearl are a primary example of a marine product used for cultural purposes. Many species of molluscs line their shells with nacre – a lustrous material consisting of platelets of aragonite (a form of calcium carbonate (see Chapter 7)) in a matrix of various organic substances (Nudelman et al., 2006). The shells with this lining give mother-of-pearl. Pearls themselves are formed of layers of nacre secreted by various species of oyster and mussel around some foreign body which has worked its way into the shell (Bondad-Reantaso et al., 2007).

Archaeological evidence shows that pearls were already being used as jewellery in the 6th millennium BCE (Charpentier et al., 2012). By the time of the Romans, they could be described as “holding the first place among things of value” (Pliny). For the ancient world, the main source was the shellfish beds along the southern coast of the Persian Gulf, with Bahrain as the main centre. The pearl fishery in the Persian Gulf maintained itself as the major source of pearls throughout most of the first two millennia CE, and by the 18th century was sufficiently profitable to support the founding of many of the present Gulf States. It developed further in the 19th century, and by the start of the 20th century the Persian Gulf pearl trade reached a short-lived peak in value at about 160 million United States dollars a year, and was the mainstay of the economies of the Gulf States (Carter, 2005).

During the 20th century, however, the Persian Gulf pearl trade declined steadily, due substantially to competition from the Japanese cultured pearl industry and general economic conditions. With the emergence of the Gulf States as important oil producers, the economic significance of the pearl trade for the area declined. The Kuwait pearl market closed in 2000, and with its closure the Persian Gulf pearl fishery ceased to be of economic importance (Al-Shamlan, 2000). However, some pearling still continues as a tourist attraction and, with Japanese support, an attempt has been made to establish a cultivated pearl farm in Ras Al Kaimah (OBG, 2013). Other traditional areas for the harvesting of natural pearls include the Gulf of Cutch and the Gulf of Mannar in India, Halong Bay in Viet Nam and the Islas de las Perlas in Panama (CMFRI, 1991; Southgate, 2007).

The great transformation of the pearl industry came with the success of Japanese firms in applying the technique developed in Australia by an Englishman, William Saville-Kent. The technique required the insertion of a nucleus into the pearl oyster

in order to provoke the formation of a pearl. Using the oyster species from the Persian Gulf, this meant that, instead of the three or four pearls that could be found in a thousand wild oysters, a high percentage of the farmed oysters would deliver pearls. The Japanese industry started in about 1916. By 1938, there were about 360 pearl farms in Japanese waters, producing more than 10 million pearls a year (15 tons). Production continued to increase after World War II and reached a peak of 230 tons in 1966, from 4,700 farms. Pollution and disease in the oyster, however, rapidly caused the industry to contract. By 1977, only about 1,000 farms remained, producing about 35 tons of pearls. Competition from Chinese cultured freshwater pearls and an oyster epidemic in 1996 reduced the Japanese industry to the production of less than 25 tons a year. Nevertheless, this industry was still worth about 130 million dollars a year. From the 1970s, other Indian Ocean and Pacific Ocean areas were developing cultured pearl industries based on the traditional pearl oyster species: in India and in Viet Nam in the traditional pearling regions, and in Australia, China, the Republic of Korea and Venezuela. Apart from China, where production had reached 9-10 tons a year, these are relatively small; the largest is apparently in Viet Nam, which produces about 1 ton a year (Southgate, 2007).

At the same time, new forms of the industry developed, based on other oyster species. The two main branches are the “white South Sea” and “black South Sea” pearl industries, based on *Pinctada maxima* and *Pinctada margaritifera*, respectively. “Black” pearls are a range of colours from pale purple to true black. Australia (from 1950) and Indonesia (from the 1970s) developed substantial industries for “white South Sea” pearls, earning around 100 million dollars a year each. Malaysia, Myanmar, Papua New Guinea and the Philippines have smaller industries. The black “South Sea” pearl industry is centred in French Polynesia, particularly in the Gambier and Tuamotu archipelagos. The industry in French Polynesia was worth 173 million dollars in 2007 (SPC, 2011). The Cook Islands, building on a long-standing mother-of-pearl industry, started a cultured-pearl industry in 1972, which grew to a value of 9 million dollars by 2000. However, in that year poor farm hygiene and consequent mass mortality of the oysters led to a collapse to less than a quarter of that value by 2005. The trade has recovered somewhat since then, largely due to increased sales to tourists in the islands. Small “black South Sea” pearl industries also exist in the Federated States of Micronesia, Fiji, the Marshall Islands and Tonga. Small pearl industries based on the oyster species *Pterea penguin* and *Pterea sterna* exist in Australia, China, Japan, Mexico and Thailand (SPC, 2011; Southgate, 2007).

Reliable information on the cultured pearl industries is not easy to obtain: for example, significant divergences exist between the statistics for the *Pinctada margaritifera* industry in the FAO Fisheries Global Information System database and those reported by the South Pacific Secretariat in their newsletters (SPC, 2011). The FAO itself noted the lack of global statistics on pearls (FAO, 2012). However, all sources suggest that the various industries suffered severe set-backs in 2009-2012 from a combination of the global economic crisis and overproduction. It is also clear that, apart from local sales to tourists, the bulk of all production passes through auctions in Hong Kong, China, and Japan.

Mother-of-pearl is produced mainly from the shells of pearl oysters, but other molluscs, such as abalone, may also be used. In the 19th century it was much used as a material for buttons and for decorating small metal objects and furniture. In many of these uses it has been superseded by plastics. It developed as an important industry in the islands around the Sulu Sea and the Celebes Sea, but substantial industries also existed in western Australia (now overtaken by the cultured-pearl industry), the Cook Islands and elsewhere (Southgate 2007). It remains important in the Philippines, which still produces several thousand tons a year (FAO, 2012).

2.2 *Tortoiseshell*

For several centuries, material from the shells of sea turtles was used both as a decorative inlay on high-quality wooden furniture and for the manufacture of small items such as combs, spectacle frames and so on. The lavish use of tortoiseshell was a particular feature of the work of André Charles Boulle, cabinetmaker to successive 18th century French kings. This established a pattern which was widely imitated (Penderel-Brodhurst, 1910). The shells of hawksbills turtles (*Eretmochelys imbricata*), in particular, were used for this purpose. The demand for the shells of hawksbill turtles produced an enormous and enduring effect on hawksbill populations around the world. Within the last 100 years, millions of hawksbills were killed for the tortoiseshell markets of Asia, Europe and the United States (NMFS, 2013). The species has been included in the most threatened category of the IUCN's Red List since the creation of the list in 1968, and since 1977 in the listing of all hawksbill populations on Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora¹ (CITES) (trade prohibited unless not detrimental to the survival of the species). Some production of objects with tortoiseshell continues (particularly in Japan), but on a very much reduced scale.

2.3 *Coral (and reef fish)*

The Mediterranean red coral (*Corallium rubrum*), was used from a very early date for decoration and as a protective charm. In the 1st century, Pliny the Elder records both its use as a charm to protect children and its scarcity as a result of its export to India (Pliny). As late as the second half of the 19th century, teething-rings were still being made with coral (Denhams, 2014). It is now principally used for jewellery. The Mediterranean red coral is still harvested. Similar genera/species from the western Pacific near Japan, Hawaii, and some Pacific seamounts are also harvested. The global harvest reached a short-lived peak at about 450 tons a year in 1986, as a result of the exploitation of some recently discovered beds on the Emperor Seamounts in the Pacific. It has fallen back to around 50 tons a year, primarily from the Mediterranean and adjoining parts of the Atlantic (CITES, 2010). This trade in the hard coral stone is estimated to be worth around 200 million dollars a year (FT, 2012), although another estimate places it at nearer 300 million dollars) (Tsounis, 2010). Despite proposals in 2007 and 2010, these corals are not listed under the CITES.

¹ United Nations, *Treaty Series*, vol.. 993, No. 14537.

Other corals of cultural interest, on the other hand, have been listed under CITES. The cultural use made of these genera and species is very different. The main use is inclusion in aquariums. Some experimental evidence exists that the ability to watch fish in aquariums has a soothing effect on humans (especially when suffering from dementia) (for example, Edwards et al., 2002). For similar reasons, many homes, offices, surgeries and hospitals have installed such aquariums. Suitable pieces of coral, either alive or dead, are seen as attractive parts of such aquarium scenes. The demand for coral for this purpose is substantial. International trade in coral skeletons for decorative purposes began in the 1950s. Until 1977 the source was largely the Philippines. In that year a national ban on export was introduced, and by 1993 the ban was fully effective. The main source then became Indonesia. Until the 1990s, the trade was mainly in dead corals for curios and aquarium decoration. Developments in the technology of handling live coral led to a big increase in the trade in live coral. CITES lists 60 genera of hard corals in Appendix II; hence their export is permitted only if the specimens have been legally acquired and export will not be detrimental to the survival of the species or its role in the ecosystem. For coral rock, the trade averaged about 2,000 tons a year in the decade 2000-2010, although declining slightly towards the end of the decade. Fiji (with 60 per cent) and Indonesia (with 11 per cent) were the major suppliers over this decade. Other countries supplying coral rock included Haiti, the Marshall Islands, Mozambique, Tonga, Vanuatu and Viet Nam, although the last five introduced bans towards the end of this period. The major importers were the United States (78 per cent) and the European Union (12 per cent). For live coral, the picture was slightly different: over the same decade, the number of pieces of live coral traded rose from some 700,000 to some 1,200,000. Of these, Indonesia supplied an average of about 70 per cent, with other important suppliers including Fiji (10 per cent), Tonga (5 per cent), Australia (5 per cent) and the Solomon Islands (4 per cent). The United States accounted for an average of 61 per cent of the imports, and the European Union took 31 per cent. For some species of coral, mariculture is possible, and by 2010 pieces produced by mariculture accounted for 20 per cent of the trade (Wood et al., 2012).

An aquarium would not be complete without fish, and this need has produced another major global trade: in reef fish. Because few marine ornamental fish species have been listed under CITES, a dearth of accurate information on the precise details of the trade exists. The FAO noted the lack of global statistics on the catches of, and trade in, ornamental fish in its 2012 Report on the State of the World's Fisheries and Aquaculture (FAO, 2012). The late Director of the trade association Ornamental Fish International, Dr. Ploeg, likewise lamented the lack of data (Ploeg, 2004). One estimate puts the scale of the trade in ornamental fish (freshwater and marine) at 15 billion dollars. In 2000 to 2004 an attempt was made to set up in UNEP/WCMC a Global Marine Aquarium Database (GMAD), drawing not only on official trade records, but also on information supplied by trade associations. This provides some interesting, albeit now dated, information, but it has not been kept up-to-date because of lack of funding. One of the most notable features was that the number of fish reported as imported was some 22 per cent more than the number reported as exported (Wabnitz et al., 2003). The need for better information is a matter of

on-going debate; the European Union has conducted a consultation exercise in 2008-2010 (EC, 2008).

The GMAD data suggested that some 3.5-4.3 million fish a year, from nearly 1,500 different species, were being traded worldwide. The main sources of fish (in order of size of exports) were the Philippines, Indonesia, the Solomon Islands, Sri Lanka, Australia, Fiji, the Maldives and Palau. These countries accounted for 98 per cent of the recorded trade, with the Philippines and Indonesia together accounting for nearly 70 per cent. The main destinations of the fish were the United States, the United Kingdom, the Netherlands, France and Germany, which accounted for 99 per cent of the recorded trade; the United States accounted for nearly 70 per cent. These figures probably do not include re-exports to other countries. It was estimated that the value of the trade in 2003 was 1 million to 300 million dollars (Wabnitz et al., 2003).

From the social perspective, the number of people depending on the trade is relatively small. A workshop organized by the Secretariat of the Pacific Community in 2008 showed that some 1,472 people in 12 Pacific island countries and territories depended on the trade in ornamental fish for their livelihoods (Kinch et al., 2010). GMAD reported an estimate of 7,000 collectors providing marine ornamental fish in the Philippines (Wabnitz et al., 2003). It also reported a much higher estimate of some 50,000 people in Sri Lanka being involved with the export of marine ornamentals, but this probably reflects the large, long-standing trade based on the aquaculture of ornamental freshwater fish.

2.4 Culinary and medicinal cultural products

Items of food, and specific ways of preparing dishes from them, can be very distinctive features of cultures. Products derived from marine ecosystems often play a significant role. One almost universal feature is salt. For millennia, salt was vital in much of the world for the preservation of meat and fish through the winter months. Although nowadays salt is mainly obtained from rock-salt and brine deposits in the ground, salt is still widely prepared by the evaporation of seawater, especially in those coastal areas where the heat of the sun can be used to drive the evaporation. Although statistics for the production of salt often do not differentiate between the sources for salt production, countries such as Brazil, India and Spain are recorded as producing many millions of tons of salt from the sea (BGS, 2014).

A further common preparation used in many forms of cooking is a sauce derived from fermenting or otherwise processing small fish and shellfish. Such sauces are recorded as *garum* and *liquamen* among the Romans from as long ago as the 1st century (Pliny). They are also crucial ingredients in the cuisines of many east Asian countries – China, Republic of Korea, Thailand, Viet Nam – and other fish-based sauces are found in many western cuisines, for example, *colatura de alici* (anchovy sauce) and Worcestershire sauce.

Cultural pressures can interact with the sustainable use of products derived from marine ecosystem services. Just as the demand for tortoiseshell inlay and objects was driven by desire to emulate the élite in both Asia and Europe, and affected the

hawksbill turtle, other species of marine turtle were also affected by the status of turtle soup as a prestige dish. In Europe, soup made from green turtles (*Chelonia mydas*) became a prestige dish when the turtles were brought back by European trading ships passing through the tropics. It was served lavishly at formal dinners – in the mid-19th century, a report of a routine large dinner refers to “four hundred tureens of turtle, each containing five pints” – that is, 1,136 litres in total (Thackeray, 1869). Large amounts were also commercialized in tins. In spite of growing conservation concerns, it was still seen as appropriate for inclusion in the dinner to welcome the victorious General Eisenhower back to the United States in 1945 (WAA, 1945). The dish has disappeared from menus since the green turtle was listed under Appendix I to CITES in 1981, except in areas where turtles are farmed or where freshwater species are used.

Another group of species where cultural forces create pressures for excessive harvesting is the sharks (see also chapter 40). Shark’s fin soup is a prestige dish in much of eastern Asia, especially among Chinese-speaking communities. Prices for shark’s fins are very high (hundreds of dollars per kilogramme). As shown in Figure 1, the trade in shark fins peaked in 2003-2004 and has subsequently levelled out at quantities 17-18 per cent lower (2008-2011). The statistics are subject to many qualifications, but trade in shark fins through Hong Kong, China (generally regarded as the largest trade centre in the world) rose by 10 per cent in 2011, but fell by 22 per cent in 2012. The FAO report from which the figure is drawn suggests that a number of factors, including new regulations by China on government officials’ expenditures, consumer backlash against artificial shark fin products, increased regulation of finning (the practice of cutting fins of shark carcasses and discarding the rest), other trade bans and curbs, and a growing conservation awareness, may have contributed to the downturn. At the same time, new figures suggest the shark fin markets in Japan, Malaysia and Thailand, though focused on small, low-value fins, may be among the world’s largest (FAO, 2014a).

Figure 1. Source: FAO, 2014a.

Similar cultural pressures exist in relation to other aspects of marine ecosystems. Traditional medicine in eastern Asia, for example, uses dried seahorses for a range of illnesses. Most dried seahorses (caught when they are about 12-16 cm in size) are exported to China. The value in 2008 was 100-300 dollars per kilogramme, depending on the size and species; the larger animals are the most valuable. Production is said to be more than 20 million sea horses (70 tons) a year. Viet Nam and China are the major producers; Viet Nam has developed its seahorse aquaculture since 2006. This trade is seen as a significant pressure on the conservation status of several species of seahorse (FAO, 2014b).

Not all consequences of the cultural uses of the ocean's ecosystem services in relation to food are necessarily negative. The Mediterranean diet, with its substantial component of fish and shellfish, was inscribed in 2013 on the UNESCO Representative List of the Intangible Cultural Heritage of Humanity (UNESCO, 2014).

3. Cultural practices

3.1 Cultural practices that enable use of the sea

Humans interact with the ocean in a large number of ways, and many of these lead to cultural practices which enrich human life in aesthetic, religious or spiritual ways, as well as in purely practical matters. Such practices are beginning to be inscribed in the UNESCO Representative List of the Intangible Cultural Heritage of Humanity. Those listed so far include a practice in Belgium of fishing for shrimp on horse-back: twice a week, except in winter months, riders on strong Brabant horses walk breast-deep in the surf, parallel to the coastline, pulling funnel-shaped nets held open by two wooden boards. A chain dragged over the sand creates vibrations, causing the shrimp to jump into the net. Shrimpers place the catch (which is later cooked and eaten) in baskets hanging at the horses' sides. In approving the inscription, the Intergovernmental Committee for the Safeguarding of the Intangible Cultural Heritage (ICSICH) noted that it would promote awareness of the importance of small, very local traditions, underline the close relations between humans, animals and nature, and promote respect for sustainable development and human creativity (UNESCO, 2014).c

Similarly, the Chinese tradition of building junks with separate water-tight bulkheads has been recognized as a cultural heritage that urgently needs protection. The ICSICH noted that, despite the historical importance of this shipbuilding technology, its continuity and viability are today at great risk because wooden ships are replaced by steel-hulled vessels, and the timber for their construction is in increasingly short supply; apprentices are reluctant to devote the time necessary to master the trade and craftspeople have not managed to find supplementary uses for their carpentry skills. Furthermore, the ICSICH noted that safeguarding measures designed to sustain the shipbuilding tradition are underway, including State financial assistance to master builders, educational programmes to make it possible for them to transmit their traditional knowledge to young people, and the reconstruction of historical

junks as a means to stimulate public awareness and provide employment (UNESCO, 2014).

Another cultural tradition linked to the sea is that of the lenj boats in the Islamic Republic of Iran. Lenj vessels are traditionally hand-built and are used by inhabitants of the northern coast of the Persian Gulf for sea journeys, trading, fishing and pearl diving. The traditional knowledge surrounding lenjes includes oral literature, performing arts and festivals, in addition to the sailing and navigation techniques, terminology and weather forecasting that are closely associated with sailing, and the skills of wooden boat-building itself. This tradition is also under threat, and the Islamic Republic of Iran has proposed a wide range of measures to safeguard it (UNESCO, 2014).

Along the north-east Pacific coast, sea-going canoes were one of the three major forms of monumental art among the Canadian First Nations and United States Native Americans, along with plank houses and totem poles. These canoes came to represent whole clans and communities and were a valuable trade item in the past, especially for the Haida, Tlingit and Nuu-Chah-Nulth. Recently, there has been a revival in the craft of making and sailing them, and they are capable of bringing prestige to communities (SFU, 2015).

Similar important navigational traditions survive in Melanesia, Micronesia and Polynesia. Using a combination of observations of stars, the shape of the waves, the interference patterns of sea swells, phosphorescence and wildlife, the Pacific Islanders have been able to cross vast distances at sea and make landfall on small islands. Although now largely being replaced by modern navigational aids, the Pacific navigational tradition shows how many aspects of the marine ecosystems can be welded together to provide results that at first sight seem impossible. Since the 1970s the tradition has been undergoing a renaissance (Lewis, 1994).

Apart from the practical cultural practices linked to the sea that support navigation, cultural practices in many parts of the world reflect the dangers of the ocean and the hope of seafarers to gain whatever supernatural help might be available. The fishing fleet is blessed throughout the Roman Catholic world, usually on 15 August, the Feast of the Assumption. This dates back to at least the 17th century in Liguria in Italy (Acta Sanctae Sedis, 1891). It spread generally around the Mediterranean, and was then taken by Italian, Portuguese and Spanish fishermen when they emigrated, and has been adopted in many countries, even those without a Roman Catholic tradition.

In many places in China and in the cultural zone influenced by China, a comparable festival is held on the festival of Mazu, also known (especially in Hong Kong, China) as Tian Hou (Queen of Heaven). According to legend, she was a fisherman's daughter from Fujian who intervened miraculously to save her father and/or her brothers and consequently became revered by fishermen, and was promoted by the Chinese Empire as part of their policy of unifying devotions. The main festival takes place on the 23rd day of the 3rd lunar month (late April/early May). A tradition of visiting a local shrine before a fishing voyage also continues in some places (Liu, 2003).

Miura, on the approaches to Tokyo Bay in Japan, developed as a military port and a harbour providing shelter to passing ships. Drawing on dances from other cities demonstrated to them by visiting sailors, the people of Miura began the tradition of Chakkirako to celebrate the New Year and bring fortune and a bountiful catch of fish in the months to come. By the mid-eighteenth century, the ceremony had taken its current form as a showcase for the talent of local girls. The dancers perform face-to-face in two lines or in a circle, holding fans before their faces in some pieces and clapping thin bamboo sticks together in others, whose sound gives its name to the ceremony. Now included in the UNESCO Representative List of the Intangible Cultural Heritage of Humanity, the ceremony is intended to demonstrate cultural continuity (UNESCO, 2014).

A specific cultural practice that acknowledges the importance of sea trade is the “Marriage of the Sea” (*Sposalizio del Mare*) in Venice, Italy. This takes the form of a boat procession from the centre of city to the open water, where the civic head (originally the Doge, now the Sindaco) throws a wedding ring into the sea. In 1177, Venice had successfully established its independence from the Emperor and Patriarch in Constantinople (Istanbul), from the Pope in Rome and from the Holy Roman Emperor, by using its leverage to reconcile the two latter powers, and had become the great entrepôt between the eastern and western Mediterranean. Pope Alexander III acknowledged this by giving the Doge a ring. Henceforth, annually on Ascension Day, the Doge would “wed” the sea to demonstrate Venice’s control of the Adriatic (Myers et al., 1971). Abolished when Napoleon dissolved the Venetian Republic, the ritual has been revived since 1965 as a tourist attraction (Veneziaunica, 2015).

3.2 *Cultural practices that react to the sea*

A verse in the Hebrew psalms speaks of the people “that go down to the sea in ships and...see...the wonders of the deep” (Psalm 107(106)/23, 24). A similar sense of awe at the sea appears in the Quran (Sura 2:164). This sense of awe at the ocean is widespread throughout the world. In many places it leads to a special sense of place with religious or spiritual connotations, which lead to special ways of behaving: in other words, to religious or spiritual ecosystem services from the ocean. A reductionist approach can see no more in such ways of behaviour than bases for prudential conduct: for example, fishing may be halted in some area at a specific time of year, which coincides with the spawning of a particular fish population, thus promoting the fish stock recruitment. But such a reductionist approach is not necessary, and can undermine a genuine sense of religious or spiritual reaction to the sea.

The risk exists that such reductionist approaches will be seen as the natural interpretation of ritual or religious practices. In a survey of the environmental history of the Pacific Islands, McNeill writes that “Lagoons and reefs probably felt the human touch even less [than the islands], although they made a large contribution to island sustenance...human cultural constraints often operated to preserve them. Pacific islanders moderated their impact on many ecosystems through restraints and restrictions on resource use. In many societies taboos or other prohibitions limited

the exploitation of reefs, lagoons, and the sea. These taboos often had social or political purposes, but among their effects was a reduction in pressures on local ecosystems. Decisions about when and where harvesting might take place were made by men who had encyclopaedic knowledge of the local marine biota” (McNeill, 1994).

This clearly sets out the external (“etic”) view of the system of taboos and beliefs, i.e., the view that can be taken by an outside, dispassionate observer. It does not allow for the internal (“emic”) view as seen by someone who is born, brought up and educated within that system. It is important to understand this distinction and allow for the way in which the insider will have a different frame of reference from the outsider.

Good examples of the way in which such an insider’s religious or spiritual reactions can underpin a whole system of community feeling can be found among the First Nations of the Pacific seaboard of Canada. A member of the Huu-ay-aht First Nation, a tribe within the Nuu-chah-nulth Tribal Group in this area, describes their traditional approach to whaling as follows:

“Whaling within Nuu chah nulth society was the foundation of our economic structure. It provided valuable products to sell, trade and barter. In essence it was our national bank... Whaling [however, also] strengthened, maintained and preserved our cultural practices, unwritten tribal laws, ceremonies, principles and teachings. All of these elements were practiced throughout the preparations, the hunt and the following celebrations. Whaling strengthened and preserved our spirituality and is clearly illustrated through the discipline that the Nuu chah nulth hereditary whaling chiefs exemplified in their months of bathing, praying and fasting in preparation for the hunt. The whale strengthened our relationships with other nations and communities. People came from great distances and often resulted in intertribal alliances, relationships and marriages. The whale strengthened the relationships between families because everyone was involved in the processing of the whale, the celebrations, the feasting, and the carving of the artefacts that can still be seen today in many museums around the world. The whale strengthened the relationships between family members since everyone shared in the bounty of the whale. And the whale strengthened our people spiritually, psychologically and physically” (Happynook, 2001).

Because of the restrictions imposed to respond to the crises in the whale population caused by commercial whaling, the Nuu-chah-nulth are not permitted to undertake whaling, and the related peoples further south in Washington State, United States, need to obtain special authorization (a request for which has been under consideration since 2005), and feel that part of their cultural heritage has been taken away from them. As the draft evaluation of the Makah request to resume whale-hunting puts it, with no authorization this element of their culture would remain a connection to the past without any present reinforcement. In effect, a cultural ecosystem service would be lost (NOAA, 2015).

3.3 Cultural practices tied to a specific sea area

Not all interactions between communities with traditions based on their long-standing uses of the ocean result in such clashes between opposing points of view. In Brazil, for example, the concept has been introduced of the Marine Extractive Reserve (*Reserva Extrativista Marinha*). These are defined areas of coast and coastal sea which aim to allow the long-standing inhabitants to continue to benefit from the resources of the reserve, applying their traditional knowledge and practices, while protecting the area against non-traditional, new exploitation, and protecting the environment (Chamy, 2002). Six such reserves have been created, and a further 12 are in the process of designation and organization (IBAMA, 2014).

In Australia, before colonization, the coastal clans of indigenous peoples regarded their territories as including both land and sea. The ocean, or “saltwater country”, was not additional to a clan estate on land: it was inseparable from it. As on land, saltwater country contained evidence of the Dreamtime events by which all geographic features, animals, plants and people were created. It contained sacred sites, often related to these creation events, and it contained tracks, or Songlines, along which mythological beings travelled during the Dreamtime. Mountains, rivers, waterholes, animal and plant species, and other cultural resources came into being as a result of events which took place during these Dreamtime journeys. The sea, like the land, was integral to the identity of each clan, and clan members had a kin relationship to the important marine animals, plants, tides and currents. Many of these land features and heritage sites of cultural significance found within landscapes today have associations marked by physical, historical, ceremonial, religious and ritual manifestations located within the indigenous people’s cultural beliefs and customary law. The Commonwealth and State Governments in Australia are now developing ways in which the groups of indigenous people can take a full part in managing the large marine reserves which have been, or are being, created, in line with their traditional culture. The techniques being used must vary, because they must take account of other vested rights and Australia’s obligations under international law (AIATSIS, 2006).

Madagascar provides an interesting example of the way in which traditional beliefs can influence decisions on sea use. On the west coast of the northern tip of the island, a well-established shrimp-fishing industry is largely, but not entirely, undertaken by a local tribal group, the Antankarana. This group has a traditional set of beliefs, including in the existence of a set of spirits – the *antandrano* – who represent ancestors drowned in the sea centuries ago in an attempt to escape a local opposing tribal group, the Merina. These spirits are honoured by an annual ceremony focused on a particular rock in the sea in the shrimp fishery area. A proposal was made to create a shrimp aquaculture farm, which would have severely reduced the scope of the shrimp fishery. The Antankarana leader successfully invoked against this proposal reports from local mediums participating in the annual ceremony that the *antandrano* spirits would oppose the aquaculture proposal (which might well have been under Merina control). Thus a religious ecosystem service from the sea was deployed to defend a provisioning ecosystem service (Gezon, 1999).

At a global level, specific marine sites were inscribed by UNESCO in the World Heritage List, and thus brought under certain commitments and controls to safeguard them. So far 42 marine or coastal sites have been designated on the basis of their natural interest:

- (a) 22 “contain superlative natural phenomena or areas of exceptional natural beauty and aesthetic importance”;
- (b) 12 are “outstanding examples representing major stages of earth's history, including the record of life, significant ongoing geological processes in the development of landforms, or significant geomorphic or physiographic features”;
- (c) 14 are “outstanding examples representing significant ongoing ecological and biological processes in the evolution and development of terrestrial, fresh water, coastal and marine ecosystems and communities of plants and animals”; and
- (d) 29 “contain the most important and significant natural habitats for in-situ conservation of biological diversity, including those containing threatened species of outstanding universal value from the point of view of science or conservation”.

(Sites can qualify under more than one criterion.)

Fifteen are islands. Three have been declared to be in danger: the Belize barrier reef (the largest in the northern hemisphere), which is threatened by mangrove cutting and excessive development (2009); the Florida Everglades in the United States, which have suffered a 60 per cent reduction in water flow and are threatened by eutrophication (2010); and East Rennell in the Solomon Islands, which is threatened by logging (2013). In addition, four marine or coastal sites have been inscribed in the World Heritage List because of their mixed cultural and natural interest – the island of St Kilda in the United Kingdom (for centuries a very remote inhabited settlement, featuring some of the highest cliffs in Europe); the island of Ibiza in Spain (a combination of prehistoric archaeological sites, fortifications influential in fortress design and the interaction of marine and coastal ecosystems); the Rock Islands Southern Lagoon (Ngerukewid Islands National Wildlife Preserve) in Palau (a combination of neolithic villages and the largest group of saltwater lakes in the world); and Papahānaumokuākea (a chain of low-lying islands and atolls with deep cosmological and traditional significance for living native Hawaiian culture, as an ancestral environment, as an embodiment of the Hawaiian concept of kinship between people and the natural world, and as the place where it is believed that life originates and where the spirits return after death) (UNESCO, 2014).

Other marine sites of cultural interest are those which offer the possibility of learning more about their past through underwater archaeology. Underwater archaeology draws on submerged sites, artefacts, human remains and landscapes to explain the origin and development of civilizations, and to help understand culture, history and climate change. Three million shipwrecks and sunken ruins and cities, like the remains of the Pharos of Alexandria, Egypt – one of the Seven Wonders of the Ancient World - and thousands of submerged prehistoric sites, including ports

and methods of marine exploitation, such as fish traps, are estimated to exist worldwide. Material here is often better preserved than on land because of the different environmental conditions. In addition, shipwrecks can throw important light on ancient trade patterns; for example, the Uluburun shipwreck off the southern coast of Turkey, which illuminated the whole pattern of trade in the Middle East in the Bronze Age in the second millennium BCE (Aruz et al., 2008). Shipwrecks can also yield valuable information about the sociocultural, historical, economic, and political contexts at various scales of reference (local, regional, global) between the date of the vessel's construction (e.g. hull design, rig, materials used, its purpose, etc.) and its eventual demise in the sea (e.g. due to warfare, piracy/privateering, intentional abandonment, natural weather events, etc.) (Gould, 1983). Many national administrations pursue policies to ensure that underwater archaeological sites within their jurisdictions are properly treated. At the global level, the UNESCO Convention on the Protection of the Underwater Cultural Heritage (2001)² entered into force in 2009, and provides a framework for cooperation in this field and a widely recognized set of practical rules for the treatment and research of underwater cultural heritage. Where such approaches are not applied, there are risks that irreplaceable sources of knowledge about the past will be destroyed. Bottom-trawling is a specific threat to underwater archaeological sites, with implications for the coordination of fisheries and marine archaeological site management. Questions also arise over archaeological sites outside national jurisdictions (mainly those of shipwrecks).

Cultural practices related to the sea, coastal sites of cultural interest (such as the UNESCO World Heritage Sites) and underwater archaeological sites form important elements for ocean-related tourism, which is discussed in Chapter 27 (Tourism and recreation). In particular, shipwrecks provide attractions for divers.

Special problems arise over recent shipwrecks where close relatives of people who died in the shipwreck are still living, particularly where the wreck occurred in wartime. Where the wrecks are in waters within national jurisdiction, many States have declared such sites to be protected, and (where appropriate) as war graves. As underwater exploration techniques improve, the possibility of exploring such wrecks in water beyond national jurisdiction increases, and this gives rise to sharp controversies.

Even without special remains or outstanding features, the ocean can provide an ecosystem service by giving onlookers a sense of place. The sense of openness and exposure to the elements that is given by the ocean can be very important to those who live by the sea, or visit it as tourists (see also Chapter 27). Even where the landward view has been spoiled by development, the seaward view may still be important. This is well demonstrated by a recent legal case in England, seeking to quash an approval for an offshore wind-farm at Redcar. Redcar is a seaside town with a large steel plant and much industrialization visible in its immediate hinterland. The beach and its view to the south-east are, however, described as spectacular. The court had to decide whether construction of the wind-farm about 1.5 kilometres offshore would introduce such a major new industrial element into the

² United Nations, *Treaty Series*, vol. 2562. No. 45694.

seascape/landscape as to undermine efforts to regenerate the seaside part of the town. The court decided that the ministry was justified in its approval, but the case underlines the importance of the aesthetic ecosystem service that the sea can provide (Redcar, 2008).

As described in Chapter 27 (Tourism and recreation), over the past 200 years there has been a growing cultural practice worldwide of taking recreation in coastal areas and at sea. Some evidence is emerging of positive links between human health and the enjoyment of the coastal and marine environment (Depledge et al., 2009; Wyles et al., 2014; Sandifer et al., 2015).

4. Cultural influences

Art reflects the society in which it is produced, and is influenced by that society's interests. The relationship between a society and the ocean is therefore likely to be reflected in its art. Much visual art therefore reflects the sense of place that is predominant in the society that generates it. The sense of place in societies that are much concerned with the sea reflects the aesthetic ecosystem services provided by the sea, hence the visual arts are also likely to reflect the same service. Examples of the way in which this occurs are not difficult to find. The Dutch painting school of the 17th century developed the seascape – ships battling the elements at sea – just at the period when the Dutch merchant ships and Dutch naval vessels were the dominant forces on the local ocean. The French impressionists of the second half of the 19th century took to painting coastal and beach scenes in Normandy just at the period when the railways had enabled the Parisian élite – their most likely patrons – to escape to the newly developed seaside resorts on the coast of the English Channel. Similarly, Hokusai's *The Great Wave at Kanagawa* is focused on a distant view of Mount Fuji rather than on the ocean – not surprising given that it was painted at a time when shipping in Japan was predominantly coastal. Today, the advances in cameras capable of operating under water, and the availability of easily managed breathing gear and protective clothing, result in the most stunning pictures of submarine life.

This reflection of the aspects of the aesthetic ecosystem services from the ocean that preoccupy the society contemporaneously with the work of the artist can also be found in literature and music. Camões's great epic *The Lusiads* appears just at the time when Portugal was leading the world in navigation and exploration. In the same period, Chinese literature saw the emergence of both fictional and non-fictional works based on the seven voyages of Admiral Zheng He in the south-east Asian seas and the Indian Ocean. It is with the emergence in the 19th century of widespread trading voyages by American and British ships that authors like Conrad, Kipling and Melville bring nautical novels into favour. Likewise, the impressionist seascapes in visual art are paralleled by impressionist music such as Debussy's *La mer*.

5. The ultimate ecosystem service for humans

Burial at sea has long been practiced as a matter of necessity during long voyages. It was specifically provided for in 1662 in the English Book of Common Prayer (BCP, 1662). Both the London Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, 1972³ and its Protocol⁴ (see chapter 24), which regulate the dumping of waste and other matter at sea, are careful to leave open the possibility of the burial of human remains at sea. Western European States regularly authorize a small number of such disposals every year (LC-LP, 2014). The United States authorities have issued a general permit for burial at sea of human remains, including cremated and non-cremated remains, under certain conditions (USA-ECFR, 2015). In Japan, increasing prices for burial plots and concerns about the expanding use of land for cemeteries have led to a growing pattern of cremation followed by the scattering of the cremated remains, often at sea. The practice started in 1991, when the law on the disposal of corpses was relaxed, and has become more popular following such funeral arrangements for a number of prominent people (Kawano, 2004).

6. Conclusions and identification of knowledge and capacity-building gaps

This chapter set out to review the ways in which ecosystem services from the sea interrelate with human aesthetic, cultural, religious and spiritual desires and needs. Five main conclusions emerge:

- (a) Several goods produced by the ocean have been taken up as élite goods, that is, goods that can be used for conspicuous consumption or to demonstrate status in some other way. When that happens, a high risk exists that the pressures generated to acquire such élite goods, whether for display or consumption, will disrupt marine ecosystems, especially when the demand comes from relatively well-off consumers and the supply is provided by relatively poor producers. The development of the market in shark's fin is a good example of this (although signs exist that that particular situation has stopped getting worse).
- (b) Some producers could be helped by a better understanding of the techniques and precautions needed to avoid ruining the production. As well as better knowledge, they may also need improved skills, equipment and/or machinery to implement that better understanding. The production of cultured pearls in the Cook Islands is a good example.
- (c) Some élite goods pass through a number of hands between the original producer and the ultimate consumer. There appears to be a gap in capacity-building to safeguard producers and ensure more equitable

³ United Nations, *Treaty Series*, vol. 1046, No. 15749.

⁴ 36 *International Legal Materials* 1 (1997).

profit-sharing in the supply chain. The case of small producers of cultured pearls is an example.

- (d) Very different perceptions of marine ecosystem services and how humans relate to them can exist between different groups in society, even when such groups are co-located. Understanding on all sides of the reasons for those differences is a prerequisite for effective management of the ecosystem services.
- (e) Aspects of the marine environment that are valued as cultural assets of humanity need constant consideration; they cannot just be left to fend for themselves. Where technology or social change has overtaken human skills that are still seen as valuable to preserve, conditions need to be created in which people want to learn those skills and are able to deploy them. Where an area of coast or sea is seen as a cultural asset of humanity, the knowledge is needed of how it can be maintained in the condition which gives it that value.

Chapter 9. Conclusions on Major Ecosystem Services Other than Provisioning Services

Contributor: Patricio A. Bernal (Lead Member)

1. Introduction

The ecosystem services assessed in Part III are large-scale; some of them are planetary in nature and provide human benefits through the normal functioning of the natural systems in the ocean, without human intervention. This makes them intrinsically difficult to value. However, some of these same ecosystem services in turn sustain provisioning services that generate human benefits through the active intervention of humans. This is the case, for example, for the global ecosystem service provided by primary production by marine plants, which by synthesizing organic matter from CO₂ and water, provide the base of nearly all food chains in the ocean (except the chemosynthetic ones), and provide the food for animal consumers that in turn sustain important provisioning ecosystem services from which humans benefit, such as fisheries.

The services in Part III are not the only ones provided by the ocean. Many other ecosystem services are directly or indirectly referred to in Parts IV to VI of this Assessment. The provisioning ecosystem services related to food security are addressed in Part IV, *Assessment of Cross-Cutting Issues: Food Security And Food Safety* (Chapters 10 through 16); those related to coastal protection are referred to in Part VI, *Assessment of Marine Biological Diversity and Habitats*, in *Warm Water Corals* (Chapter 43), *Mangroves* (Chapter 48), and in *Aquaculture* (Chapter 12), *Estuaries and Deltas* (Chapter 44), *Kelp Forests and Seagrass Meadows* (Chapter 47) and *Salt Marshes* (Chapter 49); the maintenance of special habitats are addressed in Chapters on *Open Ocean Deep-sea Biomass* (Chapter 36F); *Cold Water Corals* (Chapter 42) and *Warm Water Corals* (Chapter 43), *Hydrothermal Vents and Cold Seeps* (Chapter 45), *High-Latitude Ice* (46) and *Seamounts and Other Submarine Geological Features Potentially Threatened by Disturbance* (Chapter 51); the sequestration of carbon in coastal sediments, the so-called blue carbon, is addressed in Chapters on *Mangroves* (Chapter 48), *Estuaries and Deltas* (Chapter 44) and *Salt Marshes* (Chapter 49); the cycling of nutrients is covered in *Estuaries and Deltas* (Chapter 44) and *Salt Marshes* (Chapter 49, but also Chapter 6).

Because of the very large scale of the services analysed in Part III, although they are influenced by human activities, they cannot be easily managed, and in certain cases they cannot be managed at all. The uptake of atmospheric CO₂ (Chapter 5) and the role of the ocean in the hydrological cycle (Chapter 4) are two examples of regulatory ecosystem services that cannot be managed or valued easily.

2. Accounting for the human benefits obtained from nature

Ecosystems can exist without humans in them, but humans cannot survive without ecosystems. Throughout history, humanity has made use of nature for food, shelter, protection and engaging in cultural activities. The intensity of humanity's use of nature has changed with the evolution of society and reached high levels with the introduction of modern technologies and industrial systems. Today, at a planetary scale, including the deepest ocean, no natural or pristine systems are found without people or unaffected by the impact of human activities; nor do social systems exist that can thrive without the support of nature. Social and ecological systems are truly interdependent and constantly co-evolving.

This fundamental connection between humans and nature has received different levels of recognition with regard to how we deal with the benefits humans extract from nature in economic terms. Extractive activities, e.g., of minerals, or of living natural resources, such as fibre, timber and fish, raise the issues of irreplaceability and sustainability. The use of nature is multifaceted and, as a norm, a given ecosystem can provide many goods and several services at the same time. For example, a mangrove ecosystem provides wood fibre, fuel, and nursery habitat for numerous species (provisioning services); it detoxifies and sequesters pollutants coming from upstream sources, stores carbon, traps sediment, and thus protects downstream coral reefs, and buffers shores from tsunamis and storms (regulating services); it provides beautiful places to fish or snorkel (cultural services); and it recycles nutrients and fixes carbon (supporting services; Lubchenco and Petes, 2010). When humans convert a natural ecosystem to another use, some ecosystem services may be lost and others services gained. Such a process gives rise to trade-offs between natural services and between these and services not derived from natural capital. For example, when mangroves are converted to shrimp ponds, airports, shopping malls, agricultural lands, or residential areas, new services are obtained: food production, space for commerce, transportation, and housing, but the original natural services are lost (Lubchenco and Petes, 2010).

Therefore, human benefits can be derived from a series of different activities that simultaneously affect the same ecosystem, but that are not necessarily connected with their harvesting or production processes. Sustainability requires that users take only a fraction of the resources, preserving in this way the natural capability of the ecosystem to regenerate the same resources, making them available for use by future generations. The appropriate spatial scale and the time sufficient to recover are part of the sustainability requirement. To extract anchovies (*Engraulis spp.*) or sardines (*Sardinops spp.*) that can regenerate their populations in three to eight years has different implications than to extract orange roughy (*Hoplostethus atlanticus*) from the top of seamounts that needs 100 to 150 years or more to recover.

3. The evolution of management tools

The increase in *“the magnitude of human pressures on the natural system has caused a transition from single-species or single-sector management to multi-sector, ecosystem-based management across multiple geographic and temporal dimensions. (...) Intensification of use of ecosystems increases interactions between sectors and production systems that in turn increase the number of mutual negative impacts (i.e., externalities)”* (Chapter 3).

Because all these processes take place in an integrated socio-ecological system, we have seen an expansion of scope in the decision-making process, incorporating the simultaneous consideration of several uses or industries at the same time and the livelihoods and other social aspects connected with this ensemble of activities. These approaches enable the consideration of tradeoffs among different uses and beneficiaries, enlarging the range of policy options. Only recently have regulatory instruments for better accounting for the indirect and cumulative impacts on natural systems of these multiple uses been incorporated into the management and regulation of human activities. Mobilized by a series of high-level World Conferences addressing these issues, in Stockholm 1972, Rio de Janeiro 1992, Johannesburg 2002, and Rio de Janeiro 2012, the international community has acted to advance and implement this enlarged scope of decision-making across all societies.

Assigning value to the human benefits obtained from nature is more easily done when the goods and services obtained are traded, thereby becoming part of commerce. Prices in different markets are readily available and comparisons are possible. It is not that simple, however, for certain types of benefits, for example, when subsistence livelihoods that do not enter into trade are concerned, or other intangible cultural, recreational, religious or spiritual benefits are involved.

However, the extraction of natural products and other human benefits from wild ecosystems can affect other processes inside the ecosystems that provide valuable permanent services to humanity that are not part of commerce. Examples include the production of organic matter and oxygen through primary production in the ocean, the protection of the coast by mangrove forests, the re-mineralization of decaying organic matter at the coastal fringes, and the absorption of heat and CO₂ by the ocean that has delayed the impacts of global warming. Furthermore, fluctuations in the provision of these natural services can have significant impacts on those natural products that are in commerce.

Climate patterns drive the magnitude and variability of the circulation and heat storage capacity of the surface layers of the ocean, as described in Chapters 4 and 5. The displacement of warm and cold water pools on the surface of the ocean feeds into the dynamics of the atmosphere, generating enormous transient fluctuations in weather patterns, such as the El Niño and La Niña cycles, that cascade down affecting the production of a series of goods and services, not only in the ocean, but most notably also on land. For example, El Niño adversely affects the availability and price of fishmeal and fish oil, also key components of the diet of carnivorous species in aquaculture (see Chapter 12).

4. Scientific understanding of ecosystem services

The fundamental connection between humans and nature has received uneven levels of recognition in how we deal in economic terms with the benefits humans extract from nature.

Humans derive many benefits from all aspects of the natural world. Some of these benefits are provided by nature without human intervention and some require human inputs, often with substantial labour and economic investment. The features and functions of nature which provide these services can be regarded as “natural capital”, and the way in which this natural capital is organized and how it functions in delivering benefits to humans, has led to these types of benefits being described as “ecosystem services”. The Millennium Ecosystem Assessment characterizes ecosystem services as: provisioning services (e.g., food, pharmaceutical compounds, building material); regulating services (e.g., climate regulation, moderation of extreme events, waste treatment, erosion protection, maintaining populations of species); supporting services (e.g., nutrient cycling, primary production); and cultural services (e.g., spiritual experience, recreation, information for cognitive development, aesthetics).

The rent for land or the royalties on mineral extraction are examples of long-established approaches adopted to account for uses of nature. They are based on a one-to-one relationship between one activity or industry and one natural source of the goods or services. The effect of other industries on the same ecosystem is not considered; neither are the impacts on other members of the social system affected by these industries.

To comprehensively account for human benefits and costs, “natural capital” needs to be considered alongside the assets that humans have themselves developed, whether in the form of individual skills (“human capital”), the social structures they have created (“social capital”) or the physical assets that they have developed (“built capital”). Managing the scale of the human efforts in using natural capital is crucial. The ecosystem-services approach allows decision-making to be integrated across land, sea and the atmosphere and enables an understanding of the potential and nature of trade-offs among services given different management actions.

The increasing magnitude of human pressures on the natural system has caused a transition from an emphasis on single-species or single-sector management to multi-sector, ecosystem-based management and hence to the explicit incorporation of human actions in socio-ecological systems management.

A number of variants of the ecosystem-services approach exist. Some emphasize the functional aspects of ecosystems from which people derive benefits. Others put more emphasis on their utilitarian aspects and seek to apply mainstream economic accounting methods, assigning them monetary values obtained in the market or using non-market methodologies. Yet others emphasize human well-being and ethical values. Looking at ecosystem services requires consideration of a wide range of scales, from the completely global (for example, the role of the oceans in distributing heat around the world; Chapter 5) to the very local (for example, the

protection offered by coral reefs to low-lying islands; Chapter 42).

Most studies conducted on marine and coastal ecosystem services have been focused locally and, in general, have not taken into account benefits generated further afield. An ecosystem-services approach can help with decision-making under conditions of uncertainty, and can bring to light important synergies and trade-offs between different uses of the ocean. However, attempting to assess the relationship between the operation of ecosystem services and the interests of humans requires a much broader management approach and an understanding that many aspects of the ocean have non-linear behaviour and responses. One difficulty is that to date no generally agreed classification of goods and services derived from natural capital exists that could facilitate the task. Another obstacle is that the range of factors involved at all levels might require the consideration of their interaction at the relevant scale, making their treatment very complex.

Some ecosystem services are more visible and easily understood than others. There is a risk that the less visible an ecosystem service is, the less it will be taken into account in decision-making. There is also a risk that ecosystem services that can be valued in monetary terms will be understood more easily than others, thus distorting decisions. Likewise, the time scales over which some ecosystem services will be affected by decisions will be much longer than others, which an approach with traditionally used discount rates would completely dismiss.

4.1 Information gaps

Describing and mapping the full range of ecosystem services at different scales requires much data on the underlying functions and structure of the way in which ecosystems operate. Although much work has been done, mostly on terrestrial ecosystems, this assessment draws attention in its various chapters to the gaps in the information needed to understand the way in which individual ecosystem services operate in the ocean and along the coasts. In addition to these specific gaps, a more general, overarching gap exists in understanding how all the individual ecosystem services fit together.

4.2 Capacity-building gaps

Many skills have yet to be developed that should integrate an understanding of the operation of ecosystems: knowledge is currently too fragmented between different specialisms.

Even in cases where the appropriate skills exist, some parts of the world lack institutions with the status, resources and commitment to make the necessary inputs into decision-making that will affect a range of ecosystem services from the oceans.

The many institutions that already exist to study the ocean also require new or enhanced abilities and connections, but can be expected to work together. Some international networks already exist to facilitate this. More are needed.

5. The ocean's role in the hydrological cycle

Water is essential for life and the existence of water in a liquid state on the surface of the earth is probably a critical reason why life is found on this planet and not on others. The presence of water on the surface of the earth is the combined result of the cosmic and geological history of the planet during its 4.5 billion years of existence. These processes, at human time-scales of thousands of years, can be considered as quasi-stable.

The ocean dominates the hydrological cycle. The great majority of the water on the surface of the planet, 97 per cent, is stored in the ocean. Only 2.5 per cent of the global balance of water is fresh water, of which approximately 69 per cent is permanent ice or snow and 30 per cent is ground water. The remainder 1 per cent is available in soil, lakes, rivers, swamps, etc. (Trenberth et al., 2007).

Water evaporates from the planet's surface, is transported through the atmosphere and falls as rain or snow. Rain is the largest source of fresh water entering the ocean ($\sim 530,000 \text{ km}^3 \text{ yr}^{-1}$). At the ocean-atmosphere interface, 85 per cent of surface evaporation and 77 per cent of surface rainfall occur (Trenberth et al., 2007; Schanze et al., 2010). The residence time of all water in the atmosphere is only seven days. It is fair to say that *"all atmospheric water is on a short-term loan from the ocean"*.

However, as with many other cycles, the water cycle is a dynamic system in a quasi steady-state condition. This steady-state condition can be altered if the factors controlling the cycle change. The great glaciations, or ice ages, are processes in which, due to interplanetary and planetary changes, huge amounts of water pass from the liquid to the solid state, altering the availability of liquid water on the surface of the earth and dramatically changing the sea level. As a consequence of the change in sea level, the shape of world coastlines and the amount of emerged (or submerged) land is drastically changed.

Changes are occurring today at an unprecedentedly fast but still uncertain rate. A warmer ocean expands and, being contained by rigid basins, the only surface that can move is the free surface in contact with the atmosphere, raising sea level.

In addition, the melting of ice due to a warmer atmosphere and a warmer ocean is increasing the volume of the ocean and in the long run will dominate the amount of total change in sea level.

As the ocean warms, evaporation will increase, and global precipitation patterns will change. The IPCC assess (AR 3, 2001; AR 4, 2007; and AR 5, 2013 and 2014) that the dynamic system of water on earth, driven by global warming, is changing sea level at a mean rate of 1.7 [1.5 to 1.9] mm yr^{-1} between 1901 and 2010, increased to 3.2 [2.8 to 3.6] mm yr^{-1} between 1993 and 2010 and, due to the changes in climate, will also change the patterns of rain on land.

Warming affects the polar ice caps, and changes in their melting affect the salinity of the ocean. This in turn can affect the ocean circulation, especially the thermohaline vertical circulation, also known as the "conveyor belt" (Chapter 5) and the operation of associated ecosystem services.

Due to the concentration of human population and built infrastructure in the coastal zone, sea level rise will seriously affect the way in which humans operate. The effects of sea-level rise will vary widely between regions and areas, with some of the regions most affected least able to manage a response.

Changes in water run-off will affect both land and sea. Salinity in the different parts of the ocean has changed over time, but is now changing more rapidly. Gradients in salinity are becoming more marked. Because the distribution of marine biota is affected by the salinity of the water that they inhabit, changes in the distribution of salinity are likely to result in changes in distribution of the biota.

Changes in run-off from land are affecting the input of nutrients to the ocean. These changes will also affect marine ecosystems, due to increases in the acidity of the ocean.

The warming of the ocean is not uniform. It is modulated by oscillations such as El Niño. These oscillations cause significant transient changes to the climate and ecosystems, both on land and at sea, and have serious economic effects. The variations in ocean warming will affect the interaction with the atmosphere and affect the intensity and distribution of tropical storms.

5.1 *Information gaps*

The sheer scale of the changes that are happening to the ocean makes present knowledge inadequate to understand all the implications. There are gaps in understanding sea-level rise, and interior temperature, salinity, nutrient and carbon distributions. Many of these gaps are being addressed as part of the world climate change agenda, but more detail about ocean conditions is needed for regional and local management decisions. The information gaps are particularly serious in some of the areas most seriously affected (e.g., the inter-tropical band).

5.2 *Capacity-building gaps*

Parts of the water cycle are still subject to uncertainties due to insufficient *in situ* measurements and observations. This is particularly true for surface water fluxes at the regional meso-scale. Because changes in the ocean's role on the hydrological cycle will be pervasive, all parts of the world need to have access to, and the ability to interpret, these changes. People and institutions with the necessary skills exist in many countries, but in many others they lack the status and resources to make the necessary input to decision-making.

6. Sea-Air Interaction

Most of the heat excess due to increases in atmospheric greenhouse gases is absorbed by the ocean. All ocean basins have warmed during recent decades, but the increase in heat content is not uniform; the increase in heat content in the

Atlantic during the last four decades exceeds that of the Pacific and Indian Oceans combined.

'Recent' warming (since the 1950s) is strongly evident in sea surface temperatures at all latitudes in all part of the ocean. Prominent structures that change over time and space, including the El Nino Southern Oscillation (ENSO), decadal variability patterns in the Pacific Ocean, and a hemispheric asymmetry in the Atlantic Ocean, have been highlighted as contributors to the regional differences in surface warming rates, which in turn affect atmospheric circulation.

The effects of these large-scale climate oscillations are often felt around the world, leading to the rearrangement of wind and precipitation patterns, which in turn substantially affect regional weather, sometimes with devastating consequences.

Compared with estimates for the global ocean, coastal waters are warming faster: during the last three decades, approximately 70 per cent of the world's coastline has experienced significant increases in sea surface temperature. Such coastal warming can have many serious consequences for the ecological system, including species relocation.

These changes are also affecting the salinity of the ocean: saline surface waters in the evaporation-dominated mid-latitudes have become more saline, while relatively fresh surface waters in rainfall-dominated tropical and polar regions have become fresher.

Approximately 83 per cent of global CO₂ increase is currently generated from the burning of fossil fuels and industrial activity. Forests and grasslands that usually absorb CO₂ from the atmosphere are being removed, causing even more CO₂ to be absorbed by the ocean. The ocean thus serves as an important sink of atmospheric CO₂, effectively slowing down global climate change. However, this benefit comes with a steep bio-ecological cost. When CO₂ reacts with water, it forms carbonic acid, leading to the ocean becoming more acid – referred to as "ocean acidification". Through various routes, this imposes an additional energy cost to calcifier organisms, such as corals and shell-bearing plankton, although this is by no means the sole impact of ocean acidification (OA).

OA is not a simple phenomenon nor will it have a simple unidirectional effect on organisms. Calcification is an internal process that in the vast majority of cases does not depend directly on seawater carbonate content, since most organism use bicarbonate, which is increasing under acidification scenarios, or CO₂ originating in their internal metabolism. It has been demonstrated in the laboratory and in the field that some calcifiers can compensate and thrive in acidification conditions.

Without significant intervention to reduce CO₂ emissions, by the end of this century, average surface ocean pH is expected to be below 7.8, an unprecedented level in recent geological history. These changes will be recorded first at the ocean's surface, where the highest biodiversity and productivity occur.

The abundance and composition of species may be changed, due to OA, with the potential to affect ecosystem function at all trophic levels. Consequential changes in ocean chemistry could occur as well. Economic studies have shown that potential losses at local and regional scales may be catastrophic for communities and national

economies that depend on fisheries.

6.1 *Information Gaps*

Regular monitoring of relevant fluxes across the ocean-atmosphere interface needs to be maintained, including the regular assessment of the accumulation of heat and CO₂ (changes in alkalinity) in the surface layers of the ocean. The state of knowledge regarding OA is only currently moving beyond the nascent stage. Therefore several major information gaps are yet to be filled. Neither all areas of the globe nor all potentially affected animal and plant groups have yet been covered in terms of research. The full range of response and adaptation of organisms, although an active field of research, is very seldom known.

Additional information is required around the effects of mean changes in OA versus changes in variability and extremes; as well as multi-generational effects and adaptive potential of different organisms (Riebesell and Gattuso, 2015; Sunday et al., 2014). The tolerance level by individual organisms to changes in pH must be understood in situ rather than exclusively in laboratory conditions, along with the possible consequential changes in competition by organisms for resources. The effects of potential loss of keystone species within ecosystems are not yet clear, neither are the chemical changes due to pH.

The future agenda of research in OA should include integrating knowledge on multiple stressors, competitive and trophic interactions, and adaptation through evolution and moving from single-species to community assessments (Sunday et al., 2014). Future economic impacts of OA are being studied but much more needs to be done. Monitoring and management strategies for maintaining the marine economy will also be needed. In this regard, it has been suggested that future OA research could focus on species related to ecosystem services in anticipation that these case studies might be most useful for modellers and managers (Sunday et al. 2014).

6.2 *Capacity-Building Gaps*

OA was put in evidence only through long-term observational programmes coordinated by the international research community. To monitor OA on a regular basis, these international efforts need to be continued and institutionally consolidated. OA adaptation is a demanding field of research that requires significant infrastructure (i.e. mesocosm experimental facilities) and highly qualified human resources. These are not readily available in all regions of the world. Further understanding of the scope of adaptation capabilities to OA by plants and animals, the application of mitigation strategies, or the successful management of productive systems cultivating organisms with calcareous exo-skeletons that are regularly exposed to corrosive waters sources, require the existence of these capabilities in place.

7. Primary Production, Cycling of Nutrients, Surface Layer and Plankton

“Marine primary production” is the photosynthesis of plant life in the ocean to produce organic matter, using the energy from sunlight, and carbon dioxide and nutrients dissolved in seawater. Carbon dioxide dissolved in seawater is drawn from the atmosphere. Oxygen is produced as a by-product of photosynthesis both on land and in the ocean. Of the total annual oxygen production from photosynthesis on land and ocean, approximately half originates in marine plants. The plants involved in this process range from the microscopic phytoplankton to giant seaweeds. On land, the other 50 per cent of the world’s oxygen originates in the photosynthesis from all plants and forests. Present-day animals and bacteria rely on present-day oxygen production by plants on land and in the ocean as a critical ecosystem service that keeps atmospheric oxygen from otherwise declining.

Marine primary production, as the primary source of organic matter in the ocean, is the basis of nearly all life in the oceans, playing an important role in the global cycling of carbon. Phytoplankton absorbs about 50 billion tons of carbon a year, and large seaweeds and other marine plants (macrophytes) about 3 billion tons. At a planetary level, this ecological function plays an important role in removing CO₂ – one of the significant greenhouse gases – from the atmosphere. Total annual anthropogenic emissions of CO₂ are estimated at 49.5 billion tons, one-third of which is taken up by the ocean. This ecological service provided by the ocean has so far prevented warming of the planet above 2° C.

Marine primary production also plays a major role in the cycling of nitrogen around the world. A moderate level of uncertainty exists about the extent to which the ocean is currently a net absorber or releaser of nitrogen.

Anthropogenic nutrient loading in coastal waters, ocean warming, ocean acidification, and sea-level rise are driving changes in the phenology (see below) and spatial pattern of phytoplankton and in net primary production as well as in nutrient cycles. These changes are threatening the provision of several ecosystem services at different scales (local, regional).

Changes in macrophyte net primary production and their impacts (losses of habitat and of carbon sinks) are also well documented.

Changes in net primary production by phytoplankton or in the nutrient cycles in the upper levels of the world ocean have been the subject of recent debate. Some analyses suggested a diminishing trend in world primary production (Boyce et al., 2010). However, this result was challenged by Rykaczewski and Dunne (2011) and finally reviewed by the original authors (Boyce, et al., 2014). After recalibration of the datasets, despite an overall decline of chlorophyll concentration over 62 per cent of the global ocean with sufficient observations, they describe a more balanced picture between regional increases and decreases of primary production, without an overall globally pervasive negative trend. The wider consequences of this long-term trend are presently unresolved.

The efficient use of primary production to support animals at higher levels in the food web depends on a good relationship between the timing of bursts of primary

production and breeding periods of zooplankton and planktivorous fish. The phenology of species, i.e., the timing of events in the life cycle of species, plays a significant role here. Changes in the phenology of plankton species and planktivorous fish due to ocean warming is starting to produce significant mismatches and could produce many more, affecting the local level of production in the ocean.

Warming of the upper ocean and associated increases in vertical stratification may lead to a major decrease in the proportion of primary production going to zooplankton and planktivorous fish, and an increase in the proportion of phytoplankton being broken down by microbes without first entering the higher levels of the food web. Such a trend would reduce the carrying capacity of the oceans for fisheries and the capacity of the oceans to mitigate the impacts of anthropogenic climate change.

Coastal eutrophication (see Chapter 20) is likely to lead to an increase in the numbers and area of dead zones and toxic phytoplankton blooms. Both can have serious effects on the supply to humans of food from the sea.

Nanoparticles (microscopic fragments of plastic and other anthropogenic substances) pose a potential serious threat to plankton and the vast numbers of marine biota which depend on them.

Increases in nitrogen inputs to the ocean and in sea temperatures may have serious impacts on the type (species, size) and amount of marine primary production, although much debate still occurs about the scale of this phenomenon. Different responses are likely to be found in different regions. This may be particularly significant in the Southern Ocean, where a major drop in primary production has been forecast.

7.1 *Information gaps*

Completing a worldwide observing system for the biology and water quality of the ocean that could provide cost-effectively improved information to future assessments under the Regular Process is seen as an important gap. Routine and sustained measurements across all parts of the ocean are needed on planktonic species diversity, chlorophyll *a*, dissolved nitrogen and dissolved biologically active phosphorus. Due to their ability to enter into marine food chains, with a potential impact on both marine organism and human health, plastic microparticles need to be systematically monitored.

Without this additional information, it will not be possible to understand or predict the changes that will occur due to the accumulated and combined effect of several drivers. Some information can be derived from satellite remote sensing, but *in situ* observations at the surface and especially at sub-surface levels are irreplaceable, given the fact that the ocean is essentially opaque to electromagnetic radiation, the medium *par excellence* of remote sensing.

7.2 *Capacity-building gaps*

The gathering of such information requires a worldwide network for data collection. Both a Global Ocean Observing System (GOOS) and a Global Biodiversity Observation Network (GEO BON) are currently being developed to collect biological and ecologically relevant information that, if completed, would fill in some of the information gaps described above. The capacities to participate in these systems need to be extended worldwide. It is also important to develop the skills to explain to decision-makers and the general public the importance of plankton and its significance for the ecosystem services provided by the ocean.

8. Ocean-sourced carbonate production

Many marine organisms secrete calcium carbonate to produce a hard skeleton. These vary in size from the microscopic plankton, through corals, to large mollusc shells. Carbonate production by corals is particularly important, because the reefs that they form are fundamental to the existence of many islands and some entire States.

Sand beaches are also often formed by the fragmented shells of marine biota. Beaches are dynamic structures, under constant change from the effects of the oceans; hence a constant supply of new sand of this kind is needed to sustain them.

Sea-level rise will particularly affect beaches, causing them to move inland. In the case of small islands, this may diminish the already limited inhabitable area. Such changes may also be affected by the availability of new supplies of sand. Such changes could be very serious for States or parts of States comprised of atolls.

The impact of climate change on the rate of biogenic production of carbonate sediment is also little understood, but it seems likely to have negative consequences. Ocean warming has already led to the death (bleaching) of some coral reefs or parts of them.

The acidification of the ocean may lead to significant changes in the biogenic production of calcium carbonate, with implications for the future of coral reefs and shell beaches.

8.1 *Knowledge gaps*

Long-term data are lacking on the formation and fate of reef islands and shell beaches. Information is particularly lacking on the links between the physical structures and the environmental circumstances that may affect changes in these structures.

8.2 *Capacity-building gaps*

A gap often exists in the capacities of people living on atolls and in countries depending heavily on tourism from shell beaches to understand the drivers that

shape the development of these structures. Without such capacities it is impossible to bring the factors affecting the future of these structures into the making of decisions which can fundamentally affect them.

9. Aesthetic, cultural, religious and spiritual ecosystem services derived from the marine environment

The development of human culture over the centuries has been influenced by the ocean, through transport of cultural aspects across the seas, the acquisition of cultural objects from the sea, the development of culture to manage human activities at sea, and the interaction of cultural activities with the sea.

The ocean has been and continues to be the source of prized materials for cultural use, for example: pearls, mother-of-pearl, coral, and tortoise-shell. Some marine foodstuffs are also ingredients in culturally significant dishes. The high value given to many of these culturally significant objects can lead to their over-exploitation and the long-term damage of the ecosystems that supply them. The sea is an important element in many sites of cultural significance. Forty-six marine and coastal sites are included in the UNESCO World Heritage List.

Even where sites do not reach this high threshold of cultural significance, great aesthetic and economic importance may be attached to preserving the seascape and coastal views. This concern should also be extended to the tangible cultural heritage of past human interaction with the sea and of past human activities in periods of low sea levels. This can be particularly significant in making decisions about the location of new offshore installations.

The intangible cultural heritage of human interaction with the sea is also important. Ten per cent of the items on the UNESCO List of Intangible Cultural Heritage in Need of Urgent Safeguarding involve the ocean. Important cultural areas are derived from the need of humans to operate on the ocean, leading to skills such as navigation, hydrography, naval architecture, chronometry and many other techniques.

The need is increasingly being recognised to understand the knowledge systems developed by many indigenous peoples to understand and manage their interactions with the marine environment.

9.1 Knowledge gaps

In the current fast-changing world, it is important to record much traditional knowledge before it is lost.

9.2 Capacity-building gaps

For cultural goods derived from the sea, a gap exists in many parts of the world for the skills needed to identify and implement potential opportunities to turn local marine objects to good account. Means to support traditional cultural practices so

that they endure for future generations need to be provided, and anthropological skills to record and interpret them are also important.

10. The ecosystem services concept and the United Nations and other systems of environmental-economic accounting

As can be seen from the foregoing, there is a general need to bring together information about ecosystem services, in a way which allows judgments to be made about trade-offs. In 1992, the United Nations Conference on Environment and Development (UNCED) called for the implementation of integrated environmental-economic accounting in countries, to complement national accounts by accounting for environmental losses and gains. As a consequence, the United Nations Statistics Division (in charge of maintaining the framework as well as the world standards for the System of National Accounts) led the development of the System of Environmental-Economic Accounting (SEEA) under the auspices of the United Nations Committee of Experts on Environmental-Economic Accounting (UNCEE). The SEEA Central Framework was adopted as an international standard by the United Nations Statistical Commission at its 43rd Session in 2012 and the SEEA Experimental Ecosystem Accounting was endorsed by the same commission at its 44th session in 2013 (<http://unstats.un.org/unsd/envaccounting/seea.asp>). Both the SEEA Central Framework and SEEA Experimental Ecosystem Accounting use the accounting concepts, structures and principles of the System of National Accounts (SNA).

The SEEA provides a way of organizing information in both “physical terms” and “monetary terms” using consistent definitions, concepts and classifications. Physical measures and valuation of ecosystem services and ecosystem assets are discussed in the SEEA Experimental Ecosystem Accounting. Those ecosystem services and ecosystem assets are not typically traded on markets, as explained in Chapter 3, and are difficult to measure because observed prices cannot be used to measure these assets and services as in standard economic accounting (Statistics Division of the United Nations, 2012). Although concepts and methods are still experimental, many United Nations Member States have engaged in ambitious programmes to apply these new concepts (Figure 1).

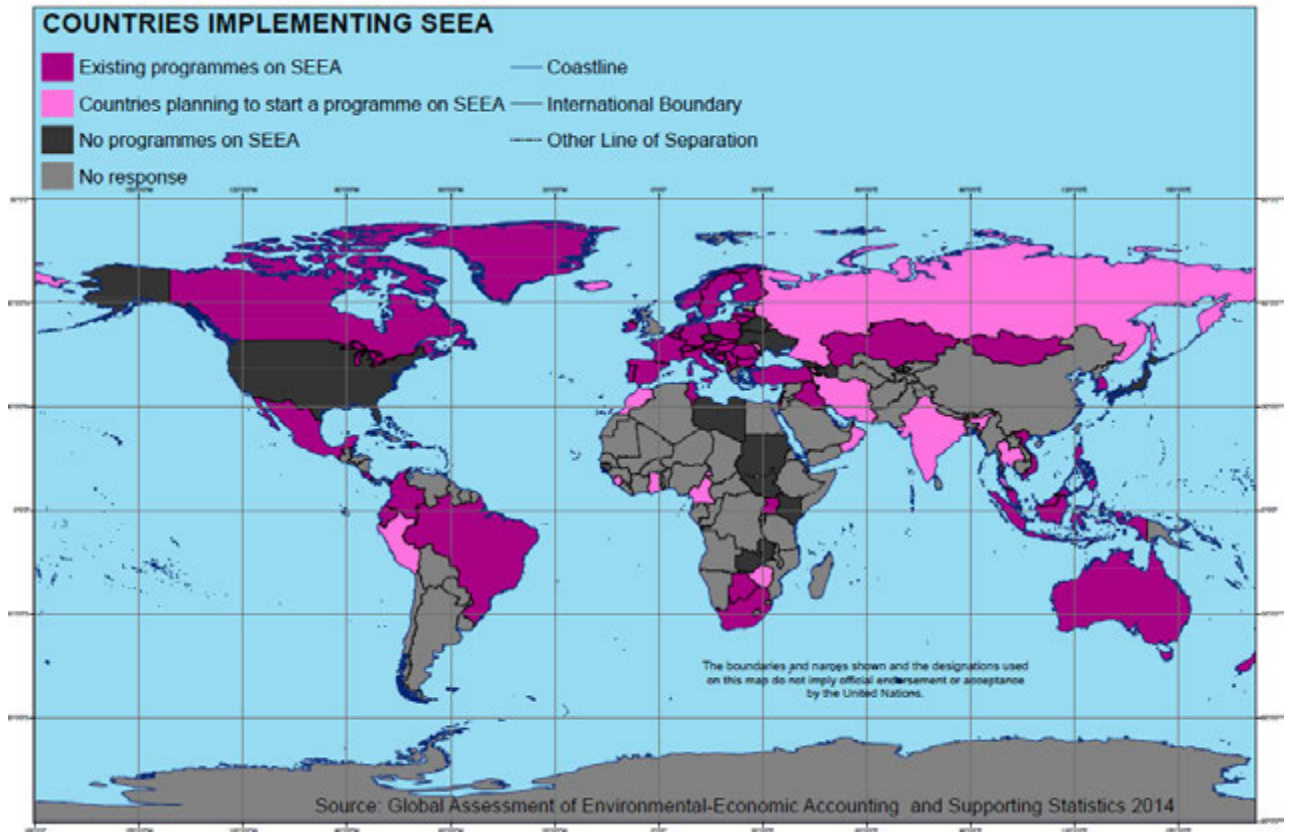

Figure 1. Countries of the world implementing natural capital accounting programmes. The map is provided by the United Nations Statistics Division.

Simplified ecosystem capital accounts are currently being implemented in Europe by the European Environment Agency, in cooperation with Eurostat, as one of the responses to recurrent policy demands in Europe for accounting for ecosystems and biodiversity (The Economics of Ecosystems and Biodiversity:TEEB). The European Union has developed the MAES programme, for Mapping and Assessment of Ecological Services in the 27 countries of the European Union (<http://www.eea.europa.eu/publications/an-experimental-framework-for-ecosystem>).

The United Kingdom Government has recently completed a national ecosystem assessment (UK National Ecosystem Assessment, 2011) and, building on this report, has made a commitment to include the value of natural capital and ecosystems fully into the United Kingdom environmental accounts by 2020.

11. Conclusions

Long-established approaches adopted to account for uses of nature, like rent or royalties, are based on a one-to-one relationship between one activity or industry and one natural source of the goods or services. The effect of other industries on the

same natural source is not considered; neither are the impacts on other members of the social system affected by these industries.

Traditionally these invisible benefits and costs are mostly hidden in the “natural system”, and usually are not accounted for at all in economic terms. The emergence and evolution of the concept of ecosystem services is an explicit attempt to better capture and reflect these hidden or unaccounted benefits and costs, expanding the scope of policy options already available in integrated management approaches through the consideration of the trade-offs among different uses and beneficiaries.

The ecosystem services approach has proven to be very useful in the management of multi-sector processes and is informing today many management and regulatory processes around the world, especially on land. However, the methodologies and different approaches to assess and measure ecosystem services, or to assign them value, as presented in Chapter 3, are far from benefiting from a common set of standards and a consensual framework for their application. Furthermore, as stated in Chapter 3, *“On land, negative impacts can be partially managed or contained in space. However, in the ocean, due to its fluid nature, impacts may broadcast far from their site of origin and are more difficult to contain and manage. For example, there is only one Ocean when considering its role in climate change through the ecosystem service of “gas regulation”.*

In Chapters 4 to 8, the ecosystems services analyzed are provided on different spatial and temporal scales. Most of those ecosystems are described only on large to very large scales, many of them, indeed, at the planetary scale. In contrast, much of the work on valuing ecosystem services in the ocean has focused on smaller systems, for example, on assessing and valuing the services provided by marine parks, marine reserves and marine protected areas, in order to enable local judgments (including such elements as making local planning decisions or establishing fees to charge to visitors). Despite a significant amount of work on ecosystem-services valuation for the ocean and coasts, as reported in Chapter 3, evidence of its broader application in decision-making at the larger scales is still very limited.

Part IV

Assessment of Marine Biological Diversity and Habitats

One of the main services provided by the oceans is food for human consumption, resulting in benefits for human health and nutrition, economic returns, and employment. These benefits can be enjoyed sustainably, but only if the intensity and nature of harvesting and culture are appropriately planned and managed, and access to the potential benefits is made available.

Part IV of the WOA reviews these issues under the headings of the Ocean as a source of food (Chapter 10), Capture fisheries (Chapter 11), Aquaculture (12), Fish stock propagation (13), Specialized marine food sources (14), and Social and economic aspects of fisheries (15). Chapter 10 summarizes the contributions of seafood¹ to human nutrition and alleviation of hunger, discussing both patterns at regional and sub-regional scales and their trends over time. Chapter 11 looks in more detail at capture fisheries, presenting trends over time both globally and regionally in overall harvest levels and fishing gear used. It also looks at major species harvested at these scales, and the sustainability of use of the harvested species. It also looks at the ecosystem effects of fishing, considering the nature, levels, and, where information is available, trends, in effects on bycatch species, marine food webs, and habitats. Chapter 12 reviews the same types of information for aquaculture, considering overall production and production of key species at global and regional scales, and, with regard to ecosystem effects, considers issues such as introduction of alien species, local degradation and conversion of habitats, use of antibiotics, genetic manipulations, and other similar factors in this form of production. Chapters 13 and 14 address focused issues of artificial propagation of fish and use of marine plants and species other than fish and invertebrates as food. Chapter 15 then assesses the magnitude of economic and social benefits from fisheries and aquaculture. The assessment again looks at trends both globally and regionally, and in addition at differences in the nature, scales, and distribution of social and economic benefits of large-scale and small-scale fisheries. The role of trade, hunger, poverty, worker safety and related issues are all addressed, with particular attention to the interactions of trade, hunger, and poverty alleviation in how benefits may be taken and distributed.

The synthesis in Chapter 16 brings these aspects of the ocean as a source of food together. It integrates the perspectives of the sustainability of harvested and cultured stocks and the impacts on marine ecosystems from fishing and aquaculture, with the perspectives of economic benefits and social / livelihoods benefits.

¹ Both the terms “seafood” and “fish” are used to include a variety of marine sources of food, depending on the source being consulted. In Part IV both terms are used generically to refer to all types of fish (including both bony and cartilaginous species) and invertebrates consumed as food. When information is presented on a subset of these taxa, the text is explicit about the intended group of species.

Chapter 10. The Oceans as a Source of Food

Contributors: Beatrice Ferreira (Co-Lead member), Jake Rice (Lead member), Andy Rosenberg (Co-Lead member)

1. Introduction

One of the main services provided by the oceans to human societies is the provisioning service of food from capture fisheries and culturing operations. This includes fish, invertebrates, plants, and for some cultures, marine mammals and seabirds for direct consumption or as feed for aquaculture or agriculture. These ocean-based sources of food have large-scale benefits for human health and nutrition, economic returns, and employment.

A major challenge around the globe is to obtain these benefits without compromising the ability of the ocean to continue to provide such benefits for future generations, that is, to manage human use of the ocean for sustainability. In effect, this means that capture fisheries and aquaculture facilities must ensure that the supporting stocks are not overharvested and the ecosystem impacts of the harvesting or aquaculture facilities do not undermine the capacity of a given ocean area to continue to provide food and other benefits to society (see Chapter 3). Further, the social and economic goals of the fisheries and aquaculture should fully consider sustainable use in order to safeguard future benefits.

2. Dimensionality of the oceans as a source of food

Capture fisheries and aquaculture operate at many geographical scales, and vary in how they use marine resources for food production. Here, “small-scale” refers to operations that are generally low capital investment but high labour activities, relatively low production, and often family or community-based with a part of the catch being consumed by the producers (Béné et al., 2007; Garcia et al., 2008). Large-scale operations require significantly more capital equipment and expenditure, are more highly mechanized and their businesses are more vertically integrated, with generally global market access rather than focused on local consumption. These descriptions are at the ends of a spectrum continuum of scales with enormous variation in between.

The geography of harvesting and food production from the sea is also important. Williams (1996) documents that until the mid-1980s, developed countries dominated both harvesting and aquaculture, but thereafter developing countries became

dominant, first in capture fisheries and later in mariculture. A general division of large-scale fisheries and mariculture in the developed world and small-scale operations in the developing world was never absolute. Small-scale operations were present in all areas, but highly mobile large-scale fisheries are increasingly operating around the globe (Beddington et al., 2007; World Bank/FAO, 2012), and large aquaculture facilities for export products are increasing in the developing world (Beveridge et al., 2010; Hall et al., 2011).

3. Trends in capture fisheries and aquaculture

According to FAO statistics reported by member States, production of fish from capture fisheries and aquaculture for human consumption and industrial purposes has grown at an annual rate of 3.4 per cent for the past half century from about 20 to above 162 mmt by 2013 (FAO, 2014a; FAO, 2015). Over the last two decades though, almost all of this growth has come from increases in aquaculture production. Chapters 11 and 12 of this Assessment describe the time course of capture fisheries and aquaculture development over the last several decades.

Globally aquaculture production has increased at approximately 8.6 per cent per year since 1980, to reach an estimated 67 mmt in 2012, although the rate of growth has slowed slightly in recent years. Of that total, however, more than 60 per cent is from freshwater aquaculture. In addition nearly 24 million tons of aquatic plants (mostly seaweeds) were cultured on 2012. Total marine aquaculture production is growing slightly faster than freshwater aquaculture in all regions, but, like freshwater aquaculture, over 80 per cent of production is concentrated in a few countries, particularly China, as well as some other east and south Asian countries (FAO, 2014a).

Some of the fish taken in capture fisheries are used as feed in aquaculture, fishmeal, fish oil and other non-human consumption uses. Thus the total harvest from capture fisheries and production from mariculture is not all available for human consumption. This use of fish is debated with regard to the best use of production from capture fisheries (Naylor et al., 2009; Pikitch et al., 2012). The total amount of fish used for purposes other than direct consumption has been declining slowly since the early 2000s from about 30 per cent to just over 20 per cent of total capture fishery harvest in 2012 (FAO 2014a). Consequently, fish for human consumption has been increasing slightly faster than the human population, increasing the importance of fish in meeting food security needs (HLPE, 2014).

Finally, fishing is also undertaken for recreational, cultural and spiritual reasons. Even though fish taken for these purposes may be consumed, they are addressed in chapters 8 and 27, and will not be considered further here.

4. Value of marine fisheries and mariculture

Fish harvested or cultured from the sea provide three classes of benefits to humanity: food and nutrition, commerce and trade, and employment and livelihoods (see Chapter 15 for additional detail). All three classes of benefits are significant for the world.

4.1 *Food and nutrition*

According to FAO (2014a) estimates, fish and marine invertebrates provide 17 per cent of animal protein to the world population, and provide more than 20 per cent of the animal protein to over 3 billion people, predominantly in parts of the world where hunger is most widespread. Asia accounts for 2/3 of the total consumption of fish. However, when population is taken into account, Oceania has the highest per capita consumption (approximately 25 kg per year), with North America, Europe, South America and Asia all consuming over 20 kg per capita, and Africa, Latin America and the Caribbean are around 10 kg per capita. Per capita consumption does not capture the full importance of the marine food sources to food security, however. Many of the 29 countries where these sources constitute more than a third of animal protein consumed are in Africa and Asia. Of these, the United Nations has identified 18 as low-income, food deficient economies (Karawazuka Béné, 2011, FAO, 2014b). Thus fish and invertebrates, usually from the ocean, are most important where food is needed most.

Table 1. Total and per capita food fish supply by continent and economic grouping in 2011¹

	Total food supply (million tonnes live weight equivalent)	Per capita food supply (kg/year)
World	132.2	18.9
World (excluding China)	86.3	15.3
Africa	11.0	10.4
North America	7.6	21.7
Latin America and the Caribbean	5.9	9.8
Asia	90.3	21.5
Europe	16.4	22.1
Oceania	0.9	25.0
Industrialized countries	26.4	27.0
Other developed countries	5.6	13.7
Least-developed countries	10.3	12.1
Other developing countries	89.9	18.9
LIFDCs ²	21.2	8.6

¹ Preliminary data

² Low-income food-deficit countries.

Source: FAO Information and Statistics Branch, Fisheries and Aquaculture Department, 2015.

Not only are marine food sources important for overall food security, fish are rich in essential micronutrients, particularly when compared to micronutrients available when meeting human protein needs from consumption of grains (WHO 1985). Compared to protein from livestock and poultry, fish protein is much richer in poly-unsaturated fatty acids and several vitamins and minerals (Roos et al., 2007, Bonhan et al., 2007). Correspondingly, direct health benefits relative to reducing risk of obesity, heart disease, and high blood pressure have been linked to diets rich in fish (Allison et al., 2013).

It should be noted, however, that there are also potential health risks from consumption of seafood, particularly as fish at higher trophic levels may concentrate environmental contaminants, and there are occasional outbreaks of toxins in shellfish. Substantial effort is invested in monitoring for these risks, and avoiding the conditions where probability of toxin outbreaks may increase. More broadly, food safety is a key worldwide challenge facing all food production and delivery sectors including all parts of the seafood industry from capture or culture to retail marketing. This challenge of

course faces subsistence fisheries as well. In the food chain for fishery products, risk of problems needs to be assessed, managed and communicated to ensure problems can be addressed. The goal of most food safety systems is to avoid risk and prevent problems at the source. The risks come from contamination from toxins or pathogens and the severity of the risk also depends on individual health, consumption levels and susceptibility. There are international guidelines to address these risks but substantial resources are required in order to continue to build the capacity to implement and monitor safety protocols from the water to the consumer.

Because of the several limiting factors affecting wild fish catch today (see Chapter 11), it is forecasted that aquaculture production will supply all of the increase in fish consumption in the immediate future. Production is projected to rise to 100 million tons by 2030 (Hall et al., 2011) and to 140 million tons by 2050, if growth continues at the same rate.

Estimates by the World Resources Institute (Waite et al., 2014), assuming (a) the same mix of fish species, (b) that all aquaculture will go to human consumption and (c) that there will be a 10 per cent decrease in wild fish capture for food, indicate that the growth in aquaculture production cited above would boost fish protein supply to 20.2 million tons, or 8.7 million tons above 2006 levels. This increase would meet 17 per cent of the increase in global animal protein consumption required by 9.6 billion people for 2050 (Waite et al. 2014).

4.2 *Commerce and trade*

The total value of world fish production from capture fisheries and marine and freshwater aquaculture was estimated to be 252 billion USD in 2012, with the “first-sale” value of fish from capture fisheries at approximately 45 per cent of that value (FAO 2014a). Consistent accounting for “value” has been elusive, providing alternative value estimates that are as much as 15-20 per cent greater (e.g., Dyck and Sumalia, 2010). The different possible accounting schemes make it correspondingly difficult to estimate the growth rate of economic value of fisheries, but all approaches project the value to have increased consistently for decades and likely to continue to increase. This increase in economic value is attributable to several factors, including increased production (primarily from aquaculture), an increasing proportion of catches directed to human consumption, improvements in processing and transportation technologies that add to the product’s value, and changing consumer demand (Delgado et al 2003). Several factors contribute to increasing consumer demand. The factors include increasing awareness of health benefits of eating fish, increasing economic consumer power in developed and developing economies, and market measures such a certification of sustainably harvested fish and aquaculture products (FAO 2014a).

Just as total per capita consumption of fish underestimates the importance of fish to food security in many food-deficit countries, the total economic value of fish sales underrepresents the value of fish sales to low-income parts of the world. There is a

“cash crop” value to fish catches of even small-scale subsistence fishers. Most of this “value” is not captured in the formal economic statistics of countries, and probably varies locally and seasonally (Dey et al., 2005). However studies have shown that the selling or trading of even a portion of their catch represents as much as a third of the total income of subsistence fishers in some low income countries (Béné et al., 2009).

4.3 *Employment and livelihoods*

These differences between large-scale and small scale fishers are particularly important in considering employment benefits from food from the ocean. Estimates of full-time or part-time jobs derived from fishing, vary widely, with numbers ranging from 58 million to over 120 million jobs being available (BNP 2009, FAO 2014a). All sources agree that over 90 per cent are employed in small-scale fisheries. This includes jobs in the processing and trading sectors, where opportunities for employment of women are particularly important (BNP 2009). The value-chain jobs are considered to nearly triple the employment benefits from fishing and mariculture, compared to direct employment from harvesting (World Bank 2012). All sources report that more than 85 per cent of the employment opportunities are in Asia and a further 8 per cent in Africa, largely in income-deficit countries or areas. It is even harder to track direct and value-chain employment from small-scale aquaculture production and break out the portion that is derived from marine aquaculture (Beveridge et al., 2010), but recent estimates for employment from aquaculture exceed 38 million persons (Phillips et al., 2013).

Of the 58.3 million people estimated to be employed in fisheries and aquaculture (4.4 per cent of total estimated economically active people), 84 per cent were in Asia and 10 per cent in Africa. Women are estimated to account for more than 15 per cent of people employed in the fisheries sector (FAO, 2014).

When full- or part-time participants in the full value-chain and support industries (boat-building, gear construction, etc.) of fisheries and aquaculture and their dependents are included, FAO estimated that between 660 and 820 million persons derive some economic and/or livelihood benefits (FAO 2012, Allison 2013). Direct employment in fishing is also growing over 2 per cent per year, generally faster than human population growth (Allison, 2013). However, there has been a shift from 87 per cent in capture fisheries and the rest in aquaculture (primarily freshwater) in 1990, to approximately a 70:30 division in 2010, with slightly faster growth in employment in mariculture than in freshwater aquaculture (FAO, 2012).

Trade in fishery products further complicates efforts to evaluate trends in the contribution of the oceans to human well-being. Fish is one of the most heavily traded food commodities on the planet, with an estimated 38 per cent of fishery production by 2010, up from 25 per cent in 1976 (FAO, 2012). This represents about 10 per cent of international agricultural exports. The direct value of international exports was over 136 billion USD in 2012, up 102 per cent in just 10 years (FAO, 2014a. <http://www.fao.org/3/a-i4136e.pdf>); European Union (EU) countries alone imported

more than 514 billion in fish products in 2013, although slightly over half of that was from trade among EU Member States (<http://www.fao.org/3/a-i4136e.pdf>). Fish trade is truly global, with FAO recording fish and fishery products exported by 197 countries, led by China, which contributes 14 per cent of the total exports.

Developing countries contribute over 60 per cent by volume and over 50 per cent by value of exports of fish and fish products. Although this trade generates significant revenues for developing countries, through sales, taxation, license fees, and payment for access to fish by distant water fleets, there is a growing debate about the true benefits to the inhabitants of these countries from these revenue sources (Bostock et al., 2004; World Bank 2012). The debate centres on whether poor fishers would benefit more from personal or community consumption of the fish than from sales of the fish to obtain cash or credit. The issue is complicated by the leasing of access rights for foreign vessels which may compete for resources with coastal small scale fishers. With small-scale and large-scale fisheries each harvesting about half of the world's fish, resolving the relative importance of large-scale and small-scale fisheries to food security, in an increasingly globalized economy, is complex. Reviews found the issue to be polarized in the early 2000s (FAO 2003; Kurien, 2004), and there has been little convergence of views over the ensuing decade (HLPE, 2014).

5. Impacts of fisheries and mariculture, on marine ecosystems

Harvesting or culturing marine fish, invertebrates or plants necessarily has at least direct and immediate, and often indirect and longer-term impacts on marine ecosystems. For over a century fisheries experts have sought ways to evaluate the short-term and long-term sustainability of varying levels of fish harvests (Smith 1994), and to manage fisheries to keep these harvests within sustainable bounds (Garcia et al., 2014). Assessing and managing the wider ecosystem impacts of fisheries and aquaculture is even more challenging (Garcia et al., 2014). These impacts may range from loss of habitat due to destructive fishing practices to impacts on the structure of marine food webs by selectively harvesting some species that play a key role in the integrity of a given ecosystem. The fact that these effects may be difficult to quantify in no way diminishes their importance in sustaining the capacity of the oceans to provide food and other benefits to human society. Moreover, the scope of assessments of impacts continues to expand, as life cycle analyses are introduced into fisheries (Avadí and Fréon, 2013). Results indicate that, for example, the carbon footprint of a kg of fish at market depends greatly on modes of capture and transport. However, the carbon footprint is often substantially lower than the footprint of a kg of poultry or livestock (Mogensen et al., 2012). Other chapters in this Assessment, primarily in Part VI, consider a broad range of impacts on the ocean of human activities. Since food production from the ocean is such an important benefit, particular care must be taken to ensure that sustained capacity to produce food from fisheries and aquaculture is not diminished.

6. Conclusions

This chapter sets the stage for assessing the role of the oceans as a source of food. The chapters to follow will assess in depth the ways that food is taken from the sea. Each chapter will consider the trends in yields, resources, economic benefits, employment, and livelihoods, the interactions among the trends, and their main drivers, on global and regional scales as appropriate. They will also look at the main impacts of the various food-related uses of the ocean on biodiversity – both species and habitats. Some of these interactions will also be considered, from the perspective of the affected components of biodiversity, in Part VI of the World Ocean Assessment. Each chapter will also consider the main factors that affect the trends in benefits, resources used and impacts. Together a picture will emerge of the importance of the ocean as a source of food, and of fisheries and mariculture as sources of commerce, wealth, and livelihoods for humankind, with a particular focus on the world's coastal peoples.

Chapter 11. Capture Fisheries

Writing team: Fábio Hazin, Enrique Marschoff (Co-Lead member), Beatrice Padovani Ferreira (Co-Lead member), Jake Rice (Co-Lead member), Andrew Rosenberg (Co-Lead member)

1. Present status and trends of commercially exploited fish and shellfish stocks

Production of fish from capture fisheries (Figure 1) and aquaculture for human consumption and industrial purposes has grown at the rate of 3.2 per cent for the past half century from about 20 to nearly 160 million mt by 2012 (FAO 2014).

Figure 1. Evolution of world's capture of marine species. From SOFIA (FAO 2014).

Globally, marine capture fisheries produced 82.6 million mt in 2011 and 79.7 million mt in 2012. The relatively small year-to-year variations largely reflect changes in the catch of Peruvian anchoveta, which can vary from about 4 to 8 million tons *per annum*.

In 2011 and 2012, 18 countries accounted for more than 76 per cent of global marine harvests in marine capture fisheries (Table 1). Eleven of these countries are in Asia.

Table 1. Marine capture fisheries production per country. From SOFIA (FAO, 2014).

Marine capture fisheries: major producer countries

In 2011-2012, the top ten species (by tonnage) in marine global landings were Peruvian anchoveta, Alaska pollock, skipjack tuna, various sardine species, Atlantic herring, chub mackerel, scads, yellowfin tuna, Japanese anchovy and largehead hairtail. In 2012, 20 species had landings over a half a million tons and this represented 38 per cent of the total global marine capture production. Many of these top species are small pelagic fishes (e.g. sardines, chub mackerels) and shellfish (squids and shrimp) whose abundance is highly sensitive to changing climatic conditions, resulting in significant interannual variability in production.

Tuna harvests in 2012 were a record high, exceeding more than seven million tons. Sharks, rays and chimaera catches have been stable during the last decade at about 760,000 tons annually. Shrimp production from marine capture fisheries reached a record high in 2012 at 3.4 million tons; much of this catch was from the Northwest and Western Central Pacific, although catches also increased in the Indian Ocean and the Western Atlantic. Cephalopod catches exceeded 4 million tons in 2012.

1.1 Regional Status

Significant growth in marine capture fisheries has occurred in the eastern Indian Ocean, the eastern central Atlantic and the northwest, western central and eastern central Pacific over the last decade, but landings in many other regions have declined. Thus, even though overall landings have been quite stable, the global pattern is continuing to adjust to changing conditions and regional development of fishing capacity (Table 2).

Table 2. Fishing areas and captures (from SOFIA, FAO, 2014)

Marine capture: major fishing areas

Fishing area code	Fishing area name	2003	2011	2012	Variation	
					(Tonnes)	(Percentage)
21	Atlantic, Northwest	2 293 460	2 002 323	1 977 710	-13.8	-1.2
27	Atlantic, Northeast	10 271 103	8 048 436	8 103 189	-21.1	0.7
31	Atlantic, Western Central	1 770 746	1 472 538	1 463 347	-17.4	-0.6

18, 48, 58, 88	Arctic and Antarctic areas	142 548	197 838	178 797	25.4	-9.6
World total		79 674 875	82 609 926	79 705 910		

An estimated 3.7 million fishing vessels operate in marine waters globally; 68 per cent of these operate from Asia and 16 per cent from Africa. Seventy per cent are motorized, but in Africa only 36 per cent are motorized. Of the 58.3 million people estimated to be employed in fisheries and aquaculture (4.4 per cent of total estimated economically active people), 84 per cent are in Asia and 10 per cent in Africa. Women are estimated to account for more than 15 per cent of people employed in the fisheries sector (FAO 2014).

2. Present status of small-scale artisanal or subsistence fishing

The FAO defines small-scale, artisanal fisheries as those that are household based, use relatively small amounts of capital and remain close to shore. Their catch is primarily for local consumption. Around the world there is substantial variation as to which fisheries are considered small-scale and artisanal. The United Nations Conference on Sustainable Development (Rio+20) emphasized the role of small-scale fisheries in poverty alleviation and sustainable development. In some developing countries, including small island States, small-scale fisheries provide more than 60 per cent of protein intake. Its addition to the diets of low-income populations (including pregnant and breastfeeding mothers and young children) offers an important means for improving food security and nutrition. Small-scale fisheries make significant contributions to food security by making fish available to poor populations, and are critical to maintain the livelihoods of vulnerable populations in developing countries. Their role in production and its contribution to food security and nutrition is often underestimated or ignored; subsistence fishing is rarely included in national catch statistics (HLPE, 2014). Anyhow, the key issues in artisanal fisheries are their access both to stocks and to markets (HLPE, 2014).

Significant numbers of women work in small-scale fisheries and many indigenous peoples and their communities rely on these fisheries. The “Voluntary Guidelines on the Responsible Governance of Tenure of Land, Fisheries and Forests in the Context of National Food Security” (FAO 2012) are important in consideration of access issues. FAO also notes the linkage to international human rights law, including the right to food. Most of the people involved in small-scale fisheries live in developing countries, earn low incomes, depend on informal work, are exposed to the absence of work regulations and lack access to social protection schemes. Although the International Labour Organization adopted the Work in Fishing Convention, 2007 (No.188), progress towards ratification of the Convention has been slow.

FAO continues to encourage the establishment of fishers’ organizations and cooperatives as a means of empowerment for small-scale fishers in the management process to establish responsible fisheries policy. They have also highlighted the need to reduce post-harvest losses in small-scale fisheries as a means of improving production. Two special sections discuss these issues in SOFIA. Besides the “Voluntary Guidelines on the Responsible Governance of Tenure of Land, Fisheries and Forests in the Context of National Food Security”, FAO also adopted the “Voluntary Guidelines for Securing Sustainable Small-Scale Fisheries in the Context of Food Security and Poverty Eradication” in June 2014.

3. Impacts of capture fisheries on marine ecosystems

The effects of exploitation of marine wildlife were first perceived as a direct impact primarily on the exploited populations themselves. These concerns were recognized in the 19th and early 20th centuries (e.g., Michelet, 1875; Garstang, 1900; Charcot, 1911) and began to receive policy attention in the Stockholm Fisheries Conference of 1899 (Rozwadowski, 2002). In 1925, an attempt to globally manage “marine industries” and their impact on the ecosystems was presented before the League of Nations (Suarez, 1927), but little action was taken. Only following WWII, with rapid increases in fishing technology, was substantial overfishing in both the Atlantic and Pacific Oceans (Gulland and Carroz, 1968) acknowledged. Establishment in 1946 of FAO, with a section for fisheries, provided an initial forum for global discussions of the need for regulation of fisheries.

Capture fisheries affect marine ecosystems through a number of different mechanisms. These have been summarized many times, for example by Jennings and Kaiser (1998) who categorized effects as:

(i) The effects of fishing on predator-prey relationships, which can lead to shifts in community structure that do not revert to the original condition upon the cessation of fishing pressure (known as alternative stable states);

(ii) Fishing can alter the population size and body-size composition of species, leading to fauna composed of primarily small individual organisms (this can include the whole spectrum of organisms, from worms to whales);

(iii) Fishing can lead to genetic selection for different body and reproductive traits and can extirpate distinct local stocks;

(iv) Fishing can affect populations of non-target species (e.g., cetaceans, birds, reptiles and elasmobranch fishes) as a result of by-catches or ghost fishing;

(v) Fishing can reduce habitat complexity and perturb seabed (benthic) communities.

Here these impacts are discussed first for the species and food webs being exploited directly, and then for the other ecosystem effects on by-catches and habitats of fishing. Part VI of this Assessment provides additional detail regarding impacts on biodiversity and habitats.

3.1 *Target species and communities*

The removal of a substantial number of individuals of the target species affects the population structure of the target species, other species taken by the gear, and the food web. The magnitude of these effects is highly variable and depends on the species considered and the type and intensity of fishing. In general, policies and management measures were instituted first to manage the impact of fisheries on the target species,

with ecosystem considerations being added to target species management primarily in the past two to three decades.

If the exploited fish stock can compensate through increased productivity because the remaining individuals grow faster and produce more larvae, with the increase in productivity extracted by the fishery, then fishing can be sustained. However, if the rate of exploitation is faster than the stock can compensate for by increasing growth and reproduction, then the removals will not be sustained and the stock will decline. At the level of the target species, sustainable exploitation rates will result in the total population biomass being reduced roughly by half, compared to unexploited conditions.

The ability of a given population of fish to compensate for increased mortality due to fishing depends in large part on the biological characteristics of the population such as growth and maturation rates, natural mortality rates and lifespan, spawning patterns and reproduction dynamics. In general, slow growing long-lived species can compensate for and therefore sustain lower exploitation rates (the proportion of the stock removed by fishing each year) than fast growing shorter lived species (Jennings et al. 1998). In addition, increased exploitation rates inherently truncate the age composition of the population unless only certain ages are targeted. This truncation results in both greater variability in population abundance through time (Hsieh et al. 2006) and greater vulnerability to changing environmental conditions, including climate impacts. Very long-lived species with low rates of reproduction may not be able to truly compensate for increased mortality, and therefore any significant fishing pressure may not be sustainable on such species. Of course there are many complicating factors, but this general pattern is important for understanding sustainable exploitation of marine species.

The concept of “maximum sustainable yield” (MSY), adopted as the goal of many national and international regulatory bodies, is based on this inherent trade-off between increasing harvests and the decreasing ability of a population to compensate for removals. Using stock size and exploitation rates that would produce MSY, or other management reference points, FAO has concluded that around 29 per cent of assessed stocks are presently overfished (biomass below the level that can produce MSY on a continuing basis; Figure 2 below). That percentage may be declining in the more recent years, but has shown little overall trend since the early 1990s. FAO estimates that if overfished stocks were rebuilt, they would yield an additional 16.5 million mt of fish worth 32 billion United States dollars in the long term (Ye et al., 2013). However, significant social and economic costs may be incurred during the transition, as many fisheries would need to reduce exploitation in the short term to allow this rebuilding.

Global trends in the state of world marine fish stocks, 1974–2011

Figure 2. State of world marine fish stocks (from SOFIA, FAO 2014)

Anyhow, for many ecological reasons, the MSY is an over-simplified reference point for fisheries (Larkin, 1997; Pauly, 1994). For example, declines in productivity can result as fewer fish live to grow to a large size, because larger, older fish produce disproportionately more eggs of higher quality than younger, smaller individuals (Hixon et al. 2013). Long-term overfishing may even change the genetic pool of the species concerned, because the larger and faster-growing specimens have a greater probability of being removed, thereby reducing overall productivity (Hard et al., 2008; Ricker, 1981). Interactions between species may also mean that all stocks cannot be maintained at or above the biomass that will produce MSY. Strategies for taking these interactions into account have been developed (Polovina 1984, Townsend et al. 2008, Fulton et al. 2011; Farcas and Rossberg 2014, <http://arxiv.org/abs/1412.0199>), but are not yet in routine practice.

3.2 Ecosystem effects of fishing

The FAO Ecosystem approach to Fisheries (FAO 2003) has detailed guidelines describing an ecosystem approach to fisheries. The goal of such an approach is to conserve the structure, diversity and functioning of ecosystems while satisfying societal and human needs for food and the social and economic benefits of fishing (FAO 2003). There are ongoing efforts around the world to implement an ecosystem approach to fisheries that encompasses the aspects considered below, among others.

3.3 *Ecosystem effects of fishing – food webs*

Marine food webs are complex and exploiting commercially important species can have a wide range of effects that propagate through the food web. These include a cascading effect along trophic levels, affecting the whole food web (Casini et al., 2008; Sieben et al., 2011). The removal of top predators may result in changes in the abundance and composition of lower trophic levels. These changes might even reach other and apparently unrelated fisheries, as has been documented, for example, for sharks and scallops (Myers et al., 2007) and sea otters, kelp, and sea urchins (Szpak et al., 2013). Because of these complexities in both population and community responses to exploitation, it is now widely argued that target harvesting rates should be less than MSY. No consensus exists on how much less, but as information about harvest amounts and stock biology is more uncertain, it is agreed that exploitation should be reduced correspondingly (FAO, 1995).

The controversial concept of “balanced harvesting” refers to a strategy that considers the sustainability of the harvest at the level of the entire food web (see, for example, Bundy, A., et al. 2005; Garcia et al., 2011; FAO 2014). Rather than harvesting a relatively small number of species at their single-species MSYs, balanced harvesting suggests there are benefits to be gained by exploiting all parts of the marine ecosystem in direct proportion to their respective productivities. It is argued that balanced harvesting gives the highest possible yield for any level of perturbation of the food web, On the other hand, the economics of the fishery may be adversely affected by requiring the harvest of larger amounts of low-value but highly productive stocks.

3.4 *Other ecosystem effects of fishing by-catches*

Fisheries do not catch the target species alone. All species caught or damaged that are not the target are known as by-catch; these include, *inter alia*, marine mammals, seabirds, fish, kelp, sharks, mollusks, etc. Part of the by-catch might be used, consumed or processed (incidental catch) but a significant amount is simply discarded (discards) at sea. Global discard levels are estimated to have declined since the early 1990s, but at 7.3 million tons are still high (Kelleher, 2005).

Fisheries differ greatly in their discard rates, with shrimp trawls producing by far the greatest discard ratios relative to landed catches of target species (Table 3).

Table 3. Discards of fish in major fisheries by gear type. From Kelleher, 2005.

Fishery	Landings	Discards ¹	Weighted average discard rate (%)	Range of discard rates (%)
Shrimp trawl	1 126 267	1 865 064	62.3	0–96
Demersal finfish trawl	16 050 978	1 704 107	9.6	0.5–83
Tuna and HMS longline	1 403 591	560 481	28.5	0–40
Midwater (pelagic) trawl	4 133 203	147 126	3.4	0–56
Tuna purse seine	2 673 378	144 152	5.1	0.4–10
Multigear and multispecies	6 023 146	85 436	1.4	n.a.
Mobile trap/pot	240 551	72 472	23.2	0–61
Dredge	165 660	65 373	28.3	9–60
Small pelagics purse seine	3 882 885	48 852	1.2	0–27
Demersal longline	581 560	47 257	7.5	0.5–57
Gillnet (surface/bottom/trammel) ²	3 350 299	29 004	0.5	0–66
Handline	155 211	3 149	2.0	0–7
Tuna pole and line	818 505	3 121	0.4	0–1
Hand collection	1 134 432	1 671	0.1	0–1
Squid jig	960 432	1 601	0.1	0–1

¹ The sum of the discards presented in this table is less than the global estimate, as a number of discard database records could not be assigned to particular fisheries.

Very few time series have been found that document trends in by-catch levels for marine fisheries in general, or even for particular fisheries or species groups over longer periods. Although both Alverson et al. (1994) and Kelleher (2005) provide global estimates of discards in fisheries that differ by a factor of three, the latter source (with the lower estimate) stresses that the methodological differences between the two estimates were so large that two estimates should not be compared (a warning confirmed in the Kelleher report by the authors of the earlier report).

When even rough trend information is available, it is for particular species of concern in particular fisheries, and is usually intended to document the effectiveness of mitigation measures that have been implemented already. As an illustration, in the supplemental information to Anderson et al. (2011), which reports a global examination of longline fisheries, of the 67 fisheries for which data could be found, two estimates of seabird by-catches were available for only 17 of them. Of those, the more recent seabird by-catch estimates were at least 50 per cent lower than the earlier estimates in 15 of the fisheries, and reduced to 5 per cent or less of the earlier estimates in 10 of the fisheries. Several reasons were given, depending on the fishery; they included reduction in effort and the use of a variety of technical and occasionally temporal and/or spatial mitigation measures. These can be taken as illustrative of the potential effectiveness of mitigation efforts, but should not be extrapolated to other longline fisheries.

The more typical case is reflected in FAO Fisheries and Aquaculture Department (2009) and the report of a FAO Expert Consultation (FAO, 2010), which call for efforts to monitor by-catches and discards more consistently, in order to provide the data needed to document trends. Even the large initiative by the United States to document by-catches in fisheries (National Marine Fisheries Service, 2011) considers the reported estimates to be a starting point for gaining insight into trends in by-catch and discards.

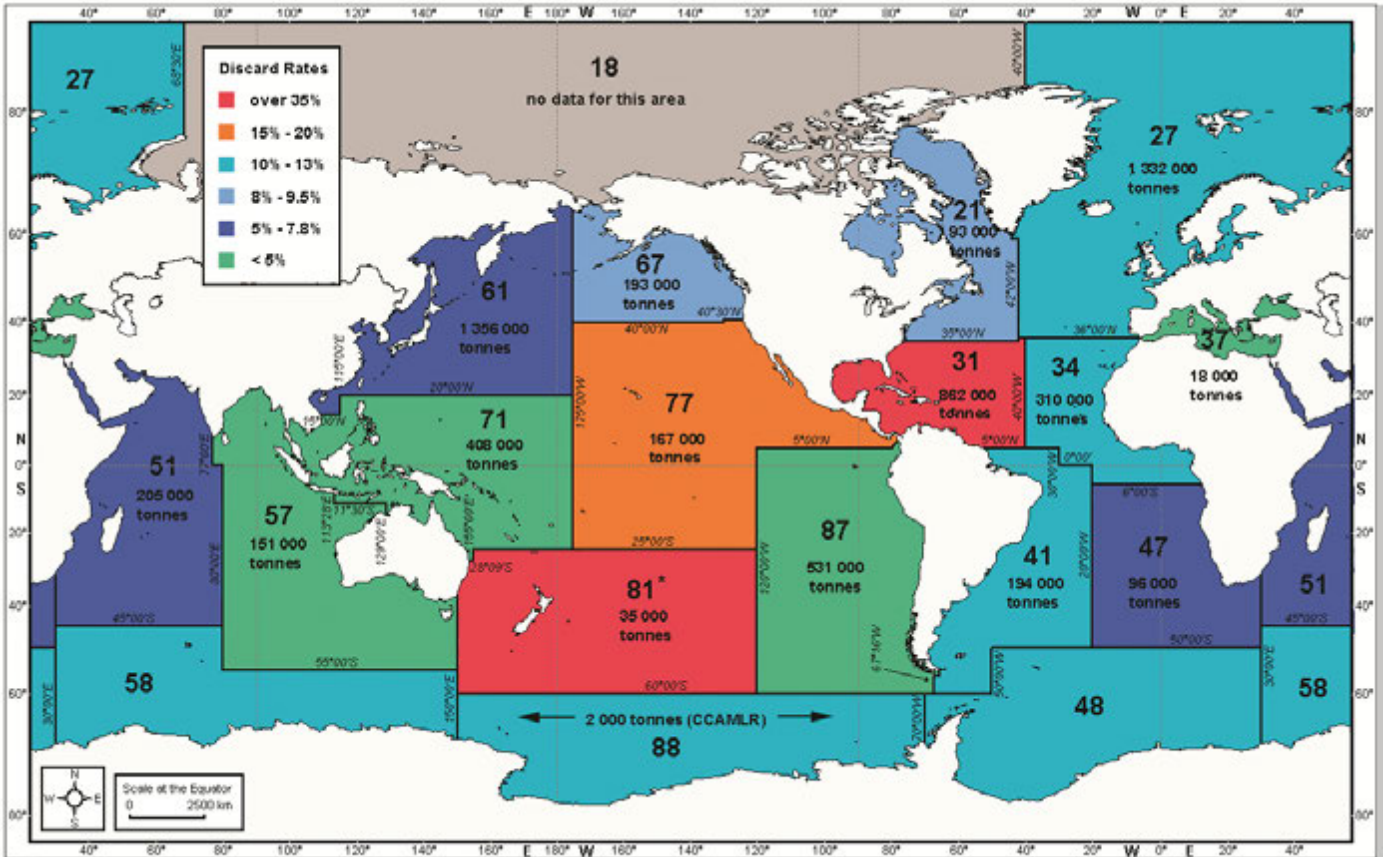

It documents the very great differences among fisheries within and among the United States fisheries management regions, but has neither tables nor figures depicting trends for any fishery.

By-catch rates may result in overfishing of species with less ability to cope with fishing pressures. The biological impact of by-catches varies greatly with the species being taken, and depends on the same life-history characteristics that were presented above for the target species of fisheries. By-catch mortality is a particular concern for small cetaceans, sea turtles and some species of seabirds and sharks and rays. These issues are discussed in the corresponding chapters in Part VI on marine mammals (Chapter 37), seabirds (38), marine reptiles (39) and elasmobranchs (40). In general, long-lived and slow-growing species are the most affected (Hall et al., 2000). Thus, the benchmarks set for a given fishery also consider by-catch species.

The geographic distribution of discard rates is shown in Figure 3 (from Kelleher, 2005).

The numbers in bold are the FAO Statistical Areas and the tonnages are of by-catch. By-catches are clearly a global issue, and can be addressed from local to global scales. The review by Kelleher (2005) reports a very large number of cases where measures have been implemented by States, by international organizations, or proactively by the fishing industry (especially when the industry is seeking independent certification for sustainability), and by-catch and discard rates have decreased and in a few cases been even eliminated.

A recent global review of practices by regional fisheries management organizations and arrangements (RFMO/As) for deep sea fisheries found that all RFMO/As have adopted some policies and measures to address by-catch issues in fisheries in their regulatory areas. However, almost nowhere was full monitoring in place to document effectiveness of these policies (UNEP/CBD/FAO, 2011). Nevertheless, extensive evidence exists that by-catches can be mitigated by changes in fishing gear, times, and places, and the incremental cost is often, but not always, small.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 3. Distribution of discards by FAO statistical areas (numbers in bold are FAO statistical areas, catches in tons). * Note: the high discard rate in FAO Area 81 is a data artefact. Source: Kelleher, 2005.

At the global level, calls for action on by-catch and discards have been raised at the United Nations General Assembly, including in UNGA resolutions on sustainable fisheries and at the Committee on Fisheries. In response, FAO developed International Guidelines on Bycatch Management and Reduction of Discards; these were accepted in 2011 (FAO, 2011).

3.5 Ecosystem effects of fishing – benthic and demersal habitats

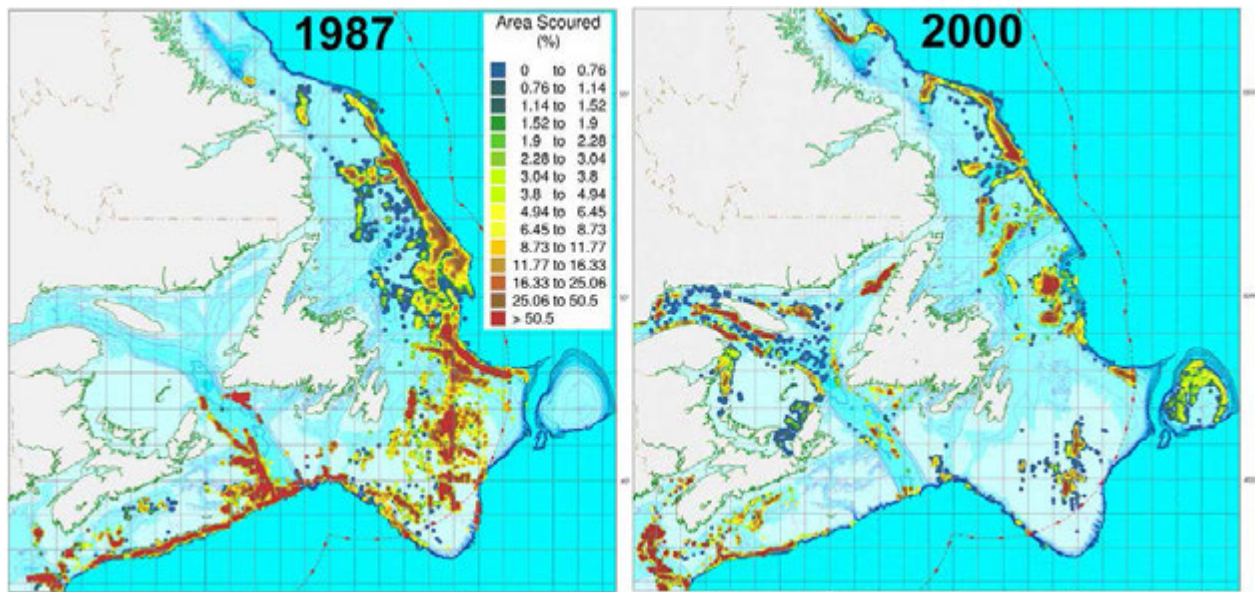

Fishing gear impacts on the seafloor and other habitats depend on the gear design and use, as well as on the particular environmental features. For example, in benthic habitats, substrate type and the natural disturbance regime are particularly important (Collie et al., 2000). Mobile bottom-contacting gear (including bottom trawls) also can resuspend sediments, mobilizing contaminants and particles with unknown ecological effects on both benthic and demersal habitats (Kaiser et al., 2001).

A very large literature exists on habitat impacts of fishing gear; experts disagree on both the magnitude of the issue and the effectiveness of management measures and policies to address the impacts. In the late 2000s, several expert reviews were conducted by FAO and the Convention on Biological Diversity in cooperation with UNEP. These reports (FAO, 2007; 2009) provide a recent summary of the types of impacts that various types of fishing gear can have on the seafloor. Most conclusions are straightforward:

- All types of gear that contact the bottom may alter habitat features, with impacts larger as the gear becomes heavier.
- Mobile bottom-contacting gear generally has a larger area of impact on the seabed than static gear, and consequently the impacts may be correspondingly larger.
- The nature of the impact depends on the features of the habitat. Structurally complex and fragile habitats are most vulnerable to impacts, with biogenic features, such as corals and glass sponges, easily damaged and sometimes requiring centuries to recover. On the other hand, impacts of trawls on soft substrates, like mud and sand, may not be detectable after even a few days.
- The nature of the impacts also depends on the natural disturbance regime, with high-energy (strong current and/or wave action) habitats often showing little incremental impacts of fishing gear, whereas areas of very low natural disturbance may be more severely affected by fishing gears.
- Impacts of fishing gears can occur at all scales of fishery operations; some of the most destructive practices, such as drive netting, dynamite and poisons, although uncommon, are used only in very small-scale fisheries (Kaiser 2001).

All gear might be lost or discarded at sea, in particular pieces of netting. These give rise to what is known as “ghost fishing”, that is fishing gear continuing to capture and kill marine animals even after it is lost by fishermen. Assessment of their impacts at either a global or local level is difficult, but the limited number of studies available on its incidence and prevalence indicate that ghost fishing can be a significant problem (Laist et al., 1999, Bilkovic et al. 2012).

Quantitative trend information on habitat impacts is generally not available. Many reports provide maps of how the geographical extent and intensity of bottom-contacting fishing gear have changed over time (e.g. Figure 4 from Gilkinson et al., 2006; Greenstreet et al., 2006). These maps show large changes in the patterns of the pressure, and accompanying graphs show the percentage of area fished over a series of years. However, these are individual studies, and broad-scale monitoring of benthic communities is not available. Insights from individual studies need to be considered along with information on the substrate types in the areas being fished to know how increases in effort may be increasing benthic impacts. Furthermore, the recovery potential of the benthic biota has been studied in some specific geographies and circumstances but broadly applicable patterns are not yet clear (e.g., Steele et al. 2002, Claudet et al. 2008).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 4. Distribution of trawling effort in Atlantic Canadian waters in 1987 and 2000, based on data of bottom-trawl activity adjusted to total effort for <150 t. From Gilkinson et al., 2006.

Even without quantitative data on trends in benthic communities, however, marine areas closed to fishing have increased. Views differ on what level of protection is actually given to areas that are labelled as closed to fishing, but the trend in increasing area protection is not challenged (c.f. CBD, 2012; Spalding et al., 2013). Moreover, the size of the areas being closed to fishing that are not already affected by historical fishing is unknown, as is the recovery rate for such areas, and high-seas fisheries continue to expand into new areas, although probably at a slower rate as RFMO/As increase their actions to implement United Nations General Assembly Resolution 61/105 (FAO, 2014). Hence the pressure on seafloor habitats and benthic communities from bottom-contacting fishing gear may be decreasing slightly, but has been very high for decades on all continental shelves and in many offshore areas at depths of less than several hundred meters (FAO, 2007).

4. Effects of pollution on seafood safety

Fish and particularly predatory fish are prone to be contaminated with toxic chemicals in the marine environment (e.g., organochlorines, mercury, cadmium, lead); these are found mostly in their liver and lipids. Because many sources of marine contamination are land-based (Chapter 20), freshwater fish may contain higher concentrations of contaminants than marine species (Yamada et al., 2014). Furthermore, contamination of the organisms found there is highly variable at the regional and local levels.

Processing methods might significantly reduce the lead and cadmium contents of fish (Ganjavi et al., 2010) and presumably those of other contaminants, whose concentrations generally increase with size (age) of fish (Storelli et al., 2010).

Some species of fish might be toxic (venomous) on their own, such as species of the genus *Siganus* and *Plotosus* in Singapore, which are being culled to reduce their presence on beaches (Kwik, 2012) and *Takifugu rubripes* (fugu), whose properties are relatively well known, such that it is processed accordingly (Yongxiang et al., 2011). However, in extreme situations, human consumption of the remains of fugu processing resulted in severe episodes (Saiful Islam et al., 2011).

Fish, mussels, shrimp and other invertebrates might become toxic through their consumption of harmful algae, whose blooms increased due to climate change, pollution, the spreading of dead (hypoxic/anoxic) zones, and other causes.

Harmful algal blooms are often colloquially known as red tides. These blooms are most common in coastal marine ecosystems but also the open ocean might be affected and are caused by blooms of microscopic algae (including cyanobacteria). Toxins produced by these organisms are accumulated by filtrators that become toxic for species at higher trophic levels, including man. Climate change and eutrophication are considered as part of a complex of environmental stressors resulting in harmful blooms (Anderson et al., 2012). The problem has prompted research to develop models to predict the behaviour of these blooms (Zhao and Ghedira, 2014). Since the 1970s, the phenomenon has spread from the northern hemisphere temperate waters to the southern hemisphere and has now been well documented at least in Argentina, Australia, Brunei Darussalam, China, Malaysia, Papua New Guinea, the Philippines, Republic of Korea and South Africa, but the expansion might also be due to increased awareness of the phenomenon (Anderson et al., 2012) The impact of toxic algal blooms is mostly economic, but episodes of severe illness, even with high mortality rates, might occur, which prompt regulations closing the affected fisheries.

One of the best-known risks in this category is ciguatera, a well-known toxin ingested by human consumption of predatory fish in some regions of the world. The toxin comes from a dinoflagellate and is passed along and concentrated up the food chain (Hamilton et al., 2010). Processed foods are usually safer from the standpoint of contamination. Thus, processing results in added value to the raw food (Satyanarayana et al., 2012). However, inadequate harvest and postharvest handling and processing of the catches might result in contamination with pathogenic organisms (Bozaris et al., 2013).

The general trend expected is an increase in the frequency of harmful algal blooms, in the bioaccumulation of chemical contaminants and in the prevalence of common food-borne pathogenic microorganisms (Marques et al., 2014), although the occurrence of catastrophic events seems to be diminishing.

5. Illegal, unreported and unregulated (IUU) fishing

The FAO International Plan of Action for IUU fishing (FAO 2001) defines IUU fishing as:

- Illegal fishing refers to activities conducted by national or foreign vessels in waters under the jurisdiction of a State, without the permission of that State, or in contravention of its laws and regulations; conducted by vessels flying the flag of States that are parties to a relevant regional fisheries management organization but operate in contravention of the conservation and management measures adopted by that organization and by which the States are bound, or relevant provisions of the applicable international law; or in violation of national laws or international obligations, including those undertaken by cooperating States to a relevant regional fisheries management organization;
- Unreported fishing refers to fishing activities which have not been reported, or have been misreported, to the relevant national authority, in contravention of national laws and regulations; or undertaken in the area of competence of a relevant regional fisheries management organization which have not been reported or have been misreported, in contravention of the reporting procedures of that organization;
- Unregulated fishing refers to fishing activities in the area of application of a relevant regional fisheries management organization that are conducted by vessels without nationality, or by those flying the flag of a State not party to that organization, or by a fishing entity, in a manner that is not consistent with or contravenes the conservation and management measures of that organization; or in areas or for fish stocks in relation to which there are no applicable conservation or management measures and where such fishing activities are conducted in a manner inconsistent with State responsibilities for the conservation of living marine resources under international law.

Notwithstanding the definitions above, certain forms of unregulated fishing may not always be in violation of applicable international law, and may not require the application of measures envisaged under the International Plan of Action (IPOA). FAO considers IUU fishing to be a major global threat to sustainable management of fisheries and to stable socio-economic conditions for many small-scale fishing communities. This illegal fishing not only undermines responsible fisheries management, but also typically raises concerns about working conditions and safety. Illegal fishing also raises concerns about connections to other criminal actions, such as drugs and human trafficking. IUU fishing activity has escalated over the last two decades and is estimated to take 11-26 million mt of fish per annum with a value of 10-23 billion United States dollars. In other words, IUU fishing is responsible for about the same amount of global harvest as would be gained by ending overfishing and rebuilding fish stocks. It is an issue of equal concern on a global scale.

International efforts by RFMO/As, States and the European Union are aimed at eliminating IUU fishing. FAO notes that progress has been slow and suggested (FAO 2014) that better information-sharing regarding fishing vessels engaged in illegal

activities, traceability of vessels and fishery products, and other additional measures might improve the situation.

6. Significant economic and/or social aspects of capture fisheries

Capture fisheries are a key source of nutrition and employment for millions of people around the world. FAO (2014) estimates that 800 million people are still malnourished and small-scale fisheries in particular are an important component of efforts to alleviate both hunger and poverty.

Growth in production of fish for food (3.2 per cent *per annum*) has exceeded human population growth (1.6 *per annum*) over the last half century. Recently the growth of aquaculture, which is among the fastest-growing food-producing sectors globally, has formed a major part of meeting rising demand and now accounts for half of the fish produced for human consumption. By 2030 this figure will rise to two-thirds of fish production.

Per capita consumption of fish has risen from 9.9 kg *per annum* to 19.2 kg in 2012. In developing countries this rise is from 5.2 kg to 17.8 kg. In 2010, fish accounted for 16.7 per cent of the global population's consumption of animal protein and 4.3 billion people obtained 15 per cent of their animal protein from fishery products.

Employment in the fisheries sector has also grown faster than the world population and faster than in agriculture. However, of the 58.3 million people employed in the fishery sector, 83 per cent were employed in capture fisheries in 1990. But employment in capture fisheries has decreased to 68 per cent of total fishery sector employment in 2012 according to FAO (2014) statistics.

7. The future status of fish and shellfish stocks over the next decade

World population growth, together with urbanization, increasing development, income and living standards, all point to an increasing demand for seafood. Capture fisheries provide high-quality food that is high in protein, essential amino acids, and long-chain poly-unsaturated fatty acids, with many benefits for human health. The rate of increase in demand for fish was more than 2.5 per cent since 1950 and is likely to continue (HPLE, 2014).

Climate change is expected to have substantial and unexpected effects on the marine environment as detailed throughout this Assessment. Some of these impacts may not negatively impact fisheries and indeed may result in increased availability for capture fisheries in some areas. Nevertheless, there will certainly be an increase in uncertainty with regard to effects on stock productivities and distributions, habitat stability, ecosystem interactions, and the configuration of ecosystems around the globe. Whether

these effects on the resources will be “mild” or “severe” will require prudent fisheries management that is precautionary enough to be prepared to assist fishers, their communities and, in general, stakeholders in adapting to the social and economic consequences of climate change (Grafton, 2009).

Small-scale, artisanal fisheries are likely to be more vulnerable to the impacts of climate change and increasing uncertainty than large-scale fisheries (Roessig et al. 2004). While small-scale fisheries may be able to economically harvest a changing mix of species, varying distribution patterns and productivity of stocks may have severe consequences for subsistence fishing. Further, the value of small-scale fisheries as providers not only of food, but also of livelihoods and for poverty alleviation will be compromised by direct competition with large-scale operations with access to global markets (Alder and Sumaila, 2004).

The data clearly indicate that the amount of fish that can be extracted from historically exploited wild stocks is unlikely to increase substantially. Some increase is possible through the rebuilding of depleted stocks, a central goal of fisheries management. Current trends diverge between well-assessed regions showing stabilization of fish biomass and other regions continuing to decline (Worm and Branch, 2012).

In Europe, North America and Oceania, major commercially exploited fish stocks are currently stable, with the prospect that reduced exploitation rates should achieve rebuilding of the biomass in the long term. In the rest of the world, fish biomass is, on average, declining due to lower management capacity. Many fisheries may still be productive, but prospects are poor (Worm et al., 2009).

The growing demand for fish products cannot be met from sustainable capture fisheries in the next decade. On the other hand, the potential for sustainable exploitation of non-traditional stocks is not well known. Particularly in light of the growth of the aquaculture sector with a need for fishmeal for feed, the pressure to exploit non-traditional resources will increase even if the impacts on marine ecosystems are not well understood.

8. Identify gaps in capacity to engage in capture fisheries and to assess the environmental, social and economic aspects of capture fisheries and the status and trends of living marine resources

Rebuilding overfished stocks is a major challenge for capture fisheries management. Another key challenge is making better, more sustainable use of existing marine resources while conserving the ecosystem upon which they depend. From a global perspective this will require filling a number of gaps, both scientific and in management capacity (Worm et al., 2009):

- The transfer of fishing effort from developed to developing countries is a process that has been accelerating since the 1960s. Almost all of the fish caught by foreign fleets is

consumed in industrialized countries and will have important implications for food security (Alder and Sumaila, 2004) and biodiversity in the developing world. In many regions there is insufficient capacity to assess and manage marine resources in the context of this pressure;

- The increase in IUU fishing operations is a major challenge for management that will require increased management capacity if it is to be controlled;
- Recovery of depleted stocks is still a poorly understood process, particularly for demersal species. It is potentially constrained by the magnitude of the previous decline, the loss of biodiversity, species' life histories, species interactions, and other factors. In other words, the basic principle for recovery is straightforward – fishing pressure needs to be reduced. But the specific application of plans to promote recovery of the stock once fishing pressure is reduced requires significant scientific and management capacity;
- Addressing the challenges of spatial management of the ocean for fisheries, conservation and many other purposes, and the overall competition for ocean space, will depend upon greater scientific and management capacity in most regions.

The average performance of stock-assessed fisheries indicates that most are slowly approaching the fully fished status (*sensu* FAO). On the other hand, recent analyses of unassessed fish stocks indicate that they are mostly in poorer condition (Costello et al., 2012). The problem is severe because most of these stocks sustain small-scale fisheries critical for the food security in developing countries. Better information and the capacity to manage many of these stocks will be needed to improve the situation.

Debates among fisheries specialists have been more concerned about biological sustainability and economic efficiencies than about reducing hunger and malnutrition and supporting livelihoods (HLPE, 2014). It is necessary to develop the tools for managing small-scale fisheries efficiently, particularly in view of the competing long-distance fleets. The fishing agreements allowing long-distance fleets to operate in developing countries had not yielded the expected results in terms of building the capacity to administer or sustainably fish their resources. IUU fishing becoming more prominent has exacerbated the situation (Gagern and van den Bergh, 2013). It is necessary for developing countries to build the capacity to develop sustainable industrial fisheries and to develop stock assessment capabilities for small-scale fisheries balancing food security and conservation objectives (Allison and Horemans, 2006).

Chapter 12. Aquaculture

Writing team: Patricio Bernal (Group of Experts), Doris Oliva

1. Scale and distribution of aquaculture

Aquaculture is providing an increasing contribution to world food security. At an average annual growth rate of 6.2 per cent between 2000 and 2012 (9.5 per cent between 1990 and 2000), aquaculture is the world's fastest growing animal food producing sector (FAO, 2012; FAO 2014). In 2012, farmed food fish contributed a record 66.6 million tons, equivalent to 42.2 per cent of the total 158 million tons of fish produced by capture fisheries and aquaculture combined (including non-food uses, see Figure 1). Just 13.4 per cent of fish production came from aquaculture in 1990 and 25.7 per cent in 2000 (FAO, 2014).

In Asia, since 2008 farmed fish production has exceeded wild catch (freshwater and marine), reaching 54 per cent of total fish production in 2012; in Europe aquaculture production is 18 per cent of the total and in other continents is less than 15 per cent. Nearly half (49 per cent) of all fish consumed globally by people in 2012 came from aquaculture (FAO, 2014).

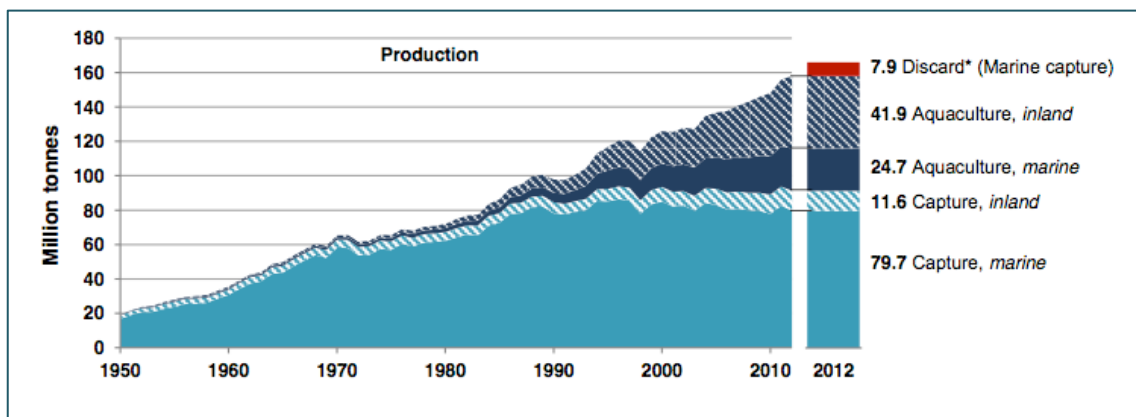

Figure 1. World capture fisheries and aquaculture production between 1950 and 2012 (HLPE, 2014).

In 2012, world aquaculture production, for all cultivated species combined, was 90.4 million tons (live weight equivalent and 144.4 billion dollars in value). This includes 44.2 million tons of finfish (87.5 billion dollars), 21.6 million tons of shellfish (crustacea and molluscs with 46.7 billion dollars in value) and 23.8 million tons of aquatic algae (mostly seaweeds, 6.4 billion dollars in value). Seaweeds and other algae are harvested for use as food, in cosmetics and fertilizers, and are processed to extract thickening agents used as additives in the food and animal feed industries. Finally 22,400 tons of non-food products are also farmed (with a value of 222.4 million dollars), such as pearls and seashells for ornamental and decorative uses (FAO, 2014).

According to the latest (but incomplete) information for 2013, FAO estimates that world food fish aquaculture production rose by 5.8 per cent to 70.5 million tons, with production of farmed aquatic plants (including mostly seaweeds) being estimated at 26.1 million tons.

2. Composition of world aquaculture production: inland aquaculture and mariculture

Although this Chapter is part of an assessment of food security and food safety from the ocean, to understand the trends in the development of world aquaculture and its impact on food security it is relevant to compare inland aquaculture, conducted in freshwater and saline estuarine waters in inland areas, versus true mariculture, conducted in the coastal areas of the world ocean.

Of the 66.6 million tons of farmed food fish¹ produced in 2012, two-thirds (44.2 million tons) were finfish species: 38.6 million tons grown from inland aquaculture and 5.6 million tons from mariculture. Inland aquaculture of finfish now accounts for 57.9 percent of all farmed food fish production globally.

Although finfish species grown from mariculture represent only 12.6 percent of the total farmed finfish production by volume, their value (23.5 billion United States dollars) represents 26.9 percent of the total value of all farmed finfish species. This is because mariculture includes a large proportion of carnivorous species, such as salmon, trouts and groupers, “cash-crops” higher in unit value and destined to more affluent markets.

FAO (2014) concludes that freshwater fish farming makes the greatest direct contribution to food security, providing affordable protein food, particularly for poor people in developing countries in Asia, Africa and Latin America. Inland aquaculture also provides an important new source of livelihoods in less developed regions and can be an important contributor to poverty alleviation.

3. Main producers of aquaculture products

In 2013, China produced 43.5 million tons of food fish and 13.5 million tons of aquatic algae (FAO, 2014, p 18), making it by far the largest producer of aquaculture products in the world. Aquaculture production is still concentrated in few countries of the world. Considering national total production, the top five countries (all in Asia: China, India, Viet Nam, Indonesia, Bangladesh) account for 79.8 per cent of world production while the top five countries in finfish mariculture (Norway, China, Chile, Indonesia, and Philippines) account for 72.9 per cent of world production (Table 1, Figure 2).

¹ The generic term “farmed food fish” used here and by FAO, includes finfishes, crustaceans, molluscs, amphibians, freshwater turtles and other aquatic animals (such as sea cucumbers, sea urchins, sea squirts and edible jellyfish) produced for intended use as food for human consumption.

4. Species cultivated

It is estimated that more than 600 aquatic species are cultured worldwide² in a variety of farming systems and facilities of varying technological sophistication, using freshwater, brackish water and marine water (FAO, 2014). In 2006, the top 25 species being farmed accounted for over 90 percent of world production (FAO, 2006a). Of the more than 200 species of fish and crustaceans currently estimated to be cultivated and fed on externally supplied feeds, just 9 species account for 62.2 percent of total global-fed species production, including grass carp (*Ctenopharyngodon idellus*), common carp (*Cyprinus carpio*), Nile tilapia (*Oreochromis niloticus*), catla (*Catla catla*), whiteleg shrimp (*Litopenaeus vannamei*), crucian carp (*Carassius carassius*), Atlantic salmon (*Salmo solar*), pangasiid catfishes (striped/tra catfish [*Pangasianodon hypophthalmus*] and basa catfish [*Pangasius bocourti*]), and rohu (*Labeo rohita*; Tacon et al., 2011). The farming of freshwater tilapias, including Nile tilapia and some other cichlid species, is the most widespread type of aquaculture in the world. FAO has recorded farmed tilapia production statistics for 135 countries and territories on all continents (FAO, 2014). In this respect, aquaculture is no different from animal husbandry, in that global livestock production is concentrated in a few species (Tacon et al. 2011).³ Among molluscs only 6 species account for the 64.5per cent of the aquaculture production (15.5 million tons in 2013) and all of them are bivalves: the cupped oyster (*Crassostrea spp*), Japanese carpet shell (*Ruditapes philippinarum*), constricted Tagelus (*Sinnovaluca constricta*), blood cocked *Anadara granosa*, Chilean mussel (*Mytilus chilensis*) and Pacific cupped oyster (*Crassostrea gigas*).

² Up to 2012, the number of species registered in FAO statistics was 567, including finfishes (354 species, with 5 hybrids), molluscs (102), crustaceans (59), amphibians and reptiles (6), aquatic invertebrates (9), and marine and freshwater algae (37).

³ On land, the top eight livestock species are pig, chicken, cattle, sheep, turkey, goat, duck and buffalo (Tacon et al. 2011)

Table 1. Farmed food fish production by 15 top producers and main groups of farmed species in 2012 (FAO, 2014).

Note: The symbol "..." means the production data are not available or the production volume is regarded as negligibly low.

5. Aquaculture systems development

The cultivation of farmed food fish is the aquatic version of animal husbandry, where full control of the life cycle enables the domestication of wild species, their growth in large-scale farming systems and the application of well-known and well-established techniques of animal artificial selection of desirable traits, such as resistance to diseases, fast growth and size.

For most farmed aquatic species, hatchery and nursery technologies have been developed and well established, enabling the artificial control of the life cycle of the species. However wild seed is still used in many farming operations. For a few species, such as eels (*Anguilla* spp.), farming still relies entirely on wild seed (FAO, 2014).

Aquaculture can be based on traditional, low technology farming systems or on highly industrialized, capital-intensive processes. In between there is a whole range of aquaculture systems with different efficiencies that can be adapted to local socioeconomic contexts.

Physically, inland aquaculture and coastal shrimp mariculture uses fixed ponds and raceways on land that put a premium on the use of land. Finfish mariculture and some farming of molluscs such as oysters and mussels tend to use floating net pens, cages and other suspended systems in the water column of shallow coastal waters, enabling these systems to be fixed by being anchored to the bottom.

Direct land use needs for fish and shrimp ponds can be substantial. Current aquaculture production occupies a significant quantity of land, both in inland and coastal areas. Aquaculture land use efficiency, however, differs widely by production system. While fish ponds use relatively high amounts of land (Costa-Pierce et al., 2012, cited in WRI, 2014), flow-through systems (raceways) use less land, while cages and pens suspended in water bodies use very little (if any) land (WRI, 2014).

The handling of monocultures with high densities of individuals in confinement replicates the risks typical to monocultures in land-based animal husbandry, such as the spread and proliferation of parasites, and the contagion of bacterial and viral infections producing mass mortalities, and the accumulation of waste products. If on land these risks can be partially contained, in mariculture, the use of semi-enclosed systems open to the natural flow of seawater and sedimentation to the bottom, propagate these risks to the surrounding environment affecting the health of the ecosystems in which aquaculture operations are implanted.

The introduction of these risks to the coastal zones puts a premium in the application of good management practices and effective regulations for zoning, site selection and maximum loads per area.

In 1999 during the early development of shrimp culture, a White Spot Syndrome Virus (WSSV) epizootic quickly spread through nine Pacific coast countries in Latin America, costing billions of dollars (McClennen, 2004). Disease outbreaks in recent years have affected Chile's Atlantic salmon production with losses of almost 50 percent to the virus of "infectious salmon anaemia" (ISA). Oyster cultures in Europe were attacked by herpes virus Os HV-1 or OsHV-1 μ var, and marine shrimp farming in several countries in Asia, South America and Africa have experienced bacterial and viral infections, resulting in partial or sometimes total loss of production. In 2010, aquaculture in China suffered production losses of 1.7 million tons caused by natural disasters, diseases and pollution. Disease outbreaks virtually wiped out marine shrimp farming production in Mozambique in 2011 (FAO, 2010, 2012).

New diseases also appear. The early mortality syndrome (EMS) is an emerging disease of cultured shrimp caused by a strain of *Vibrio parahaemolyticus*, a marine micro-organism native in estuarine waters worldwide. Three species of cultured shrimp are affected (*Penaeus monodon*, *P. vannamei* and *P. chinensis*). In Viet Nam, about 39 000 hectares were affected in 2011. Malaysia estimated production losses of 0.1 billion dollars (2011). In Thailand, reports indicated annual output declines of 30–70 percent. The disease has been reported in China, Malaysia, Mexico, Thailand and Viet Nam (FAO, 2014).

It is apparent that intensive aquaculture systems are likely to create conditions that expose them to disease outbreaks. When semi-enclosed systems are used, as in mariculture, pathogens in their resting or reproductive stages propagate directly to

the environment, where they can persist for long periods of time as a potential source of recurring outbreaks.

Optimization of industrial systems selects for few or a single preferred species. This is the case in the oyster culture with the widespread culture of *Crassostrea gigas* and in the shrimp industry by the dominance of *Penaeus vanamei*, the white shrimp as the preferred species. This can be also an additional source of risk, if evolving pathogens develop resistance to antibiotics or other treatments used to control well-known diseases.

6. Fed and non-fed aquaculture

Animal aquaculture production can be divided among those species that feed from natural sources in the environment in which they are grown, and species that are artificially fed. The output of naturally-fed aquaculture represents a net increase of world animal protein stock, while the contribution of fed aquaculture, consuming plant or animal protein and fat, depends on conversion rates controlled by the physiology of the species and the effectiveness of the farming system.

In 2012, global production of non-fed species from aquaculture was 20.5 million tons, including 7.1 million tons of filter-feeding carps and 13.4 million tons of bivalves and other species. Accordingly, 46.09 million tons or 69.2 per cent of total farmed food fish (FAO, 2014) was dependent upon the supply of external nutrient inputs provided in the form of (i) fresh feed items, (ii) farm-made feeds or (iii) commercially manufactured feeds (Tacon et al., 2011).

The share of non-fed species in total farmed food fish production continued to decrease to 30.8 percent in 2012 compared with about 50 percent in 1982, reflecting stronger growth in the farming of fed species, especially of high value carnivores (FAO, 2014).

Figure 2. World aquaculture production, fed and non-fed between years 2000 and 2012 (FAO, 2014)

In Europe, after much publicly and privately sponsored research, the technology to farm cod was fully developed and supported by large amounts of venture capital, and industrial production of cod started. In the early 2000s this industrial development suffered from the financial crisis of 2008, and further growth and development almost stopped. Although the participation of risk capital in the development of aquaculture might be an option in particular places and circumstances, it is far from being the preferred option. Development of aquaculture systems, supplying domestic and international markets, has a better chance to succeed if supported by a mix of long-term public support systems (credit, technical assistance) for small and rural producers coupled with entrepreneurial initiatives well implanted in the markets.

Marine finfish aquaculture is rapidly growing in the Asia-Pacific region, where high-value carnivorous fish species (e.g. groupers, barramundi, snappers and pompano) are typically raised in small cages in inshore environments. In China this development has led to experiments in offshore mariculture using larger and stronger cages. (FAO, 2014).

These examples show that at least to the present, decision-making for the development of mariculture, particularly finfish mariculture, tends to be dominated by economic growth and not by food security considerations. To balance this trend, the intergovernmental High Level Panel of Experts on Food Security has recently advocated the need to define specific policies to support current targets on food security in view of the projected growth of human population (HLPE, 2014).

The potential for non-fed mariculture development is far from being fully explored particularly that of marine bivalves in Africa and in Latin America and in the Caribbean. Limited capacity in mollusc seed production is regarded as a constraint in some countries (FAO, 2014).

7. Aquafeed production

Total industrial compound aquafeed production increased, from 7.6 million tons in 1995 to 29.2 million tons in 2008 (last estimate available, Tacon et al., 2011). These are estimates because there is no comprehensive information on the global production of farm-made aquafeeds (estimated by FAO at between 18.7 and 30.7 million tons in 2006) and/or on the use of low-value fish/trash fish as fresh feed.

Fishmeal is used as high-protein feed and fish oil as a feed additive in aquaculture (FAO, 2014). Fishmeal and fish oil are produced mainly from harvesting stocks of small, fast-reproducing fish (e.g., anchovies, small sardines and menhaden) and for which there is some, but limited, demand for human consumption. This use, promoted in the 1950s by FAO as a means to add value to the massive harvesting of small pelagic fish, raises the question of the alternative use of this significant fish biomass for direct human consumption (HLPE 2014).

In 2012 about 35 per cent of world fishmeal production was obtained from fisheries by-products (frames, off-cuts and offal) from the industrial processing of both wild caught and farmed fish. Commercial operations harvesting myctophids⁴ for fishmeal and oil are being piloted in some regions, though the ecological consequences of exploiting these previously untapped resources have not been evaluated. In 2007 the largest producer of fishmeal was Peru (1.4 million tons) followed by China (1.0 million tons) and Chile (0.7 million tons). Other important producers were Thailand, the United States of America, Japan, Denmark, Norway and Iceland (Tacon et al., 2011).

Estimates of total usage of terrestrial animal by-product meals and oils in compound aquafeeds ranges between 0.15 and 0.30 million tons, or less than 1 percent of total global production.

Patterns in the use of fishmeal and fish oil have changed in time due to the growth and evolution of the world aquaculture industry. On a global basis, in 2008 (the most recent published estimate), the aquaculture sector consumed 60.8 percent of global fishmeal production (3.72 million tons) and 73.8 percent of global fish oil production (0.78 million tons, Tacon et al., 2011). In contrast, the poultry and pork industries each used nearly 26 per cent and 22 per cent respectively of the available fishmeal in 2002 while aquaculture consumed only 46 percent of the global fishmeal supply and 81 percent of the global fish oil supply (Pike, 2005; Tacon et al., 2006)

Fish oil has become also a product for direct human consumption for health reasons. Long-chain Omega-3 fatty acids, specifically EPA and DHA, have been shown to play a critical role in human health: EPA in the health of the cardiovascular system and DHA in the proper functioning of the nervous system, most notably brain function. In 2010 fish oil for direct human consumption was estimated at 24 per cent of the total world production, compared with 5 per cent in 1990. (Shepherd and Jackson, 2012).

The total use of fishmeal by the aquaculture sector is expected to decrease in the long term in favour of plant-based materials (Figure 3). It has gone down from 4.23 million tons in 2005 to 3.72 million tons in 2008 (or 12.8 percent of total aquafeeds by weight), and is expected to decrease to 3.49 million tons by 2020 (at an estimated 4.9 per cent of total aquafeeds by weight) (Tacon et al., 2011).

These trends reflect that fishmeal is being used by industry as a strategic ingredient fed in stages of the growth cycle where its unique nutritional properties can give the best results or in places where price is less critical (Jackson, 2012). The most commonly used alternative to fishmeal is that of soymeal. Time series of the price of both products show that use of fishmeal is being reduced in less critical areas such as grower feeds, but remains in the more critical and less price-sensitive areas of hatchery and brood-stock feeds. (Jackson and Shepherd, 2012)

⁴ Myctophids are small-size mesopelagic fish inhabiting between 200 and 1000 metres that vertically migrate on a daily basis. Biomass of myctophids is estimated to be considerable worldwide.

Figure 3. The aquaculture industry has reduced the share of fishmeal in farmed fish diets (percent) (FAO, 2014).

The use of fish oil by the aquaculture sector will probably increase in the long run albeit slowly. It is estimated that total usage will increase by more than 16 percent, from 782,000 tons (2.7 percent of total feeds by weight) in 2008 to the estimated 908,000 tons (1.3 percent of total feeds for that year) by 2020. It is forecast that increased usage will shift from salmonids, to marine finfishes and crustaceans because of the current absence of cost-effective alternative lipid sources that are rich in long-chain polyunsaturated fatty acids. (Tacon et al., 2011)

8. Economic and social significance

At the global level, the number of people engaged in fish farming has, since 1990, increased at higher annual rates than that of those engaged in capture fisheries. The most recent estimates (FAO 2014, Table 2) indicate that about 18.9 million people were engaged in fish farming, 96 per cent concentrated primarily in Asia, followed by Africa (1.57 percent), Latin America and the Caribbean (1.42 percent), Europe (0.54 per cent), North America (0.04 per cent) and Oceania (0.03 per cent). The 18,175 million fish farmers in 2012 represented 1.45 per cent percent of the 1.3 billion people economically active in the broad agriculture sector worldwide. (FAO, 2014).

Table 2. FAO (2014) estimates that the total number of fish farmers in the world has grown from 8 million in 1995 to close to 19 million today, representing an increasing source of livelihoods. Not all these jobs are permanent and year-around, since many are seasonal.

	1995	2000	2005	2010	2011	2012
	<i>(Thousands)</i>					
Of which, fish farmers						
Africa	65	91	140	231	257	298
Asia	7 762	12 211	14 630	17 915	18 373	18 175
Europe	56	103	91	102	103	103
Latin America and the Caribbean	155	214	239	248	265	269
North America	6	6	10	9	9	9
Oceania	4	5	5	5	6	6
World	8 049	12 632	15 115	18 512	19 015	18 861

Out of the 18.8 million of fish farmers in the world (Table 2), China alone employs 5.2 million, representing 27.6 per cent of the total, while Indonesia employs 3.3 million farmers, representing 17.7 per cent of the total. Employment at farm level includes full-time, part-time and occasional jobs in hatcheries, nurseries, grow-out production facilities, and labourers. Employment at other stages along aquaculture value-chains includes jobs in input supply, middle trade and domestic fish distribution, processing, exporting and vending (HLPE, 2014). More than 80 percent of global aquaculture production may be contributed by small- to medium-scale fish farmers, nearly 90 per cent of whom live in Asia (HLPE, 2014). Farmed fish are expected to contribute to improved nutritional status of households directly through self-consumption, and indirectly by selling farmed fish for cash to enhance household purchasing power (HLPE, 2014)

The regional distribution of jobs in the aquaculture sector reflects widely disparate levels of productivity strongly linked to the degree of industrialization of the dominant culture systems in each region. In Asia, low technology is used in non-fed and inland-fed aquaculture, using extensive ponds, which is labour intensive compared with mariculture in floating systems. In 2011, the annual average production of fish farmers in Norway was 195 tons per person, compared with 55 tons in Chile, 25 tons in Turkey, 10 tons in Malaysia, about 7 tons in China, about 4 tons in Thailand, and only about 1 ton in India and Indonesia (FAO, 2014).

Extrapolating from a ten-country case study representing just under 20 percent of the global aquaculture production, Phillips and Subasinghe (2014, personal communication, cited in HLPE, 2014) estimated that *“total employment in global aquaculture value chains could be close to 38 million full-time people.”*

Table 3. Per capita average outputs per fish farmer by region (in FAO, 2014).

	Production ¹ per person				
	2000	2005	2010	2011	2012
	<i>(Tonnes/year)</i>				
Aquaculture					
Africa	4.4	4.6	5.6	5.4	5.1
Asia	2.3	2.7	2.9	3.0	3.2
Europe	19.8	23.5	24.9	26.0	27.8
Latin America and the Caribbean	3.9	6.3	7.8	9.0	9.7
North America	91.5	68.2	70.0	59.5	59.3
Oceania	23.1	29.5	33.8	30.4	32.7
World	2.6	2.9	3.2	3.3	3.5

¹ Production excludes aquatic plants.

Fish is among the most traded food commodities worldwide. Fish can be produced in one country, processed in a second and consumed in a third. There were 129 billion dollars of exports of fish and fishery products in 2012 (FAO, 2014)

In the last two decades, in line with the impressive growth in aquaculture production, there has been a substantial increase in trade of many aquaculture products based on both low- and high-value species, with new markets opening up in developed and developing countries as well as economies in transition.

Aquaculture is contributing to a growing share of international trade in fishery commodities, with high-value species such as salmon, seabass, seabream, shrimp and prawns, bivalves and other molluscs, but also relatively low-value species such as tilapia, catfish (including *Pangasius*) and carps (FAO 2014). *Pangasius* is a freshwater fish native to the Mekong Delta in Viet Nam, new to international trade. However, with production of about 1.3 million tons, mainly in Viet Nam and all going to international markets, this species is an important source of low-priced traded fish. The European Union and the United States of America are the main importers of *Pangasius*. (FAO, 2014)

9. Environmental impacts of aquaculture

Environmental effects from aquaculture include land use and special natural habitats destruction, pollution of water and sediments from wastes, the introduction of non-native, competitive species to the natural environment through escapes from farms, genetic effects on wild populations (of fish and shellfish) from escapes of farmed animals or their gametes, and concerns about the use of wild forage fish for aquaculture feeds.

9.1 Land use

WRI (2014) estimate that inland aquaculture ponds occupied between 12.7 million ha and 14.0 million ha of land in 2010, and that brackish water or coastal ponds

occupied approximately 4.4 million ha—for a combined area of roughly 18 million hectares, overwhelmingly in Asia. Many of these ponds were converted from rice paddies and other existing cropland rather than newly converted natural lands—but even so, aquaculture adds to world land use demands.

In 2008, global land use efficiencies of inland and brackish water ponds averaged 2.3 tons of fish per hectare per year (t/ha/yr). Expanding aquaculture to 140 million tons by 2050 without increases in that average efficiency would imply an additional area of roughly 24 million ha directly for ponds—about the size of the United Kingdom. (WRI, 2014)

9.2 *Interaction with mangroves*

Land conversion for aquaculture can lead to severe ecosystem degradation, as in the case of the proliferation of extensive low-yield shrimp farms that destroyed large extensions of mangrove forests in Asia and Latin America (Lewis et al., 2002, cited in WRI, 2014). Since the 1990s, non-governmental organizations and policy-makers have focused on curbing the expansion of extensive, shrimp farms into mangrove forests in Asia and Latin America (FAO et al., 2006b). As a result, mangrove clearance for shrimp farms has greatly decreased, thanks to mangrove protection policies in affected countries and the siting of new, more high-yield shrimp farms away from mangrove areas. (Lewis et al., 2002).

9.3 *Pollution of water and sediments*

Wastes from mariculture generally include dissolved (inorganic) nutrients, particulate (organic) wastes (feces, uneaten food and animal carcasses), and chemicals for maintaining infrastructure (anti-biofouling agents) and animal health products (antiparasitics, disinfectants and antibiotics). These wastes impose an additional oxygen demand on the environment, usually creating anoxic conditions under pens and cages.

Research in Norway has shown that benthic effects decline rapidly with increasing depth of water under salmon nets, but situating farms as close to shore as possible may be a prerequisite for economic viability of the industry. Following periods of several years have been found necessary in Norway to allow benthic recovery. Research elsewhere indicates that benthic recovery may be quicker under some conditions (WHOI, 2007)

9.4 *Impact of escapes*

With the use of floating semi-enclosed systems, escapes are inevitable in mariculture and inland aquaculture. Catastrophic events (e.g., hurricanes or other storms), human error, seal and sea lion predation and vandalism will remain potential paths for farmed fish to escape into the wild. Advancements in technology are likely to continue to reduce the frequency and severity of escape events but it is unlikely that this ecological and economic threat will ever disappear entirely. There is considerable evidence of damage to the genetic integrity of wild fish populations when escaped farmed fish can interbreed with local stocks. Furthermore, in semi-enclosed systems, cultured organisms release viable gametes into the water.

Mariculture industry has undertaken a significant effort to produce and use variants of cultivated species that are infertile, diminishing the risk of gene-flow from cultivated/domesticated species to their wild counterparts when escapes occur.

9.5 *Non-native species.*

Aquaculture has been a significant source of intentional and unintentional introductions of non-native species into local ecosystems worldwide. The harm caused by invasive species is well documented.

Intensive fish culture, particularly of non-native species, can be and has been involved in the introduction and/or amplification of pathogens and disease in wild populations (Blazer and LaPatra, 2002, cited in WHOI, 2007).

Non-native oysters have been introduced in many regions to improve failing harvests of native varieties due to diseases or overexploitation. The eastern oyster, *Crassostrea virginica*, was introduced to the West Coast of the United States in 1875. The Pacific or Japanese oyster *Crassostrea gigas*, native to the Pacific coast of Asia, has been introduced in North and South America, Africa, Australia, Europe, and New Zealand and has also spread through accidental introductions either through larvae in ballast water or on the hulls of ships (Helm, 2006).

9.6 *Genetically modified organisms*

Although the use of transgenic, or genetically modified organisms (GMOs), is not common practice in aquaculture (WHOI, 2007), nevertheless the potential use of GMOs would pose severe risks. The production and commercialization of aquatic GMOs should be analyzed considering economic issues, environmental protection, food safety and social and health well-being (Muir, et al., 1999; Le Curieux-Belfond et al., 2009).

9.7 *Use of chemicals as pesticides and for antifouling*

A wide variety of chemicals are currently used in aquaculture production. As the industry expands, it requires the use of more drugs, disinfectants and antifouling compounds (biocides)⁵ to eliminate the microorganisms in the aquaculture facilities. Among the most common disinfectants are hydrogen peroxide and malachite green. Pyrethroid insecticides and avermectins are used as anthelmintic agents (Romero et al., 2012). Organic booster biocides were recently introduced as alternatives to the organotin compounds found in antifouling products after restrictions were imposed on the use of tributyltin (TBT). The replacement products are generally based on copper metal oxides and organic biocides. The biocides that are most commonly used in antifouling paints include chlorothalonil, dichlofluanid, DCOIT (4,5-dichloro-2-n-octyl-4-isothiazolin-3-one, Sea-nine 211®), Diuron, Irgarol 1051, TCMS pyridine

⁵ Biocides are chemical substances that can deter or kill the microorganisms responsible for biofouling.

(2,3,3,6-tetrachloro-4-methylsulfonyl pyridine), zinc pyrithione and Zineb. (Guardiola et al., 2012). The use of biocides is not as well-regulated as drug use in aquaculture because the information available on their effects on ecosystems is still limited.

9.8 Use of antibiotics

Antibiotic drugs used in aquaculture may have substantial environmental effects. The use of antibiotics in aquaculture can be categorized as therapeutic, prophylactic or metaphylactic. Therapeutic use is the treatment of established infections. Metaphylaxis are group-medication procedures, aimed at treating sick animals while also medicating others in the group to prevent disease. Prophylaxis means the precautionary use of antimicrobials in either individuals or groups to prevent the development of infections (Romero et al., 2012).

In aquaculture, antibiotics at therapeutic levels are frequently administered for short periods of time via the oral route to groups of fish that share tanks or cages. Fish do not effectively metabolize antibiotics and will pass them largely unused back into the environment in feces. 70 to 80 per cent of the antibiotics administered to fish as medicated pelleted feed are released into the aquatic environment via urinary and fecal excretion and/or as unused medicated food (Romero et al., 2012). For this among other reasons, antibiotic use in net, pen or cage mariculture is a concern because it can contribute to the development of resistant strains of bacteria in the wild. The spread of antimicrobial resistance due to exposure to antimicrobial agents is well documented in both human and veterinary medicine. It is also well documented that fish pathogens and other aquatic bacteria can develop resistance as a result of antimicrobial exposure. Examples include *Aeromonas salmonicida*, *Aeromonas hydrophila*, *Edwardsiella tarda*, *Yersinia ruckeri*, *Photobacterium damsela* and *Vibrio anguillarum*. Research has shown that antibiotics excreted tend to degrade faster in sea-water, while they persist more in sediments. (Romero et al., 2012)

The public health hazards related to antimicrobial use in aquaculture are twofold: the development and spread of antimicrobial-resistant bacteria and resistance genes and the presence of antimicrobial residues in aquaculture products and the environment (Romero et al., 2012). The high proportions of antibiotic-resistant bacteria that persist in sediments and farm environments may provide a threat to fish farms because they can act as sources of antibiotic-resistance genes for fish pathogens in the vicinity of the farms. Because resistant bacteria may transfer their resistance elements to bacterial pathogens, the implementation of efficient strategies to contain and manage resistance-gene emergence and spread is critical for the development of sustainable aquaculture practices.

Industry faced with uncertainties created by the limited knowledge of infectious diseases and their prevalence in a particular environment tends to abuse the use of antibiotics. Defoirdt et al. (2011, cited by Romero et al., 2012) estimated that approximately 500–600 metric tons of antibiotics were used in shrimp farm production in Thailand in 1994; he also emphasized the large variation between different countries, with antibiotic use ranging from 1 g per metric ton of production in Norway to 700 g per metric ton in Viet Nam. In the aftermath of the ISA infection in the salmon culture in Chile, SERNAPESCA, the Chilean National Fisheries and

Aquaculture Service, recently released data reporting unprecedentedly high amounts of antibiotics used by the salmon industry.⁶ Inefficiencies in the antibiotic treatment of fish illnesses now may lead to significant economic losses in the future (Romero et al., 2012).

Antimicrobial-resistant bacteria in aquaculture also present a risk to public health. The appearance of acquired resistance in fish pathogens and other aquatic bacteria means that such resistant bacteria can act as a reservoir of resistance genes from which genes can be further disseminated and may ultimately end up in human pathogens. Plasmid-borne resistance genes have been transferred by conjugation from the fish pathogen *A. salmonicida* to *Escherichia coli*, a bacterium of human origin, some strains of which are pathogenic for humans (Romero et al., 2012).

9.9 Diseases and parasites

Farming marine organisms in dense populations results in outbreaks of viral, bacterial, fungi and parasite diseases. Diseases and parasites constitute a strong constraint on the culture of aquatic species and disease and parasite translocation by host movements in different spatial scales is common. In molluscs the main parasites are protozoans of the genus *Bonamia*, *Perkinsus* and *Marteilia*. The pathogens *Haplosporidium*, bacteria (rickettsial and vibriosis) and herpes-type virus have a great impact on the rates of mortality. In shrimps the most relevant diseases are viral (white spot disease, WPS, yellow head disease, YHD, taura syndrome disease, TSD) (Bondad-Reantaso et al., 2005).

The “Sea lice (Copepoda, Caligidae) have been the most widespread pathogenic marine parasite” in Salmon farming, affecting also other cultured fishes and wild species (Ernst et al., 2001; Costello, 2006). The global economic cost of sea lice control was estimated at over 480 million dollars in 2006 (Costello, 2009); however, there are other impacts such as the decrease in conversion efficiency (Sinnott, 1998) and the depression of immune systems, which allow the outbreak of bacterial (vibriosis and furunculosis) and viral diseases (infectious salmon anaemia virus, ISA, infectious pancreatic necrosis, IPN and pancreas disease, PD) (Robertson, 2011).

Chapter 13. Fish Stock Propagation

Contributors: Kai Lorenzen, Stephen Smith, Michael Banks, Chang Ik Zhang, Zacharie Sohou, V. N. Sanjeevan, Andrew Rosenberg (Lead Member)

1. Definition

Fish stock propagation, more commonly known as fisheries enhancement, is a set of management approaches involving the use of aquaculture technologies to enhance or restore fisheries in natural ecosystems (Lorenzen, 2008). "Aquaculture technologies" include culture under controlled conditions and subsequent release of aquatic organisms, provision of artificial habitat, feeding, fertilization, and predator control. "Fisheries" refers to the harvesting of aquatic organisms as a common pool resource, and "natural ecosystems" are ecosystems not primarily controlled by humans, whether truly natural or modified by human activity. This places enhancements in an intermediate position between capture fisheries and aquaculture in terms of technical and management control (Anderson, 2002).

The present chapter focuses primarily on enhancements involving releases of cultured organisms, the most common form of enhancements often described by terms such as 'propagation', 'stock enhancement', 'sea ranching' or 'aquaculture-based enhancement'.

2. Enhancements in marine resource management

Enhancements are developed when fisheries management stakeholders or agencies take a proactive, interventionist approach towards achieving management objectives by employing aquaculture technologies instead of relying solely on the protection of natural resources and processes. Enhancement approaches may be used effectively or ineffectively in resource management. To understand how enhancement initiatives can give rise to such different outcomes, it is important to consider not only the technical intervention but the management context in which the initiative has arisen, including ecological and socioeconomic factors as well as the governance arrangements (Lorenzen, 2008).

2.1 *Effective enhancements*

Enhancement approaches may be employed towards different ends commonly referred to as sea ranching, stock enhancement and restocking (Bell et al. 2008). Sea ranching entails releasing cultured organisms to maintain stocks that do not recruit naturally in

the focal ecosystem. This may involve stocks that once recruited naturally but no longer do so due to loss of critical habitat, or it may involve creation of fisheries for desired “new” species for which the focal system provides a habitat suitable for adult stages but not for spawning or for juveniles. Stock enhancement is the practice of releasing cultured organisms into natural stocks of the same species on a regular basis, with the aim of increasing abundance or harvest beyond the level supported by natural recruitment. Restocking entails temporary releases of cultured organisms into wild stocks that have been depleted by overfishing or extreme environmental events, with the aim of accelerating recovery or enabling recovery of stocks “trapped” in a depleted or declining state. The use of enhancement approaches represents a spectrum from strongly production/catch-oriented applications to strongly conservation/restoration-oriented ones, and entails quite different management practices (Section 13.5; Table 2).

The technical intervention of enhancements interacts synergistically with governance arrangements. Stakeholders or management agencies invest in enhancements when they have incentives to do so, either because they stand to gain material benefits (e.g. increase in harvests) or because engaging in enhancement activities increases the perceived legitimacy of management arrangements or agencies (for example, stakeholders may be more supportive of a management agency that engages in fisheries enhancement activities than of one that only regulates fishing). Enhancements require a reasonable level of governance control to emerge at all (they are unlikely to emerge under unregulated open access), and they tend to further strengthen governance control when implemented (Anderson, 2002; Drummond, 2004; Lorenzen, 2008). By helping to strengthen and transform governance arrangements, enhancement initiatives can sometimes generate fisheries management benefits beyond those directly attributable to the technical intervention.

Economic and social benefits of enhancements may arise from biological outcomes such as increased catches or maintenance of fisheries and other ecosystem services in highly modified environments. Successful enhancements often have further, more derived benefits. Pinkerton (1994), for example, describes economic benefits of Alaska salmon enhancements that result from greater consistency and quality of harvests, as well as greater volume. Enhancements can make economic and social benefits from aquaculture technologies available to stakeholders, such as traditional fishers who may lack the assets, skills or interest to engage in conventional aquaculture.

In addition to direct management benefits, enhancements provide opportunities for advancing basic knowledge of ecology, evolution and exploitation dynamics of marine resources (Lorenzen 2014).

2.2 *Ineffective enhancements*

Often, enhancements are initiated under conditions that are fundamentally unsuitable for their effective use, or designed inappropriately. Such ineffective enhancements can nonetheless persist for a considerable time and sometimes do considerable ecological

and economic damage. Incentives for stakeholders or management agencies to engage in enhancement activities can exist even in the absence of evidence of their technical effectiveness, and once investments have been made and stakeholders have become vested, it becomes increasingly difficult to discontinue such initiatives. These issues point to the need for constructive science and management engagement with the development of new, and the reform of existing, enhancements (Section 13.4).

2.3 *Examples of enhancement efforts*

The following examples illustrate the potential for well-managed enhancements to contribute to fisheries management goals and the interactions between the technical and governance dimensions of such initiatives.

Very large-scale enhancement efforts are undertaken in the Pacific Northwest of the United States of America (Naish et al., 2007). These efforts include enhancements to support commercial and recreational fisheries (Knapp et al., 2007), enhancement and restocking initiatives to meet tribal treaty obligations (Smith, 2014), and restoration efforts for endangered populations (Kline and Flagg, 2014). Pacific Northwestern habitats once hosted a tremendous biomass of salmon that comprised a significant component of food and nutrient webs linking ocean and freshwater biomes. For example, it is estimated that the Columbia River once hosted returns of 10-16 million wild salmon (Johnson et al., 1997). Historical overharvest, irrigation withdrawals, hydropower dams and other factors have reduced returns. Of the current returns of around 1 million, hatchery fish make up around 80 per cent (95 per cent of the coho, 70 to 80 per cent of the spring and summer chinook, 50 per cent of the fall chinook, and 70 per cent of the steelhead) (NMFS, 2000)). In Oregon, Nicholas and Hankin (1989) estimated that 21 of 36 coastal stocks of spring and fall chinook salmon were almost entirely comprised of wild fish. In the remaining stocks, the percentage of hatchery fish in the runs ranged from 10 to 75 per cent. Oregon's hatchery programme annually releases 74 million salmonids: 60.4 million salmon, 6.4 million steelhead and 7.6 million trout (ODFW, 1998). Such hatchery programmes can maintain fisheries when essential habitats are degraded or inaccessible and help conserve or restore endangered populations, but they also pose ecological and genetic risks to wild populations. A major scientific review of Columbia River hatchery programmes successfully used population modelling to identify hatchery operation and harvest policies that simultaneously improve the conservation status of wild populations and provide moderate increases in harvest (Paquet et al., 2011). In Alaska, large-scale salmon enhancements are run by community-based Aquaculture Associations. Since the mid-1970s, Aquaculture Associations produce and release juvenile salmon and, in return, gain exclusive rights to a share of the harvest in the form of "cost-recovery fish". The associations have since become engaged in many aspects of salmon fisheries management, effectively creating a co-management system with the State of Alaska.

The world's largest marine invertebrate fisheries enhancement is the scallop enhancement operation run by fishing cooperatives in Hokkaido, Japan (Uki, 2006). Development of an effective spat collecting, on-growing and releasing technology in the mid-1960s created the opportunity to seed scallop grounds with high densities of juveniles. Fishing cooperatives adopted rotational seeding and harvesting of fishing grounds, combined with predator control, and increased regional production from an average of 40,000 tons to around 300,000 tons per year. The success of this enhancement has been attributed to a combination of factors including suitable habitat, the species' biology (young optimal harvest age, low post-release dispersal), integration of spat releasing with predator control and rotational harvesting, and devolution of management to a fishing cooperative with exclusive rights over the resource (Uki, 2006).

In New Zealand, the Japanese scallop enhancement technology was adapted to revive the Southern Scallop Fishery in what became a restocking initiative combined with far-reaching changes in governance. Adoption of aquaculture technology allowed the fishery to opt out of the fisheries management framework of the time and transition to an individual quota-based regime and rotational seeding and harvesting. Cultured juveniles contributed strongly to initial recovery but natural recruitment became dominant as the fishery was rebuilt (Drummond, 2004). More recently, low spat survival has led to a sharp reduction in catches and to the closure of some of the main grounds (Williams et al. 2014). This decline in survival may be related due to changes in productivity due to increasing sedimentation in the area.

In the Republic of Korea, the National Fisheries Research and Development Institute (NFRDI) developed seed production technology to release healthy juveniles of rockfish and sea bream. Since 1998, seed production and fish release have successfully enhanced fishery resources and increased the income of fishermen. In the early stages of seed production, national facilities took the lead to develop techniques, but currently private companies produce the seed. Between 1986 and 2012, 46 marine species including abalone, various flatfish, sea bream and sea slugs were targets for production and 1,410 million juveniles of fish and shellfish species were stocked in the sea in the Republic of Korea. In the Republic of Korea, habitat restoration tools are also widely applied together with fish release in situations where habitat has been identified as the primary factor limiting production. These tools refer to the increase in available habitat and/or access to key habitat for at least some stages of the life history of a target species. Although artificial habitats are currently popular in some areas and widely used, scientific evaluation of the effectiveness of habitat restoration is incomplete. In the Republic of Korea, construction of artificial reefs is aimed at improving productivity of devastated fishing grounds by providing fish resources with habitats, and spawning and nursery grounds. Since 1971, about 3,000 fishing grounds have been augmented, with artificial reefs covering a total area of 216 kha as of 2012. Fifty-five per cent of the area with artificial reefs is utilized as fishing grounds and the other 45 per cent is preserved as spawning and nursery grounds of fish resources. Enhanced fisheries are managed cooperatively with fishing communities and marine enhancement in the Republic of

Korea is becoming integrated into a comprehensive ecosystem-based fisheries management approach (Zhang et al., 2009).

In India, efforts with regard to stock enhancement of Penaeid prawns along the Kerala coast have not met with the desired success. This probably reflects heavy mortality of hatchery grown post larvae on their release to the sea, as they are neither acclimatized to the stress conditions of the sea nor have they acquired adequate predator avoidance skills. An additional effort in India is intended to revive depleted marine snail species along the coast of Tamil Nadu; *Xancus pyrum* (sacred chank), *Babylonia spirata* (whelk), *Hemifusus pugilinus* (spindle shells), *Chicoreus ramosus* (murex) and *C. virgineus*. Wild stocks of all of these species are heavily exploited for their meat (India exports 700 to 900 tons of frozen whelk meat every year), shells (used as a trumpet in temples and for the manufacture of ornaments) and opercula (which have medicinal value and are exported to Australia, France, Germany, Italy, Japan). About 10,000 juveniles and 0.5 million larvae of the above species were sea-ranched in the Gulf of Mannar in October 2010. It is premature to comment on the success of this experiment, but regular surveys of the-grow out site show only a few dead organisms.

2.4 *Global extent of enhancements*

Marine fisheries enhancement is a widespread activity. Between 1984 and 1997, 64 countries reported stocking over 30 billion individuals of over 180 species in marine environments (Born et al., 2004). The global contribution of enhancements to marine fish production is difficult to quantify exactly, but is unlikely to exceed one to two million tons per year (around 1-2 per cent of global marine fisheries and aquaculture production) (Lorenzen 2014). This modest contribution to global production should not distract from the fact that considerable efforts and monetary investments are expended on enhancement initiatives, and that enhancements contribute substantially to several high-value fisheries as well as to restoration efforts for various species of conservation concern.

2.5 *Developing or reforming enhancements*

According to the reviewed assessments, enhancements are often initiated or promoted by fisheries stakeholders, but require scientific and management engagement in order to assess the potential of such initiatives, to develop effective enhancement systems where the potential exists, and to discontinue initiatives that are likely to be ineffective or harmful. Constructive science and management engagement with enhancements may be guided by the widely used and recently updated “responsible approach” (Blankenship and Leber, 1995; Lorenzen et al., 2010). The updated responsible approach consists of 15 recommended actions, divided into three stages of development or reform (Table 1). A staged approach ensures that the basic potential of enhancements is assessed (Stage I) prior to investment in technology development and pilot studies (Stage II), which in turn precede operational-scale implementation (Stage III). Qualitative

and quantitative modelling are crucial in Stage I, and experimental (adaptive) management is central to assessing enhancement capacity and ecological impacts in later stages. This requires monitoring of temporal and spatial controls where fisheries are not enhanced and possibly not exploited (Caddy and Defeo 2003; Leleu et al., 2012; Costello, 2014). The most systematic and rigorous application of many ideas summarized in the responsible approach can be found in the Hatchery Reform process being applied to Pacific salmon hatchery programmes (Moberg et al., 2005; Paquet et al., 2011).

3. Management considerations

3.1 The fisheries system and management context

Enhancements enter into existing fisheries systems and it is crucial to gain a broad-based understanding of the system prior to defining management objectives and assessing possible courses of action. At a minimum the following should be considered: the biology and status of the target fish stock (biological resource), the supporting habitat and ecosystem, the aquaculture operation, stakeholder characteristics (of fishers, aquaculture producers and resource managers), markets for inputs and outputs, governance arrangements, and the linkages between these components. A framework for enhancement-fisheries system analysis is outlined in Lorenzen (2008).

3.2 Stakeholder involvement

Stakeholder involvement is central to effective scientific and management engagement with enhancement initiatives because stakeholders tend to have a large influence on the initiation and development of such initiatives. Only when stakeholders are constructively involved in the assessment and decision-making process is the enhancement initiative likely to develop towards a beneficial conclusion (which may be an effective enhancement or the discontinuation of an ineffective or damaging initiative). Stakeholder involvement also makes the often considerable knowledge and experience of stakeholders accessible to the scientific and management process.

3.3 Identifying appropriate biological and technical system designs

Different enhancement strategies, such as sea ranching, stock enhancement and restocking, involve quite different management approaches and considerations (Utter and Epifanio, 2002; Naish et al., 2007 and Lorenzen et al., 2010; Lorenzen et al., 2012). Table (2) outlines the different practices involved with regards to aquaculture, stock and genetic management (based on Lorenzen et al., 2012).

3.4 *Stock dynamics and management*

Quantitative assessment of stock dynamics and the potential of enhancement as well as alternative management options, such as harvest restrictions to contribute to stock management objectives, is important at all stages of enhancement initiatives (Caddy and Defeo, 2003; Walters and Martell, 2004; Lorenzen, 2005). Different considerations apply to ranching, stock enhancement and restocking systems (Table 2). In ranching systems where maintaining natural recruitment is not a management goal, stock structure could be manipulated to maximize biomass production in food fisheries or to maximize abundance of 'catchable' size fish in put-and-take recreational fisheries. In stock enhancements where cultured fish are released into wild populations, it would be desirable to manage stocking and harvesting activities so as to limit negative impacts on naturally recruiting stock components which may arise from compensatory ecological responses to stocking or from overfishing of the natural spawning stock (Hilborn and Eggers 2000; Lorenzen, 2005). Such effects may reduce or eliminate net benefits from enhancement and pose conservation threats to wild stocks. Impacts of enhancements on wild stocks could be reduced by separating the cultured and wild population components as far as technically possible at the point of stocking, and through differential harvesting and possibly induced sterility of cultured fish (Lorenzen, 2005; Naish et al., 2007; Mobrand et al., 2005). According to these authors, restocking is likely to be advantageous over natural recovery only for populations that have been depleted to a very low fraction of their carrying capacity and requires concomitant reductions in fishing effort (Lorenzen 2005). Fisheries models and assessment tools are now available to conduct such quantitative assessment at all stages in the development or reform of enhancements (Lorenzen, 2005; Michael et al. 2009).

3.5 *Aquaculture production for enhancements*

Rearing of marine organisms in culture facilities subjects them to domestication processes that have strong and almost always negative impacts on their capacity to survive, grow, and reproduce in the wild (Le Vay et al., 2007; Lorenzen et al., 2012). A variety of measures, such as rearing in near-natural environments, environmental enrichment, life-skills training and soft release strategies, can counteract such domestication effects, but none are likely to be wholly effective (Olla et al., 1998; Brown and Day, 2002). Aquaculture production for release into natural ecosystems may benefit from culture practices that differ from those normally employed in facilities producing organisms for on-growing in aquaculture facilities and may also require different genetic management.

3.6 *Genetic management*

Genetic management is important for maximizing post-release fitness and enhancement effectiveness, and for minimizing risks to the genetic integrity of wild stocks. Three main sets of issues need to be considered: (1) potential disruption of neutral and adaptive

spatial population structure due to translocation; (2) impacts of hatchery spawning and rearing on the genetic diversity of stocked fish and the enhanced, mixed stock; (3) impacts of hatchery rearing on the fitness of released fish and their naturally recruiting offspring; and (4) hybridization between stocked and wild species (Utter and Epifanio, 2002; Tringali et al., 2007; Araki et al., 2008). Appropriate sourcing and management of brood stock, possibly combined with rearing practices that minimize domestication selection are key genetic management actions and it may also be necessary to limit the contribution of cultured fish to the naturally spawning population (Miller and Kapuscinski, 2003; Tringali et al., 2007; Baskett and Waples, 2013). Different genetic management approaches may apply in sea ranching systems or “separated” stock enhancement programmes where direct genetic interactions between stocked and wild fish are absent and where, for example, selective breeding may be used to improve the post-release performance of hatchery fish (Table 2; Jonasson et al., 1997).

3.7 Pathogen interactions

Impacts on wild stocks from pathogen and parasite interactions that may cause disease may occur via three mechanisms: (1) introduction of alien pathogens, (2) transfer of pathogens that have evolved increased virulence in culture, (3) changes in host population density, age/size structure, or immune status that affect the dynamics of established pathogens. It is therefore important to implement an epidemiological, risk-based approach to managing disease interactions that accounts for ecological and evolutionary dynamics of transmission and host population impacts (Bartley et al., 2006).

3.8 Governance

Enhancements require governance systems that are effective at restricting exploitation and ensuring that those who invest in the resource through stocking can reap at least a sufficient share of the benefits. Depending on the wider governance framework, such arrangements can be based on individual or communal use rights (e.g., individual quotas or territorial use rights) or on government regulation (and taxation to recoup costs). A second important requirement of governance systems for enhanced fisheries is coordination of the fisheries and aquaculture components in terms of stock, genetic and health management.

3.9 Impacts on marine ecosystems

Potential impacts of enhancements on marine ecosystems differ between types of enhancement system. Impacts on non-target species are of the most concern in ranching systems where organisms that do not recruit naturally in the receiving ecosystem may be released in high numbers and harvested intensively. Species introduced outside their native range pose particular risks (many have minimal impacts,

but a small proportion become invasive and inflict massive ecological and economic damage). In stock enhancement systems, ecological and genetic impacts on the wild stock component tend to be of the most concern. Restocking initiatives will have broadly positive impacts on marine ecosystems as long as good stock and genetic management approaches are in place. Although potential impacts of marine enhancement activities are well understood, empirical evidence for such impacts is limited except for the large-scale salmon enhancements in the Pacific Northwest and the Laurentian Great Lakes of North America (Naish et al., 2007; Crawford, 2001). This paucity of information likely reflects the limited scale of marine enhancements to date.

3.10 Interactions with other sectors

Aquaculture technologies enable enhancements in the first place and availability of cultured organisms from the commercial aquaculture sector can greatly reduce the barriers for fisheries stakeholders to engage in enhancements. Interactions with fisheries may occur in terms of access conflicts or impacts on wild target or non-target species and such interactions may increase as marine enhancements become more common. Market interactions between products from enhancements and from aquaculture and capture fisheries can be significant where enhancements account for substantial market share as in the case of salmon (Knapp et al., 2007). However, the market share of enhancements is small for most species and products, so that enhancements are more often impacted through the market by developments in the aquaculture and capture fisheries sectors than vice versa.

3.11 Technical and economic performance

As discussed previously, the technical and economic performance of marine enhancements is highly variable. Reviews by Hilborn (1998) and Arnason (2001) concluded that only a small proportion of documented enhancements are demonstrably economically successful, but for many information is insufficient to assess economic viability, and some are demonstrably unsuccessful. Further assessments and comparative analyses are urgently required.

4. International agreements and guidelines

There are currently no international agreements pertaining directly to fisheries enhancements. Some FAO instruments, including the FAO Technical Guidelines for Responsible Fisheries, deal with issues associated with fisheries enhancements (e.g., FAO, 2008). In addition, eco-labelling of products from enhanced fisheries has been considered at the Expert Consultation on the Development of Guidelines for the Ecolabelling of Fish and Fishery Products from Inland Capture Fisheries held in 2010 (FAO, 2010). The FAO Committee on Fisheries adopted these Guidelines in 2011 (FAO,

2011). The *ICES Code of Practice on the Introductions and Transfers of Marine Organisms* (ICES, 2005) is widely accepted and applies to introductions carried out for the purpose of fisheries enhancements.

5. Future trends

Enhancements are likely to become more widespread as burgeoning demand for seafood and increasingly severe human impacts on the coastal oceans create greater demand for proactive management, aquaculture technologies become available for an ever-increasing number of marine species, and governance arrangements for many fisheries move towards rights-based systems that provide strong incentives for investment in resources (Lorenzen et al., 2013). Greater scientific and management attention to enhancements is required to aid the development of potentially effective initiatives and to avoid widespread investment in ineffective or damaging enhancements (Lorenzen, 2014).

6. State of scientific knowledge, application and recommendations

Rapid progress has been made in the scientific understanding of marine enhancements over the past 20 years (Leber, 2013). Unfortunately, the scientific knowledge and tools now available to aid the development or reform of enhancements are not widely applied (Lorenzen 2014). Reasons may include that mainstream fisheries and aquaculture scientists are often unaware of developments in this interdisciplinary area or not adequately trained to conduct the necessary assessments. Research providers and management agencies need to build capacity for engaging with enhancement initiatives using current science. Improved reporting on enhancement initiatives and outcomes at national and international level is also important. Currently, harvests from enhanced fisheries tend to be lumped into either capture fisheries or aquaculture production figures in national and international statistics (Born et al., 2004; Klinger et al., 2012).

Table 1. Elements of the updated “responsible approach” to fisheries enhancement (Lorenzen et al., 2010).

Stage I: Initial appraisal and goal setting

- (1) Understand the role of enhancement within the fishery system
- (2) Engage stakeholders and develop a rigorous and accountable decision-making process
- (3) Quantitatively assess contributions of enhancement to fisheries management goals
- (4) Prioritize and select target species and stocks for enhancement
- (5) Assess economic and social benefits and costs of enhancement

Stage II: Research and technology development including pilot studies

- (6) Define enhancement system designs suitable for the fishery and management objectives
- (7) Design appropriate aquaculture systems
- (8) Use genetic resource management to avoid deleterious genetic effects
- (9) Use disease and health management
- (10) Ensure that released hatchery fish can be identified
- (11) Use an empirical process for defining optimal release strategies

Stage III: Operational implementation and adaptive management

- (12) Devise effective governance arrangements
- (13) Define a stock management plan with clear goals, measures of success and decision rules
- (14) Assess and manage ecological impacts
- (15) Use adaptive management

Table 2. Design criteria for biological-technical components of marine enhancement fisheries systems serving different objectives (adapted from Lorenzen et al., 2012).

	Sea ranching	Stock enhancement	Re-stocking
Aim of enhancement	Increase fisheries catch	Increase fisheries catch while conserving or increasing naturally recruiting stock	Rebuild depleted wild stock to higher abundance
Wild population status	Absent or insignificant	Numerically large Possibly depleted relative to carrying capacity	Numerically large or small Depleted relative to carrying capacity
Aquaculture management	Production-oriented Partial domestication Conditioning for release Possibly induced sterility	Integrated programmes: as for re-stocking Separated programmes: as for sea ranching	Conservation-oriented Minimize domestication Conditioning for release
Genetic management	Maintain genetic diversity Selection for high return	Integrated programmes: as for re-stocking Separated programmes: as for sea ranching; also selection to promote separation	Preserve all wild population genetic characteristics
Population management	Stocking and harvesting to create desired population structure	Integrated programmes: restricted stocking and harvesting to increase catch while conserving naturally recruiting stock Separated programmes: as for sea ranching; also measures to promote separation	High stocking density over short period; temporarily restricted harvesting or moratorium

Chapter 14. Seaweeds

Contributors: John West and Hilconida P. Calumpong (Co-lead member), Georg Martin (Lead member)

1. Introduction

Seaweeds are a group of photosynthetic non-flowering plant-like organisms (called macroalgae) that live in the sea. They belong to three major groups based on their dominant pigmentation: red (Rhodophyta), brown (Phaeophyta) and green (Chlorophyta). Seaweeds were traditionally and are currently still used as food in China, Japan and the Republic of Korea. About 33 genera of seaweeds, mostly red and brown, are harvested and farmed commercially (McHugh, 2003), although close to 500 species in about 100 genera are collected and utilized locally (Mouritsen, 2013). Currently about 80 per cent of total seaweed production is for direct human consumption, eaten dried or fresh for its nutritional value or for flavouring (see Kilinc et al., 2013 for a comprehensive listing of nutrients and compounds) in the form of sushi, salad, soup, dessert and condiments, and the remaining 20 per cent is used as a source of the phycocolloids extracted for use in the food, industrial, cosmetic, and medical industry (Browdy et al., 2012, Critchly et al., 2006, Lahaye, 2001, McHugh, 2003, Mouritsen, 2013, Ohno and Critchley, 1993), as well as for animal feed additive, fertilizer, water purifier, and probiotics in aquaculture (Abreu et al., 2011, Chopin, 2012, Chopin et al., 2001, Chopin et al., 2012, Fleurence et al., 2012, Kim et al., (2014), Neori et al., 2004, Pereira and Yarish, 2008, 2010, Rose et al., 2010). Carrageenan and agar are extracted from red seaweeds, and alginates and fucoïdan are extracted from brown seaweeds, generally from kelp species. Recently, the kelp species *Saccharina latisima* was considered for bioethanol production (Adams et al., 2009).

2. Production

World production of seaweeds comes from two sources: harvesting from wild stocks and from aquaculture (including land-based culture, mariculture and farming). Production from harvesting of wild stocks has been stable at over 1 million tons (wet weight) in the last 10 years (2003 to 2012) according to FAO (2014) statistics (see Figure 1). Top producers in 2012 were Chile (436,035 tons representing 39 per cent of total world production), China (257,640 tons or 23 per cent), Norway (140,336 or 13 per cent), Japan (98,514 or 9 per cent), France (41,229 tons or 4 per cent), Ireland (29,500 tons or 2.73 per cent), Iceland (18,079 tons or 2 per cent), South Africa (14,509 tons or 1 per cent) and Canada (13,833 tons or 1 per cent). Contributing less than 1 per cent each were 24 other countries. Chile has consistently been the number one top producer

since 2003, except in 2007 when China exceeded Chile's production by 1 per cent. Norway and Japan have maintained their position as third and fourth top producers, respectively, since 2003.

Three countries posted only one year's production in 10 years (Namibia in 2003 with 408 tons, Samoa in 2004 with 478 tons, Senegal in 2012 with 1,028 tons. India posted 1 ton of production in 2004 to 2008, except in 2005 when it posted 2 tons of production).

Figure 1. World seaweed production from wild stocks in 2003-2012 by country/territory in tons wet weight. Data from FAO, 2014. Four countries with production in 10 years of less than 1000 tons or with only one production within 10 years are lumped under Others (see text). [tp://www.fao.org/fishery/statistics/software/fishstatj/en](http://www.fao.org/fishery/statistics/software/fishstatj/en).

The bulk of seaweeds produced worldwide come from aquaculture. The FAO (2014) reported that the production of aquatic seaweeds from mariculture, reached 24.9 million tons in 2012, valued at about \$6 billion United States dollars. The red, brown and green seaweeds constitute about 88 per cent (21 million tons). About 96 per cent (23.8 million tons) of the total production were produced from aquaculture (see Figure 14.2). Data from FAO showed a steady increase of about 8 per cent per year over the last 10 years (range of 4-12 per cent), specifically for red seaweeds (Figure 3) with the brown seaweeds showing stable production. The cultured seaweeds are mainly those that produce carrageenan (*Kappaphycus alvarezii* and *Eucheuma* spp. - 8.3 million tons), followed by the alginate-producing brown seaweeds (kelps - 5.7 million tons). China is the consistent top supplier, although showing a decreasing trend, with 50 per cent of the world production over a 10-year period (2003-2012). The Philippines ranked second in 2003 to 2006, producing 9-10 per cent, after which it was overtaken by Indonesia. The Democratic People's Republic of Korea, the Republic of Korea, and Japan produced between 2-5 per cent of the annual total, and 31 other countries produced less than 1 per cent of the annual total, except for Malaysia, which showed an increasing production equivalent to 1.09-1.39 per cent of the annual global quantity during 2010 to 2012.

3. Social and economic impacts and challenges

Harvests from wild populations are affected by overexploitation and climatic changes. In Northern Ireland, for example, which is listed as one of the top 10 producers of wild stocks globally (FAO, 2014), McLaughlin et al., (2006) described in detail the adverse impacts of seaweed harvesting at small, artisanal and commercial scales on areas of conservation importance, protected and priority habitats and species, including disturbance of birds and wildlife, disruption of food webs, damage to substrata, habitat destruction, localized biodiversity changes, and changes in particle-size distribution in sediments. Direct effects on the seaweed population include mortalities due to increased growth rate and cover of other algae which are not harvested, such as filamentous green algae and the brown seaweed, *Fucus vesiculosus*, which outcompete the desired species, and die-back due to increased predation. In several areas of Norway, the kelp *Saccharina lattisima* has been reported by Moy and Christie (2012) to have suffered dieback by 40-80 per cent due to sea urchin predation.

The brown seaweed kelps are most affected by rising water temperature, because sexual reproduction (gamete formation) in most kelps will not occur above 20°C (Dayton 1985, Dayton et al., 1999). Already along the European coasts and especially in Brittany,

France, the brown kelp, *Laminaria digitata*, which is heavily harvested for commercial uses, is reported to be on the verge of local extinction. The already reduced reproductive potential of the kelp due to dwindling population and harvesting-induced ecosystem changes may be exacerbated by climate-caused increase in sea temperature (Brodie et al., 2014, Raybaud et al., 2013). Two other kelp species, *Laminaria ochroleuca*, a warm-temperate perennial, and *Saccorhiza polyschides*, a wide-ranging cool- to warm-temperate annual, have somewhat higher temperature tolerances for sexual reproduction than other kelps (Pereira et al., 2011); however, *Saccorhiza* outcompetes *L. ochroleuca* in shared habitats. Brittany is the northern limit of *L. ochroleuca*'s range. Since 1940, *L. ochroleuca* has been found on the coasts of southern England, which is apparently indicative of a slow northward extension of warmer waters. Anticipated increasing ocean temperatures in the future in the boreal region may result in *L. ochroleuca* possibly replacing *L. hyperborea* (Brodie et al., 2014). On the other hand, the kelp *Ecklonia maxima* is extending eastward on the tip of South Africa because of a northward intrusion by cooler inshore water (Bolton et al., 2012); this could greatly benefit the whole ecosystem and provide more food for the abalone industry there. All this is quite a contrast from southward intrusion patterns by warm water on the east and west coasts of Australia, causing extensive retreat of kelps and fucoids (another group of brown algae) southward from their previous northern-most limits (Wernberg et al., 2011, Millar, 2007).

Seaweed farming and culture are seriously affected by diseases. *Ice-ice* disease has impacted the farming of the kappa-carrageenan-producing *Kappaphycus alvarezii*, commercially called "cottonii". Another species, *Eucheuma denticulatum*, commercially called "spinosum," is *ice-ice*-resistant, but contains iota-carrageenan which fetches a much lower price on the world market (Valderrama, 2012). This problem may be a result of the low genetic variation in *K. alvarezii*, all of whose cultured stocks around the world have a similar mitochondrial haplotype, which is not the case for *E. denticulatum* (Halling et al., 2013; Zuccarello et al., 2006). Significant diseases affecting cultivated kelps (e.g., *Saccharina japonica*) include green-rot, white-rot, blister disease, which may be environmentally induced, and malformation disease of summer sporelings and swollen stipe or "frond twist disease" which are caused by bacteria (Brinkhaus et al., 1987, Tseng, 1986). Parasites such as *Pythium*, an oomycete fungus, causes "red rot" or "red wasting" disease in the red seaweed *Pyropia* commonly used in making sushi (Hurd et al., 2014). However, based on case studies from six countries, Valderrama (2012) reported that the socioeconomic impacts of seaweed farming have been positive. He attributed this mainly to small-scale, family operations resulting in the generation of substantial employment as compared to other forms of aquaculture. He added that seaweed farming is often undertaken in remote areas where coastal communities face fewer economic alternatives and where many of these communities have traditionally relied on coastal fisheries which are currently being affected by overexploitation. Valderrama stated that the impact of seaweed farming in these cases goes beyond its immediate economic benefits to communities as it also reduces the incentives for overfishing. However, one challenge faced by farmers in these remote areas is low

profits due to high shipping costs. This disadvantage is exacerbated by the dependence of farmers on processors for the procurement of their farming materials and their lack of farm-management skills. In addition, food safety issues can sometimes affect markets and prices. This is because seaweeds are efficient nutrient extractors (Kim et al., 2014) and may accumulate compounds that pose harm to human health (Mouritsen 2013; see also Chapter 10).

4. Information and Knowledge Gaps

Despite the long history of utilization, it is reported that kelp-dominated habitats along much of the NE Atlantic coastline have been chronically understudied over recent decades in comparison with other regions such as Australasia and North America. For example, McLaughlin et al. (2006) noted that information on the distribution and biomass of commercial seaweeds in Northern Ireland is lacking. Smale and Wernberg (2013) highlight the changing structure of kelp forests in the North- East Atlantic in response to climate- and non-climate-related stressors, which will have major implications for the structure and functioning of coastal ecosystems. This paucity of field-based research is impeding ability to conserve and manage this important resource.

Chapter 15. Social and Economic Aspects of Sea-Based Food and Fisheries

Contributors: Ratana Chuenpagdee, Patrick McConney, and Gordon Munro;
Beatrice Ferreira, Enrique Marschoff, Jake Rice, Andrew Rosenberg (Group of experts)

1. Introduction

Fish are one of the most internationally traded foods, and the value of global fish trade exceeds the value of international trade of all other animal proteins combined (World Bank, 2011). In 2012, international trade represented 37 per cent of the total fish production in value, with a total export value of 129 billion United States dollars, of which 70 billion dollars constituted developing countries' exports (FAO, 2014). Estimates indicate that small-scale fisheries contribute about half of global fish catches (FAO, 2014; HLPE, 2014). When considering catches destined for direct human consumption, the share contributed by the subsector increases, as small-scale fisheries generally make broader direct and indirect contributions to food security through affordable fish and employment to populations in developing countries.

This chapter, in addressing the economic and social aspects of marine fisheries, examines both macro and micro issues. The macro issues considered are some aspects of the economics of marine capture fishery. Among the micro issues explored are local to regional socioeconomic effects, competition for space between various ocean activities and user groups, the relationship between capture fisheries and aquaculture, and gender issues in fisheries and aquaculture.

The contribution of small-scale fisheries has been increasingly recognized as a major factor for food security and livelihoods at household and community levels, particularly for poor communities around the world. Information on small-scale fisheries is often not captured in national statistics as a result of difficulties due to many factors, including their socioeconomic complexity and the highly dynamic nature of their operation (Chuenpagdee, 2011). Numerous initiatives around the world reflect their importance, including those led by FAO in the development of the Voluntary Guidelines for Securing Sustainable Small-Scale Fisheries.¹

2. Marine Capture Fisheries Social and Economic Value

The global marine capture fisheries harvest expanded rapidly from the early 1950s, and is currently estimated to be about 80 million tons per annum (see Chapter 11 and FAO,

¹ The Guidelines have recently been adopted at the 31st Session of the Committee on Fisheries, June 2014. The final text is available at www.fao.org.

2014). This harvest is estimated to have a first value (gross) in the order of 80 billion US dollars (World Bank and FAO, 2009). Although it is difficult to produce accurate employment statistics, capture fisheries provide, direct and indirect employment, for at least 120 million persons worldwide (*ibid.*).

Global and regional fishery catch statistics in most cases do not distinguish between large scale and small-scale fisheries, so the small-scale sector is often poorly covered in official statistics and chronically under-evaluated in general. The Big Numbers Project (BNP)² carried out case studies in populous developing countries and the results from these case studies, together with other available information, formed the basis for a first disaggregated review of the fisheries sector as a whole (WorldFish Center, 2008). Tentative estimates were calculated for developing countries at 28-30 million MT/year for marine fisheries. This represents half of the catch in those countries, of which 90-95 per cent is destined for domestic human consumption. Those figures highlight the importance of small-scale fisheries for food security in developing countries.

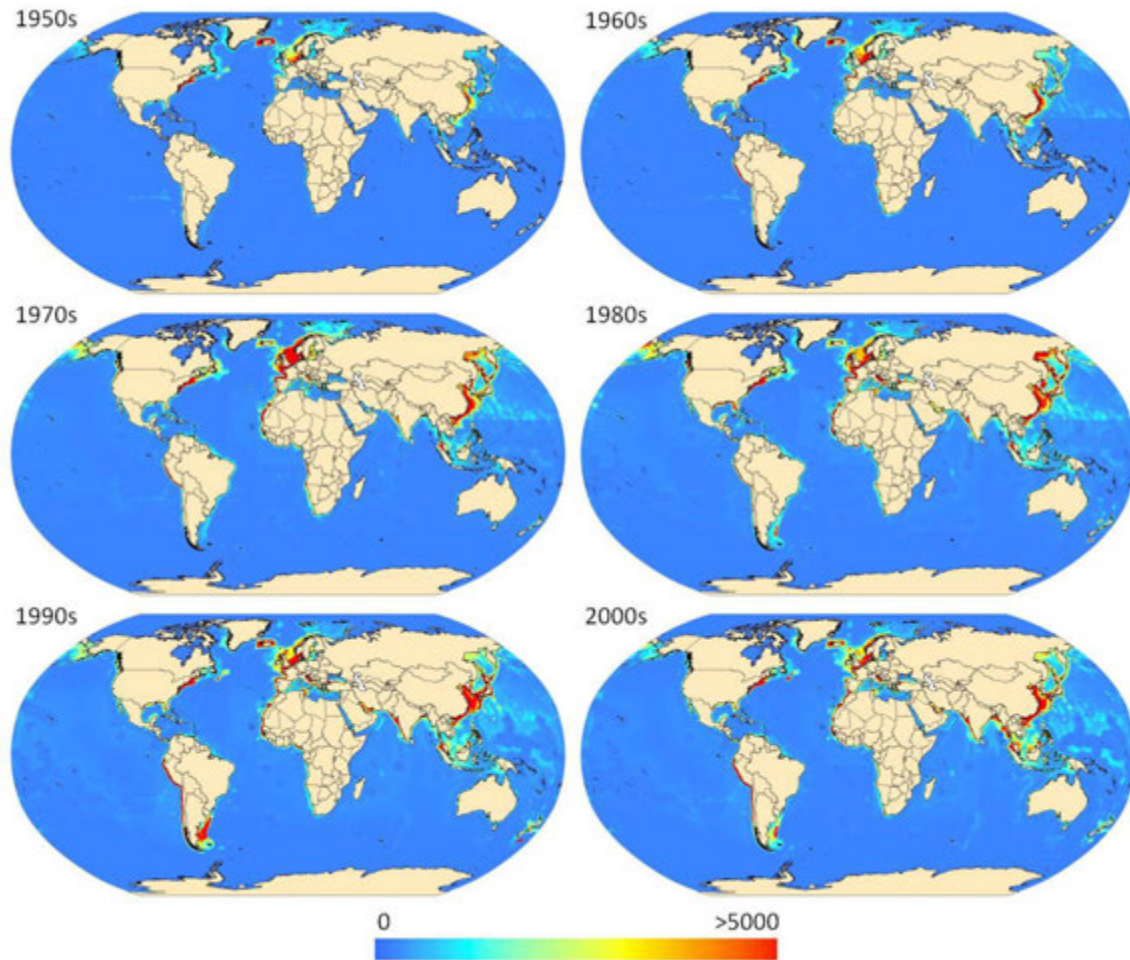

Small-scale fisheries employ more than 90 per cent of the world's capture fishers and fish workers, about half of whom are women. In addition to employment as full- or part-time fishers and fish workers, seasonal or occasional fishing and related activities provide vital supplements to the livelihoods of millions. These activities may be a recurrent sideline activity or become especially important in times of difficulty. Many small-scale fishers and fish workers are self-employed and engaged in directly providing food for their household and communities as well as working in commercial fishing, processing and marketing (FAO, 2014).

The quality of such employment is increasingly seen as an important social and economic aspect of fisheries as attested to by the attention to decent work in the FAO Voluntary Guidelines on Securing Small-Scale Fisheries (SSF Guidelines) that draws from several international instruments concerning, gender, child labour, workers' rights and the like. Much of this labour is linked directly, through short value chains, to providing critical income along with food and nutrition security, especially in rural coastal communities.

Over time, there has been a shift in the relative scale and geography of capture fisheries. In the 1950s, capture fisheries were largely undertaken by developed fishing States in the northern hemisphere. Since then, developing countries increased their share of the total. Consider Figure 1, which presents geo-referenced distributions of decadal averages of annual landed values of the world's fisheries and highlights the southward and offshore expansion of the fishing grounds over time (Swartz et al., 2013). Although the two hemispheres do not reflect developed vs. developing fishing States precisely, the figures are, nonetheless, indicative. In the 1950s, the Southern hemisphere accounted for no more than 8 per cent of landed values. By the last decade,

² This is a joint activity of FAO and the WorldFish Center and funded through the World Bank's PROFISH1 Partnership.

the Southern hemisphere's share had risen to 20 per cent of the total. This change likely resulted from a combination of factors including transfer of fishing effort from north to south, overall increases in fisheries in the south and improvement in reporting systems. Nevertheless, the relative contribution to global landings from the two hemispheres has changed.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Spatial distribution of average annual landed values (2005 United States dollars per square kilometre per year) by decade (from Swartz et al 2013; with permission of Springer).

In terms of volume, the shift seen in Figure 1 is even more striking; as shown in Figure 2, the top ten capture fisheries producers include seven developing countries³.

Indeed, net exports of fish and fishery products from developing countries have grown significantly in recent decades, rising from 3.7 billion dollars in 1980 to 18.3 billion

dollars in 2000, 27.7 billion dollars in 2010, and reaching 35.1 billion dollars in 2012. For Low-Income Food-Deficit Countries (LIFDCs) net export revenues amounted to 4.7 billion dollars in 2010, compared with 2.0 billion dollars in 1990 (HLPE, 2014). The share of exports from developing countries is close to 50 per cent (value) and 60 per cent (in volume of live weight equivalent) of global fish exports (FAO, 2012).

Marine and inland capture fisheries: top ten producer countries in 2008

Figure 2. From FAO, 2010.

This also reflects the impacts of globalization of fish markets, which have grown at an accelerating rate in the last decades. This has been viewed either as positive or negative, depending on the value systems used (Taylor et al., 2007). Although fish trade contributes to food security through the generation of revenues, adverse effects by international trade on the environment, small-scale fisheries culture, livelihoods and special needs related to food security are a matter of concern. Articulation with global demand may provide incentives to overexploit or waste resources, endanger the lives of fisherfolk, change cultural traditions and more – much of which can be unintended – shark finning, spiny lobster dive fisheries, and sea cucumber fisheries are examples. Small-scale fisheries stakeholders cannot often adapt to, and benefit equitably from, opportunities of global market trends (FAO, 2014-consultation). Also, there have been evidences that when global figures are considered, although there is quantity equivalence in trade, a quality exchange also takes place, with developing countries

exporting high-quality seafood in exchange for lower quality seafood (Asche et al., 2015).

Regarding the trends in world marine capture fisheries, production has levelled off as the capacity of the ocean to produce ongoing harvest is approached (FAO, 2014- SOFIA). Overall production might be increased however, if overfished stocks are rebuilt and fisheries and ecosystems are used more sustainably. This requires overall reductions in exploitation rates, achievable through a range of context dependent management tools (Worm et al., 2009).

As noted in Chapter 11, global fisheries agreements and the FAO generally utilize the concept of Maximum Sustainable Yield (MSY) as a reference point for gauging whether a fishery resource is fully exploited, overexploited, and less than fully exploited. According to this reference point, FAO classifies the status of marine capture fishery resources (Table 1).

Table 1. Status of World Marine Capture Fishery Resources 2011. Source: FAO, 2014, p.7.

Status	Percentage
Less than fully exploited	10
Fully exploited	61
Overexploited	29

In the beginning of the 1950s, fully exploited and overexploited fishery resources *combined* accounted for less than 5 per cent of the total. Over 95 per cent fell into the less than fully exploited category (FAO, 1997, p. 7).

Over the following 25 years, the percentage of overexploited marine capture fish stocks rose to 10 per cent of the total. The percentage of these overexploited stocks then increased alarmingly from 10 to 26 per cent between the mid-1970s and the end of the 1980s. That percentage has continued to increase, but at a much slower pace (FAO, 2014).

The FAO states that:

“[...] the declining global marine catch over the last few years together with the increased percentage of overexploited fish stocks [...] convey the strong message that the state of world marine fisheries is worsening [...] which leads to negative social and economic consequences“ (FAO, 2012, p.12).

Further, these analyses of individual stocks do not fully account for the broader, ecosystem-level effects of fisheries exploitation that may be hindering future productivity in various ways, such as loss of habitat, or impacts on food webs and ecological functions needed to continue to produce desirable fish for harvest. There are

two inter-related general considerations regarding management of these ecosystem-level effects: 1) the potential impacts of fisheries themselves on the ecosystems, in order to maintain overall ecosystem function including productivity, usually referred to as ecosystem-based fishery management (FAO, 2003); 2) the interaction of fisheries with other sectors of human activity and consideration of the cumulative impact of all sectors on marine ecosystems, usually referred to as ecosystem-based management (McLeod and Leslie, 2009).

The discussion here and in Chapter 11 on full exploitation and overexploitation of capture fishery resources was essentially cast in biological terms. When examined in economic terms, the situation portrayed in Table 1 implies a loss in the potential of economic returns accruing to society from capture fisheries compared to the situation where all fisheries were managed to maximize economic benefits. The maximum economic yield (MEY), when adopted as a reference point, is more conservative and reached at lower fishing effort levels than the MSY, the latter argued to be used as an upper limit rather than a management target (Worm et al., 2009; Froese and Proelß, 2010).

Translated into monetary terms, the figures in Table 1 have been estimated in some analyses to cost to the world economy in the order of 50 billion dollars per year in lost resource rent (World Bank and FAO, 2009). This implies that, the economic return from marine capture fisheries could be improved compared to the current situation. If other incentives such as subsidies of the fisheries sector are taken into account, there are some estimates that this global economic return amounts to *minus* 5 -12 billion dollars per year (World Bank and FAO, 2009; Munro, 2010; Sumaila et al., 2012). Some estimates of world fishery subsidies are in the order of 25-30 billion dollars per year (Sumaila, et al., 2010). Other estimates are of lower levels of subsidies (Cox and Schmidt, 2002). The differences may be largely due to definitional issues with regard to what is considered to be a subsidy in the different analyses.

This is not to say that all world capture fisheries are yielding negative economic returns. Clearly several capture fisheries are yielding positive, and in some cases large positive, net economic returns. From a global perspective, however, the positive returns from these fisheries are more than offset by those yielding negative net economic returns. No clear divide between developed and developing fishing States is observed. (Sumaila et al., 2012, p.3).

From an economic standpoint, the extent of the capture fishery's resource depletion shown in Table 1, which was due to the rapid expansion of the world capture fishing industry over several decades, involved the running down of world's stock of the capture fishery's natural capital.

Rebuilding capture fishery resources requires reducing harvests below the net growth rates of the fish stock. As the resources grow, potential resource rent can be expected to emerge, which must go unrealized in all or in part, if the resource investment is to continue – hence the cost. Using a 50-year time horizon, Sumaila et al. (2012) estimate that after 12 years of resource investment, the net economic returns from the

investment would begin to outweigh the costs. Over the 50-year period, the returns would far outweigh the costs⁴ (Sumaila, et al., 2012). Economic and technical considerations that arise in rebuilding fisheries were explored in additional detail in an Organisation for Economic Co-operation and Development workshop (OECD, 2012).

3. Issues in Regulation of Marine Capture Fisheries

It has now long been recognized that the inherent difficulties in regulating marine capture fishery resources are a problem of scope and management objectives in the decision-making process, and are often framed as the well-known “Tragedy of the Commons” (Hardin, 1968). When access is open to all for exploitation, incentives are created that promote inefficiencies, including: (1) loss of economic “rent” because of the “race to fish”, (2) high transaction and enforcement costs incurred to reduce overuse and (3) low productivity, because no one has an incentive to work hard in order to increase their private returns (Ostrom, 2000). All of these factors reduce the net economic return from fisheries. The management of common property requires a minimum set of rules, defining access conditions and conservation measures to ensure sustainability and economic returns.

Where social, economic, and governance circumstances allow effective management of entry into a fishery and effort by those allowed to participate, substantial progress can be made at improving both the ecological and economic performance of a fishery, but often at the cost of few people receiving employment. On the west coast of Canada, for example, a move to Individual Transferrable Quotas in a complex, multispecies fishery for rockfish (*Sebastes* spp) resulted in improved stock status for the entire complex, and particularly reduced catches of the stocks most in need of reduced fishing mortality, while improving economic returns to the fishery. However, the fleet size and employment dropped by nearly half from the period before the programme was introduced (Rice, 2003; Branch, 2006; Branch and Hilborn, 2008).

In the context of fisheries, management efforts also need to take into consideration how the legitimacy of rules and regulations may be perceived differently when applied to large- vs. small-scale. The majority of the world’s fisheries comprise small-scale, multi-species, multi-gear, commercial fishing vessels, operating in all bodies of water (inland, brackish and marine), both near urban centres and in remote areas. Their operation involves family members, in pre-harvest, harvest and post-harvest parts of the fish chain. Women and children often participate in the fisheries. Small-scale fisheries catches are landed relatively close to where fishing occurs and are distributed through various channels. A certain portion is generally sold to local markets or to intermediaries by family members and some remains for household consumption. These characteristics of the fisheries imply that they require different management approaches than large-scale, industrialized fisheries. As at least half of the world’s fish

catches derive from small-scale fisheries, success in fisheries management needs to be demonstrated, not only where large-scale fisheries dominate, but also in the small-scale sector, with its high potential to address global food security.

Community-based resource management has been shown to be effective in establishing fishery rules (Berkes, 2005). Cinner and Aswani (2007), however, found that customary management was effective in smaller, remote communities with high levels of equality, but it is susceptible to economic pressures and by fishermen who do not practice customary fishing traditions.

4. Impacts of Illegal, Unreported, and Unregulated (IUU) fishing

There are additional economic and social considerations related to IUU fishing (see also Chapter 11). It is a complex phenomenon involving vessel owners, vessels, crew, flag State authorities and logistics. Often IUU vessels are related, through ownership, to authorized vessels obtaining cover to sell their catches.

Marine Resources Assessment Group (2005) states that the most obvious impact of IUU fishing is direct loss of the value of the catches that could be taken by the coastal State if the IUU fishing was not occurring. This is mostly from vessels operating without licences and licensed vessels misreporting catches (quantity, species, fishing area, etc.) and illegal trans-shipment of catches. Secondary economic impacts from the loss of fish to IUU vessels may include reduced revenue from seafood exports and reduced employment in the harvest and postharvest sectors. Reduced fishing port activity has a ripple or multiplier effect across economies, adversely affecting labour and transportation as well as the manufacturing sector.

IUU fishing may also increase poverty and reduce food security and food sovereignty. Conflict between authorized, compliant vessels and IUU vessels is common in some fisheries and can become violent with threats to both life and livelihoods on a large scale. Armed resistance to surveillance and enforcement is increasing in some locations with the potential to undermine all monitoring, control and surveillance (MCS) as resources are allocated to address what may be seen as a threat to national security rather than fisheries management. It can be noted that conflicts and IUU fishing generally occur between vessels of any size. There may also be gender and socio-cultural effects, depending upon the composition of the harvest and post-harvest labour forces.

5. Space-use conflicts: industrial capture fisheries vs. artisanal capture fisheries; aquaculture vs. artisanal capture fisheries

Due to recent improvements in technology and affordability, vessel monitoring systems (VMS) are increasingly available for both large- and small-scale fishing vessels, and thus can provide geo-referenced data that accurately describe fishing areas on geographic scales applicable to MSP. Combined with validated logbook data, rich time-series data are potentially available from intensely fished and monitored sea areas in developed countries. The data situation is slowly improving in developing countries. Land tenure systems that extend to parcels of seabed and water for aquaculture also provide clear boundaries. Superimposed on these spaces are increasingly sophisticated layers of information on the interactions among fisheries, and between aquaculture and fisheries. Although not all fisheries conflicts concern spatial use, or can be managed through MSP, many are potential candidates for spatial conflict management.

Sources of conflict between large and small-scale fisheries are a well-reported concern (FAO, 2014). Spatial components of conflict concern:

- Sea tenure and territorial use rights
- Fishery resource allocations by site
- Fishing gear and method interactions
- Ecosystem (species) interactions
- IUU fishing (several aspects)
- Port access and market transactions
- Management jurisdiction and governance

Sources of conflict between fisheries and aquaculture with spatial components concern:

- Sea tenure and territorial use rights
- Natural resource allocations by site
- Fishing interactions with infrastructure
- Ecosystem (species) interactions
- Area access and market transactions
- Management jurisdiction and governance

The lists are quite similar, although the specific nature of the conflicts varies greatly between the lists and site-specific situations. The next section looks more closely at fisheries-aquaculture conflicts (see also Chapter 12).

Cataudella et al. (2005) note that the FAO (1995) Code of Conduct for Responsible Fisheries (CCRF) defines the global framework in which marine aquaculture and capture

fisheries are to be considered as interactive parts of the same system. The assessment of such interactions is crucial for implementing the CCRF, especially in areas where the use of the coastal zone results in conflicts between many resource users competing for space (e.g. fisheries, aquaculture, tourism, shipping, energy). The CCRF treats aquaculture as an important part of the fisheries system to be responsibly developed and managed for sustainability (FAO, 1999), but in the nearly two decades that have intervened, this has proven to be challenging.

The relationships between marine aquaculture and capture fisheries can be complex, operating at multiple levels of governance and crossing several spatial and temporal scales, affecting different points along value chains, as well as ecosystems or target and culture species in a variety of ways. Cataudella et al. (2005) categorize the conflict interactions as old and new, somewhat based arbitrarily on the currency of the topic.

Old interactions are issues generated by the:

- Allocation of public financial resources
- Likelihood of disease spreading and new outbreaks
- Environmental pollution
- Employment threats and opportunities
- Introduction of exotic or invasive species
- Need for stocking programmes
- Ownership of resources and of confined environments
- Use of wild seed to supply aquaculture
- Use of fishery products to supply the fish-feed farming industry.

New interactions are issues concerning the:

- Stocking and restocking models
- Genetic origin of cultured organisms
- Biodiversity conservation and value
- Genetic improvement through breeding programmes and genetic engineering
- Development of aquaculture in sensitive environments
- Direct impact of farmed products on markets and prices
- Growing role of aquaculture in meeting the demand for fishery products
- Product quality and labelling
- Feasibility of capture fisheries and aquaculture within a sustainable system.

The above interactions are most in need of conflict management through legislation and policy related to planning for integrated coastal zone management and marine spatial

planning. However, considerable guidance is available on appropriate approaches that include conflict management (e.g. Ehler and Douvère, 2009) as well as enabling policy (e.g. EU Marine Strategy Framework Directive).

Marine spatial planning (MSP) is the public process of analyzing and allocating the spatial and temporal distribution of human activities in marine areas to achieve ecological, economic, and social objectives that are usually specified through a political process (Ehler and Douvère, 2006). It is linked to ecosystem-based management (EBM) (see McLeod and Leslie, 2009), the ecosystem approach to fisheries (EAF) (see FAO, 2003), marine protected areas (MPAs) (FAO report on MPAs and Fisheries, 2011) and similar endeavours that have the potential to assist in managing conflicts through participation among diverse stakeholders (Ehler and Douvère, 2009). Managing space use conflicts between large- and small-scale fisheries and with other sectors is an increasingly important issue in many parts of the world.

6. Gender in fisheries

On a global level, fisheries are often perceived as male-dominated, laden with culturally stereotypical images of fishermen. The term “fishing industry”, for example, conjures an image that focuses attention on harvest and men’s work more than the term “seafood industry” which is more equitable (Aslin et al., 2000). The involvement of women is now reflected by the increasing use of gender-neutral terms such as “fisher” and “fisherfolk”, and more international discussion of gender (Williams et al., 2005). Yet recent global investigation has shown that if post-harvest (e.g., fish processing and trade) and ancillary activities (e.g., fishing inputs and financing) are taken into account, then the gendered image is quite different. Overall, women may be in the majority in fisheries, or nearly so (FAO et al., 2008). This does not take into account the growing number of women engaged worldwide in fisheries policy, planning, management, science, education, civil society advocacy and other activities related to fisheries that were previously more male-dominated.

The post-harvest situation is particularly inequitable. Women outnumber men in fish processing and trading across the world, but their informal sector activities are often not recorded, and they are invisible in national labour and economic statistics. Thus the socioeconomic contribution of women to fisheries is underestimated at national and global levels. Only a few countries in the developing world collect and use gender-disaggregated statistical data and other information data for fisheries policy and planning (Weeratunge and Snyder, 2009). Without comparative data for women and men, it is difficult in most places to determine the disparity between female and male socioeconomic activities and well-being. This scarcity of gender-disaggregated fisheries data constrains gender-sensitive policies and mainstreaming, with little action taken to address the disadvantageous position of women (Sharma, 2003).

It is widely accepted in the developing world that women strongly influence the social, economic and cultural aspects of fishing households and the industry as a whole. There are increasing numbers of women in technical, scientific and managerial fisheries jobs around the world, but this varies markedly by region. In some societies where men engage in the most conspicuous fisheries-related socioeconomic and political activities, the women are labelled “fisher wives”, but the implied subordination is misleading (Weeratunge and Snyder, 2009). In Ghana, “fisher wives” or “fish mammies” support the entire small-scale fishing industry as they invest in fishing boats and gear, and provide loans to husbands and other fishers while running small socioeconomic empires without formal political power (Walker, 2001). Although addressing gender-inequity is critical, interventions need to be carefully designed. ‘Women in development’ projects have contributed to reducing the real power that women held, for example, by introducing poorly designed credit and fish marketing schemes that exacerbate unsustainable fishing for short-term monetary gain or loan servicing.

Small-scale fisheries in developed and developing countries have striking similarities. In both, gender issues are often overlooked or misunderstood because of an analytical focus that looks at the fisheries sector in isolation from the broader society, and is concerned primarily with narrow ecological and economic factors such as maintaining fish stocks to ensure a viable long-term harvest. Interventions have been directed more at men harvesting at sea, rather than at women engaged in postharvest on shore, or at the interconnections between harvest and postharvest (Weeratunge and Snyder, 2009). Although this narrow, male sectoral perspective is changing as the EAF becomes more widely adopted (FAO 2003), gender is not yet mainstreamed into this approach despite advances in incorporating other social, cultural and institutional dimensions (De Young et al, 2008). EAF is just one facet of the changing face of fisheries governance. Gender issues are more appropriately considered in the wider context of fisheries governance than fisheries management.

Gender remains a key governance issue in both developed and developing countries. Its many interconnected dimensions relate to vulnerabilities, assets, opportunities, capabilities, coping strategies, outcomes, food security, empowerment and more. With new attention to sustainable development goals based on blue and green economies, gender in fisheries should feature more prominently. State and civil society agencies realize that well-being will not be improved and poverty will not be reduced if gender is not adequately addressed. Gender mainstreaming should be an integral part of fisheries, but this is not occurring, because gender research to support fisheries policy is insufficient. As the links between gender in fisheries and poverty, climate, health and other major developmental issues become apparent (Bene and Merten, 2008; Bennett, 2005; FAO, 2006; Neis et al., 2005), more attention will need to be paid to gender in fisheries in the context of the development post-2015 agenda.

Certain issues, particularly at the micro level, demand additional research. The state of small-scale fisheries throughout the world, and gender issues in fisheries are particularly prominent. A further issue that has been seriously under-researched is that of the relationship between capture fisheries and aquaculture.

7. Climate change and small-scale fisheries

Pollution, environmental degradation, climate change impacts and natural and human-induced disasters pose serious challenges to fisheries sustainability. Because of the heavy reliance on fisheries for food security, employment and livelihoods, these factors become additional threats facing small-scale fishing communities (FAO, 2011-2015).

Expected impacts of climate change include increase in the severity and intensity of natural disasters and changes in the local distribution and abundance of harvested fish and shellfish populations (Barange et al., 2014), with consequences on the post-harvest and trade (FAO, 2011-2015; HPLE, 2014). Impacts of climate change are predicted to be more severe where the relative importance of fisheries to national economies and diets is higher and there is limited societal capacity to adapt to potential impacts and opportunities (Allison et al., 2009). The severity of threats increases due to combined effects of climate change and ecosystem degradation and overfishing, highlighting the importance of appropriate co-management measures (HPLE, 2014).

A comprehensive understanding of how communities respond to these threats and other global change, in their environmental, social and political contexts, is required (Bundy et al., 2015). These issues are also treated in the Summary (under Impacts of the Climate Changes).

8. Specific additional issues raised in regional workshops for the World Ocean Assessment

Fisheries management requires time-consuming and dedicated human resources and failure to meet or prioritize these efforts is a widespread problem, leading to poor fisheries management. During the regional workshops for this World Ocean Assessment it became apparent that lack of data, including difficulties in maintaining data collection and conducting stock assessments, as well as obtaining fishery-independent data, was an issue for all developing countries. Problems with databases and data integration, due to different methods of data collection and lack of long time-series, were raised in all regions. Lack of data on the small-scale, as well as recreational fisheries, was a problem in developed and developing States. In particular, catches from subsistence fishing are often missing from national catch statistics, leaving a gap in the ecological, social and economic aspects of fisheries. Ecosystem-based management is seldom applied due to the lack of practical examples and applications, and difficulties in assessing ecosystem impacts.

Fish is one of the most internationally-traded foods. This has an impact on the infrastructure needed to commercialize the product, especially given the fact that fish is a perishable commodity. The difficulties to adapt to international-market requirements -

including means to abide by regulations - and the lack of fish preserving and processing facilities was a recurring issue, especially in developing countries that are near, or trade often with, developed countries.

Contamination of fish products as well as the effects on catches caused by pollution and habitat degradation were raised at the workshops. Developing countries reported difficulties in assessing those risks and monitoring those impacts. The main focus of fish certification has been eco-labelling that addresses environmental sustainability issues. With limited exceptions, certification concerns predominantly developed countries and large-scale fisheries. Fish certification is progressively moving to include social responsibility and labour considerations, but it is unclear whether food security and nutrition considerations can or will be included in future.

9. Conclusion

Fisheries around the world are deeply embedded in the issues of food and economic security, livelihoods for large numbers of people, gender equity and poverty alleviation. Both large and small-scale fishery operations provide essential economic and social benefits to society. Small-scale fisheries, in particular, constitute half of the world's total catches and involve more than 90 per cent of total fishing population (in harvest and post-harvest activities). The significant contribution to food security, livelihoods and local economic development means that small-scale fisheries can no longer be overlooked. Instead, management and governance of fisheries needs to incorporate key features distinguishing small-scale fisheries from their large-scale counterpart. This implies changes in information systems, fisheries assessment, monitoring and surveillance, and research and development. Importantly, issues related to fishing rights, tenure and access to resources, health and safety, gender and social justice, among others, deserve special attention in policy and decision-making. Finally, it is worth noting that small-scale fisheries governance would have different priorities, focusing for instance on stakeholder participation and subsidiarity principles. Tension and conflicts between different scales of operations, and with other marine activities, will continue to challenge policy-makers in many areas. They can be overcome, however, with an attempt to create policy coherence through a holistic and integrated approach to fisheries governance. During the regional workshops the need to improve the capacity of States to more effectively manage these critical resources, and in particular in regions where sustainability of fisheries needs to be improved, was recognized. The need to build capacity is also essential to address issues of equity and broader sustainable development efforts.

Chapter 16. Synthesis of Part IV: Food Security and Safety

Group of Experts: Andrew A. Rosenberg

Fish products, including finfish, invertebrates and seaweeds, are a major component of food security around the world. In addition to providing a source of high-quality protein and critical long chain omega-3 fatty acids with well-known nutritional benefits in many countries, fish and fishery products are the major source of animal protein for a significant fraction of the global population, and in particular in countries where hunger is widespread. Even in the most developed countries, consumption of fish is increasing both *per capita* and in absolute terms, with implications for both global food security and trade.

Fisheries and aquaculture are a major employer and source of livelihoods in coastal States. Significant economic and social benefits result, including providing a key source of both subsistence food and much-needed cash for many of the world's poorest peoples. As a mainstay of many coastal communities, fisheries and aquaculture play an important role in the social fabric of many areas.

Small-scale fisheries, particularly those that provide subsistence in many poor communities, are often a key source of employment, cash, and food in coastal areas. Many such coastal fisheries are under threat due to over-exploitation, conflict with larger fishing operations, and loss of productivity in coastal ecosystems due to a variety of other impacts. These include habitat loss, pollution and climate change, as well as loss of access to space as coastal economies and uses of the sea diversify.

Globally, world capture fisheries are near the ocean's productive capacity with catches in the order of 80 million metric tons. Only a few means to increase yields are available. More effectively addressing sustainability concerns including ending overfishing, eliminating illegal, unreported and unregulated (IUU) fishing, rebuilding depleted resources, reducing broader ecosystem impacts of fisheries, and adverse impacts on them from pollution, are important aspects of improving fishery yields and thereby food security. For example, ending overfishing and rebuilding depleted resources may result in an increase of as much as 20 per cent in potential yield, if the transitional costs of rebuilding depleted stocks can be addressed.

In 2012, more than one-quarter of fish stocks worldwide were classified by FAO as overfished. Although these stocks clearly will benefit from rebuilding once overfishing has ended, other stocks may still be classed as fully fished despite being on the borderline of overfishing; these stocks could yield more if effective governance mechanisms were in place.

Current estimates of the number of overfished stocks do not take into account broader effects of fishing on marine ecosystems and their productivity. These impacts, including by-catch, habitat modification, and food web effects, are important elements in the

sustainability of the ocean's capacity to continue to produce food and must be carefully managed. These very real threats endanger some of the most vulnerable populations and marine habitats around the world and need to be directly addressed to improve food security and answer other social needs.

Fish stock propagation may provide a tool to help rebuild depleted fishery resources in some instances. Propagation programs must be carefully designed and maintained in order to really benefit resource sustainability.

Fishing effort is subsidized by many mechanisms around the world and many of these subsidies undermine the net economic benefits to States. Subsidies that encourage over-capacity and overfishing result in losses for States and these losses are often borne by communities dependent upon fishery resources for livelihoods and food security.

Aquaculture production, including seaweed culture, is increasing more rapidly than any other source of food production in the world and is expected to continue to increase. Aquaculture, not including the culture of seaweeds, now provides half of the fish products covered in the global statistics.

Aquaculture and capture fisheries are co-dependent in some ways, as feed for cultured fish is in part provided from capture fisheries. They are also competitors for space in coastal areas, for markets, and potentially for other resources (labour, governmental support and attention, etc.). Significant progress has been made in replacing feed sources from capture fisheries with agricultural production (e.g., soybeans), although more work is certainly needed.

Aquaculture itself poses some environmental challenges, including potential pollution, competition with wild fishery resources, potential contamination of gene pools, disease problems, and loss of habitat (e.g., from the construction of shrimp ponds). Examples of these challenges, and measures that can mitigate them, have been observed worldwide and need to be directly addressed by management action.

In both capture fisheries and aquaculture, gender and other equity issues arise. A significant number of women are employed in both types of activities, either directly or in related activities along the value chain. Women are particularly prominent in product processing, but often their labour is not equitably compensated, and working conditions do not meet basic standards. Poor communities are often subject to poorer market access, unsafe conditions for labour, and other inequitable practices that need to be remedied.

The ongoing impacts of a changing climate, including ocean acidification, pose great challenges for fisheries and aquaculture. Climate change is already resulting in shifts in the distribution and productivity of fishery resources and marine ecosystems more generally. This impacts fishing businesses and communities, yields and food security. Changes in availability and yields for individual resources may be positive or negative but in any case result in greater uncertainty for fishers, communities, businesses and fishery governance frameworks.

There are major capacity-building needs with regard to food security and food safety.

- The complexity of the issues concerning food provisioning from the sea requires a multidisciplinary approach to research. While the fields of fishery and aquaculture science are well developed, there are critical needs for research on small-scale subsistence uses of the marine environment as well as recreational, cultural and spiritual aspects of marine resources. In addition, greater understanding must be developed of the structure, function and dynamics of marine ecosystems and of the economic and social aspects of human society that depend upon these resources.
- It is necessary to improve understanding of the role of fisheries and aquaculture in commerce, employment and the support livelihoods. Therefore advanced capacity building is necessary for appropriate skills to be able to use advanced technologies to create wealth from capture fisheries and aquaculture in a sustainable way.

1. Capture fisheries

- Efforts have been made to create awareness to reduce post-harvest losses, especially in small-scale fisheries, as a means of increasing production. However, little is known about what new methods are being implemented and to what extent they impact on production. There is a gap in capacities needed to develop, deploy, and evaluate approaches to reduce waste and post-harvest losses and ensure that new technology is transferred to those that need it most.
- Efforts have been made to reduce by-catch and other broader ecosystem impacts of fishing and to increase awareness of these problems. For example, globally it is still poorly known whether by-catch excluder devices have been successfully adopted in terms of the relative ratio of the target catch landed and the by-catch either landed or discarded. It is necessary to build capacity to monitor and ensure compliance with measures such as these that are intended to reduce ecosystem level impacts.
- If ecosystem-based approaches to management are to be implemented, integrating fisheries governance with governance of other marine sectors, greater scientific and technical capacity will be needed to inform the process.
- If further depletion of fishery stocks due to overfishing, climate impacts or other pressures is to be avoided, trends in fishing effort, landings, geographical scope, species composition and other key attributes must be ascertained and consistently monitored, and data must be made broadly available. It is necessary to build enough capacity with appropriate technological and scientific skills and the necessary equipment to provide adequate information and data to facilitate regional and global management.
- Technical capacity to monitor and control seafood safety is urgently needed. Methodologies must be shared and deployed and greater training in procedures that safeguard seafood supplies is necessary.

- Certain issues, particularly at the micro level, demand additional research and therefore need capacity-building to address them. The state of small-scale fisheries throughout the world, and gender issues in fisheries, are particularly prominent and are poorly studied. A further issue that has been seriously under-researched is the relationship between capture fisheries and aquaculture.

2. Aquaculture

- Much better data and analysis of the trends, character and factors influencing aquaculture production are needed. In principle these data should be more accessible than capture fisheries data but in practice this is not the case. Understanding this rapidly growing sector is vital to the understanding of food security patterns and needs.
- Disease and product safety are a key challenge for aquaculture. Greater scientific and technical capacity is needed to address these challenges in many countries and data and scientific information must be shared in order to exchange lessons learned.
- Aquaculture technology crosses the spectrum from relatively simple small-scale operations to larger-scale enterprises. It includes breeding, feeding, health and safety aspects. Sharing both technology and approaches to improve efficiency and sustainability is an important aspect of improving food security and safety.

3. Fish stock propagation

- For propagation efforts to be successful, capacity must be developed that will promote efficient and effective approaches and comprehensive monitoring of these efforts. These must be well designed experiments that rely on lessons learned from other efforts around the globe.
- Proposed propagation efforts will benefit from a comprehensive, integrated, ecosystem-based fisheries-management approach. Capacity is needed in terms of individuals, infrastructure and institutions to deliver effective stock propagation.

4. Seaweeds as a resource

- Seaweed aquaculture is seriously affected by disease, as with other forms of intensive aquaculture. Research on seaweed diseases and new techniques for combating the diseases are needed along with the technical capacity to deploy new methods.
- Undertaking and building capacity for biochemical research on seaweed extracts from various species will enable them to be harnessed for their wide variety of nutrient, medicinal and food values.

Chapter 17. Shipping

Contributors: Alan Simcock (Lead member) and Osman Keh Kamara (Co-Lead member)

1. Introduction

For at least the past 4,000 years, shipping has been fundamental to the development of civilization. On the sea or by inland waterways, it has provided the dominant way of moving large quantities of goods, and it continues to do so over long distances. From at least as early as 2000 BCE, the spice routes through the Indian Ocean and its adjacent seas provided not merely for the first long-distance trading, but also for the transport of ideas and beliefs. From 1000 BCE to the 13th century CE, the Polynesian voyages across the Pacific completed human settlement of the globe. From the 15th century, the development of trade routes across and between the Atlantic and Pacific Oceans transformed the world. The introduction of the steamship in the early 19th century produced an increase of several orders of magnitude in the amount of world trade, and started the process of globalization. The demands of the shipping trade generated modern business methods from insurance to international finance, led to advances in mechanical and civil engineering, and created new sciences to meet the needs of navigation.

The last half-century has seen developments as significant as anything before in the history of shipping. Between 1970 and 2012, seaborne carriage of oil and gas nearly doubled

(98 per cent), that of general cargo quadrupled (411 per cent), and that of grain and minerals nearly quintupled (495 per cent) (UNCTAD, 2013). Conventionally, around 90 per cent of international trade by volume is said to be carried by sea (IMO, 2012), but one study suggests that the true figure in 2006 was more likely around 75 per cent in terms of tons carried and 59 per cent by value (Mandryk, 2009). Not only has the quantity of cargo increased, the average length of voyages has also increased: between 2000 and 2013 the estimated amount of international seaborne shipments measured in ton miles increased by 65 per cent from 30,648 to 50,506 billion ton miles, while the total amount of international cargo rose by only about 50 per cent (UNCTAD, 2013). This growth in the average length of voyages has been largely in the carriage of coal, grain and ores.

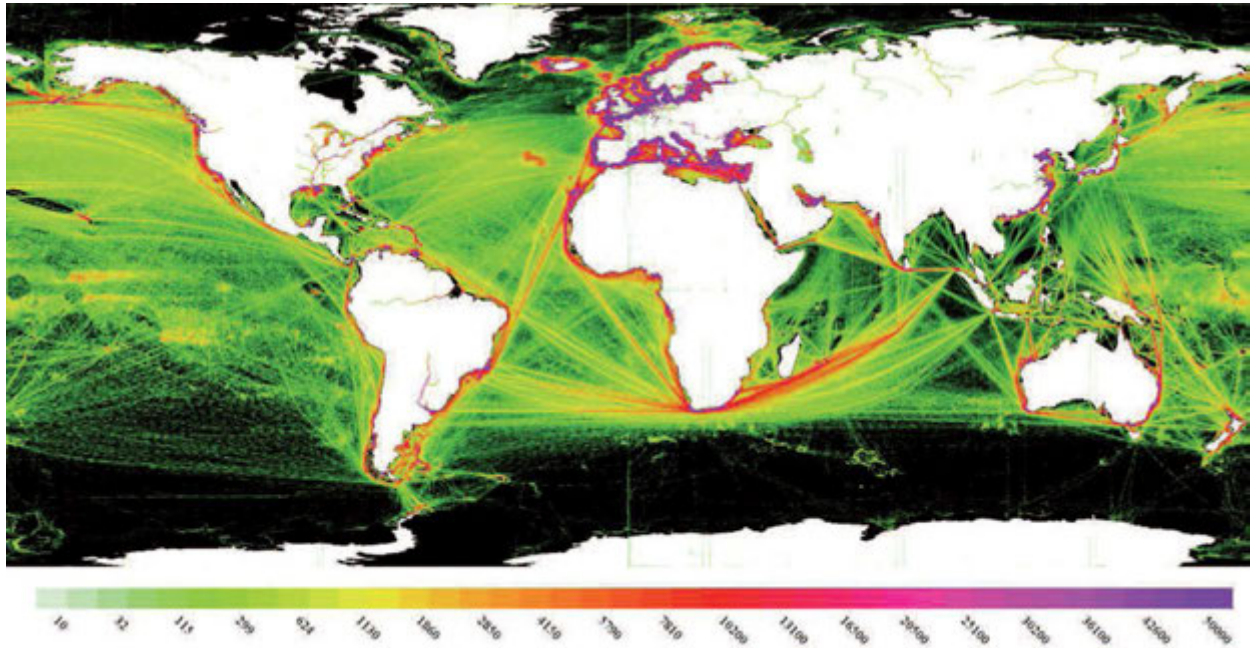

Figure 1. International Seaborne Trade: selected years 1980 – 2013. *Millions of tons loaded*. The “Five Major Bulks” are iron ore, grain, coal, bauxite/alumina and phosphate rock. “Other Dry Cargo” includes agricultural produce, metals, and forest products). Source: UNCTAD, 2013.

2. Nature and Magnitude of World Shipping Movements

2.1 Cargo traffic

Global shipping movements naturally mirror the world economy. The modern period up to 2008 therefore generally showed a steady increase. The economic crisis of 2008, not surprisingly, produced a drop in activity, but this was less than the drop in the world’s Gross Domestic Product, largely because of the continuing demand in eastern Asia for bulk movement of iron ore and coal (UNCTAD, 2013). Figure 1 shows the way in which world cargo movements are increasing. Figure 2 shows the distribution of total shipping movements around the world. The different main trades have substantially different distributions and patterns of sailings: the container routes are concentrated in the East/West belt around the southern part of the northern hemisphere and are very regular in their sailings, while both the five main bulk dry cargoes (iron ore, coal, grain, bauxite/alumina and phosphate rock) and the oil and gas trade are focused on the sources of these cargoes. Their sailings are also affected by changes in the market prices for these commodities. The carriage of bulk dry cargoes and oil and gas tends to have a higher proportion of return journeys in ballast. The mineral cargoes, in particular, have strong emphases on routes from Africa, South America, Australia and Indonesia to eastern Asia (Kaluza et al., 2010). Significant changes in maritime traffic routes could result from developments in extracting hydrocarbons from the earth: the growth of the shale gas industry of the United States of America, for example, is leading to major falls in United States imports, and growth of United States exports, with consequent changes in trade routes (EIA, 2014a).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Global Network of Ship Movements (data 2012). Data derived from daily Automatic Identification System (AIS) messages recorded for each $0.2^\circ \times 0.2^\circ$ grid square. The coloured scale shows the number of messages recorded over the year for the grid squares. Source: IMO, 2014o.

For a long time there was an imbalance in cargo movements between developed and developing countries: cargo volumes loaded in the ports of developing countries far exceeded the volumes of goods unloaded. This reflected the difference in volume of exports from developing countries (dominated by raw materials) and their imports (substantially finished goods). As Figure 3 shows, over the past four decades a steady change has occurred: loadings and unloadings in the ports of developing countries reached near parity in 2012, driven by the fast-growing import demand in developing regions, fuelled by their industrialization and rapidly rising consumer demand.

Figure 3. Cargoes loaded and unloaded in the ports of developing countries 1970 – 2012. Percentage share in tonnage of global loadings and unloadings. Source: UNCTAD, 2013.

General cargo transport has been transformed by the introduction of container shipping. Before 1957, when the first container shipment was made from Houston to New York in the United States, general cargo had to be loaded and unloaded package by package, with relatively long times needed to turn ships around, and high labour costs. The introduction of standardized containers (the Twenty-foot Equivalent Unit (TEU) and the Forty-foot Equivalent Unit (FEU)) enabled ships and ports to be constructed so that compatibility was not an issue. (Ninety per cent of current shipments are of FEU, but the TEU is widely used for statistical purposes) (Levinson, 2007). The convenience of being able to handle practically all forms of general cargo in this way is a major factor in producing the massive expansion of long-distance maritime transport. For a long time, growth in the volume of container traffic was three to four times the growth in world GDP (the average was 3.4 times over the period 1990–2005). A variety of factors now seem to be changing and some analysts suggest that the multiplier has fallen to only 1.5 times in 2012, and may continue at this level. This would imply that in future the global shipping industry would grow more slowly (UNCTAD, 2013). Table 1 shows how trade levels and the consequent distribution of container movements between parts of the world vary widely.

Table 1. Container movements on the 10 most heavily trafficked routes 2006.

Route	Number of TEU Movements ('000)
Far East to Far East	21,750
Far East to North America	13,764
Far East to North-West Europe	8,951
North America to Far East	3,950
Far East to Mediterranean	3,750
North-West Europe to Far East	3,571
Far East to the Persian Gulf and Indian Subcontinent	3,322
North-West Europe to North America	3,191
Latin America to North America	2,791
North-West Europe to North-West Europe	2,518

Source: Adapted from Mandryk, 2009.

Increases in the size of cargo vessels, and consequent efficiency gains, have been a major factor in enabling unit freight costs for containers, for oil and gas and for bulk traffic to be contained, thus encouraging growth in trade. It seems likely that the trend of increases in the size of vessels will continue. This trend is, however, constrained by the limitations on the size of vessels that ports can handle and by navigational choke-points. At present, three main choke-points constrain the size of vessels. These are the Panama Canal, the Suez Canal and the Straits of Malacca. The approximate maximum dimensions of vessels that can navigate these three passages are shown in Table 2. Vessels larger than these dimensions must seek alternative routes: around Cape Horn, around the Cape of Good Hope and around or through the Indonesian archipelago, respectively. These alternative routes add significantly to the costs of some of the main shipping routes, but may be offset by economies of scale in using larger vessels. Work is in progress to provide a new set of locks on the Panama Canal, which are expected to open in 2016, enabling ships within the “New Panamax” classification to pass through the canal (ACP, 2014). This is expected to result in significant changes in patterns of shipping between the Atlantic and Pacific. Proposals exist for a further canal through Nicaragua, which might (if completed) have even larger effects. Work has already started on expanding the Suez Canal. Subject to such changes and the emergence of alternative routes, the scope for efficiency savings from increasing the size of ships, and thus for containing costs, is likely to diminish, as the limits at the choke-points restrict further growth in the size of vessels.

Table 2. Choke-points in international shipping: maximum sizes of vessels.

Classification	Length	Beam	Draft	Air-draft (overhead clearance above water)	Approximate dead-weight tonnage ¹	Approximate Twenty-foot Unit (TEU) container capacity
Malaccamax	333-400 metres	59 metres	25 metres	Unlimited ²	300,000	15,000 – 18,000
Panamax	294.13 metres	32.31 metres	12.04 metres	57.91 metres	65,000 – 85,000	5,000
New Panamax	366 metres	49 metres	15.2 metres	57.91 metres	120,000	13,000
Suezmax	Unlimited	50 metres	20.1 metres	68 metres	120,000 – 200,000	14,500
<i>Largest current crude-oil tankers</i>	<i>415 metres</i>	<i>65 metres</i>	<i>35 metres</i>		<i>320,000 – 500,000</i>	
<i>Largest current container ships</i>	<i>400 metres</i>	<i>59 metres</i>	<i>16 metres</i>		<i>184,600</i>	<i>19,100</i>

Source: STH 2014.

The other source of potential increases in the deployment of larger vessels is the effects of climate change. As a result of the warming of the Arctic, it is becoming possible (at least in summer) to navigate between the Pacific and the Atlantic through both the North-West Passage (through the Canadian Arctic archipelago) and the Northern Sea Route (NSR - along the Arctic coast of the Russian Federation). These possibilities are currently only open to ice-class vessels. The extent to which larger vessels can be deployed depends on the routes that are feasible: Arctic shipping routes, especially the NSR, are subject to significant draft and beam restrictions (Humpert et al., 2012). Increases in the frequency and severity of northern hemisphere blizzards and Arctic cyclones may also limit the use these routes (Wassman, 2011). The *Nordic Orion* (75,600 dead-weight tons (dwt)) became the first commercial vessel to pass through the North-West Passage in October 2013 (G&M, 2014). The NSR has been used for Russian internal traffic since the 1930s. Some international transit traffic took place (with the aid of icebreakers) in the early

¹ Dead-weight tonnage (DWT) is a measure of how much weight a ship can safely carry. It is the aggregate of the weights of cargo, fuel, fresh water, ballast water, provisions, passengers, and crew.

² There are now proposals for a bridge across the Malacca Strait, which would introduce a limit.

1990s and the number of ships using the transit passage rose from four in 2010 to 71 in 2013 (Liu, 2010 and Economist, 2014). The route between Shanghai and Rotterdam via the NSR is approximately 4,600 km (about 40 per cent) shorter than the route via the Suez Canal, and would take 18–20 days compared to 28–30 days via the Suez Canal (Verny and Grigentin, 2009). Some estimates suggest that, in the longer term, up to 20 per cent - 25 per cent of global shipping movements could be affected by possible Arctic routes, which could offer up to 35 per cent savings in movement time and, hence, costs (Laulajainen, 2009). Others are more pessimistic, but can see some possibilities (Liu et al., 2010). The International Maritime Organization (IMO) has developed a new International Code for Ships Operating in Polar Waters (the Polar Code), covering both Arctic and Antarctic waters. The Code has been made mandatory under the International Convention on the Safety of Life at Sea (SOLAS) and the International Convention for the Prevention of Pollution from Ships (MARPOL) through the adoption of relevant amendments to those Conventions, respectively in November 2014 and May 2015. The expected date of entry into force for the Code is 1 January 2017. Nevertheless, the requirements in the Code will need support through infrastructure such as improved charts and emergency response plans and waste-reception and other facilities capable of dealing with activities on a much larger scale than at present exists (COMNAP 2005, TRB 2012).

As well as the global, long-haul traffic, sea transport also carries much freight on shorter routes. Comparable statistics on this are difficult to find. Within Europe, a study for the European Commission in 1999 showed that 43 per cent of the total freight ton-miles within Europe (including both international and national traffic) were carried on short-sea journeys – an amount about the same as the ton-miles of road haulage. This high proportion was due to the fact that the average movement length by sea was much greater: the average sea movement was nearly 14 times that of the average road movement. Efforts are being made to increase the amount of freight carried on short-sea movements, in order to reduce both the pressure on roads and air pollution emissions (EC, 1999). Similar motives underlie the “America’s Marine Highway Program”, under which the United States is investing to increase the amount of short-sea freight movements along the Atlantic and Pacific coasts and from the Gulf of Mexico to the east coast (MARAD, 2014). Elsewhere, containerization is leading to rapid growth in short-sea coastal freight movements: for example, in Brazil, the volume of containers carried in coastwise traffic has grown between 1999 and 2008 from 20,000 TEU to 630,000 TEU (+3,050 per cent) (Dias, 2009). To a large extent, the scale of coastwise freight transport reflects the need to distribute more locally the large number of containers arriving in global movements in very large ships. Roll-on/roll-off ferries also play an important role in the more local movement of containers and other cargo, often combined with passenger traffic.

One specialised form of maritime transport that attracts concern in some quarters is the transport of radioactive materials. A wide range of materials need to be transported, from supplies for nuclear medicine to the components in the nuclear fuel cycle. Since 1961 the International Atomic Energy Agency (IAEA) has published advisory regulations on the safe transport of radioactive material, which are

generally adopted. Particular concern has been expressed about the shipment of used nuclear fuel for recycling. Since 1971, some 7,000 civil shipments of over 80,000 tons of used nuclear fuel have been reported, mostly to the reprocessing plants at Cap la Hague (France) and Sellafield (United Kingdom of Great Britain and Northern Ireland). These include 160 shipments (totalling 7,140 tons) from Japan to Europe (WNA, 2014). A 2011 survey of the transport of radioactive material in northern Europe confirmed that there had been no maritime transport accidents involving a release of radioactive materials (KIMO, 2011), and none have been reported since then (European Union, 2013).

2.2 Passenger traffic

Since the advent of large aircraft, maritime passenger traffic has effectively been confined to short-sea ferries and cruise ships. Every State with inhabited offshore islands too far offshore for the strait to be bridged has ferry services. States consisting of, or containing, archipelagos rely heavily on ferries for internal passenger transport. International passenger ferries are particularly important in the Baltic Sea, the North Sea and the Caribbean, where several States face each other across relatively short sea-crossings. Roll-on/roll-off ferries (where passenger vehicles and their passengers can make the journey together) have substantially aided the growth of short-sea passenger transport. Roll-on/roll-off ferries are also important for local freight movements, especially in Europe. Growth in passenger transport by ferries is governed mainly by improvements in the facilities and general economic growth in the countries concerned. Over the past decade, for example, the traffic on Greek passenger ferries has stagnated in the light of the Greek economic crisis, while traffic on passenger ferries in Indonesia and the Philippines has continued to grow substantially. Total ferry passengers worldwide in 2008 and its regional components are shown in Table 3.

Table 3. World ferry traffic volume and distribution 2008.

	Passengers	Cars	Buses	Freight vehicles
World traffic volumes (millions of journeys)	2,052	252	677	32
<i>Percentages of world total in each region</i>				
America and Caribbean	14.6	29.7	11.9	2.7
Baltic	10.9	33.7	38.6	24.3
Mediterranean	21.2	14.3	14.9	26.7
North Sea	4.4	7.5	32.4	31.7
Pacific	1.5	0.4	<0.1	1.5

Red Sea and Persian Gulf	3.7	0.5	0.9	0.2
South-East Asia	43.7	13.9	1.3	12.9

Source: Adapted from Wergeland, 2012.

2.3 Cruise ships

The other major sector of passenger maritime transport is cruise ships. Although maritime tourist travel can be traced back to 1837, and a substantial business developed, especially in the Mediterranean Sea in the 19th century (P&O, 2014), the modern cruise ship industry emerged in the 1960s and 1970s as a means of employing ocean-going passenger liners at a time when mass long-distance passenger air-travel was emerging and coming to dominate the long-distance passenger market. When the market demand became clear, specialized cruise ships began to be built, with less emphasis on speed than passenger liners, and more on space for entertainment and relaxation. The market has grown steadily and rapidly since then: the estimated numbers were 3,774,000 journeys in 1990 and 21,556,000 journeys in 2013 (Figure 4). The total turnover of the cruise market was estimated at 37.1 billion United States dollars (CMW, 2014). Growth has slowed somewhat since 2008, but has continued.

Figure 4. Growth in numbers of passenger cruise journeys 2007 – 2014.

(millions of journeys). Note: ROW is "Rest of the World" Source: CLIA, 2014.

Over half the market demand in 2013 was from the United States (51.7 per cent). The remaining demand is reported as 26.6 per cent from Europe, 3.6 per cent from Australia and New Zealand, 3.4 per cent from Brazil, 3.4 per cent from Canada and 11.3 per cent from the rest of the world. The main target areas in terms of itineraries and ship deployment for cruises in 2013 are reported as: the Caribbean (34 per cent), the Mediterranean (22 per cent), the rest of Europe (11 per cent),

Australia (5 per cent), Alaska (5 per cent), South America (4 per cent), Asia (3 per cent) and other areas (16 per cent) (CLIA, 2014).

There appears to be a trend towards larger vessels. In the Baltic Sea, the Helsinki Commission has calculated that the average number of passengers on the cruise ships calling at Baltic ports rose between 2006 and 2012 by 49 per cent, from 1,099 to 1,635 (HELCOM, 2014a).

2.4 The world fleet of ships

The size of the world's fleet of ships has been increasing rapidly in the period from 2000 – 2013 (Figure 5). The persistence of a high rate of growth after the economic crisis of 2008 is accounted for by the lead time between the ordering and delivery of vessels: 2012 was the first year since 2001 in which the tonnage of ships delivered fell below the tonnage delivered in the previous year (UNCTAD, 2013).

Figure 5. Total size of the world fleet of ships 1980 – 2013. Source: UNCTAD, 2013. Note: Figure 5. includes all propelled seagoing merchant vessels of 100 GT and above, excluding inland waterway vessels, fishing vessels, military vessels, yachts, and offshore fixed and mobile platforms and barges (with the exception of floating production storage and offloading units (FPSOs) and drillships).

The age profile of the world fleet has also been changing: by January 2013, 20 per cent of all seagoing merchant ships were less than five years old, representing 40 per cent of the world's deadweight tonnage. At that point, the average age (per ship) in January 2013 was 9.9 years for dry-bulk carriers, 10.8 years for container ships, 16.7 years for oil tankers, and highest for general-cargo ships (25 years) and the miscellaneous ships (22.6 years). The average ages of oil tankers and dry bulk carriers are lower because of the rapid increases in their numbers. The figure for oil tankers also reflects the phasing out of single-hulled oil tankers (UNCTAD, 2013).

The practice of registering ships in flag States other than that of the owner’s nationality has grown, particularly under what are called “open registries”, which (among other things) may not impose requirements on the nationality of officers or other crew. The proportion of vessels over 1,000 gross tonnage³ flying a flag different from that of their owner’s nationality has increased steadily from less than 41.5 per cent in 1988 to 73 per cent in 2013. In 2013, more than half the tonnage of the world’s ships was registered with four registries – Panama (21.52 per cent), Liberia (12.16 per cent), the Marshall Islands (8.60 per cent) and Hong Kong, China (7.97 per cent) (UNCTAD, 2013) (Figure 6). Because of the attractions of “open registries”, a number of States have created international shipping registers. These usually have less stringent requirements on the nationality of crew, but may not be open to ships trading solely within national waters.

Figure 6. Share of the World’s Gross Tonnage by Registry 2013. (12 Registries with the largest gross tonnage on the register and the total gross tonnage of all other Registries). Source: compiled from UNCTAD, 2013).

The pattern of ownership of vessels varies widely between the registries. For example, among the 12 largest registries, some have negligible proportions owned or controlled by nationals. For others (China and Greece), the tonnage is predominantly controlled by nationals. Yet others have substantial, but not predominant, proportions controlled by nationals. This variable pattern is also found among all the other registries. Figure 7 shows the estimated spread of ownership and/or control for ships of over 1,000 gross tonnage between the 12 largest ship-owning States and the rest of the world. Owners from five countries (China,

³ “Gross tonnage” is a measure of “the moulded volume of all enclosed spaces of the ship” (International Convention on Tonnage Measurement of Ships, 1969) and is calculated from the volume of the ship multiplied by a reduction factor which increases with the size of the ship.

Germany, Greece, Japan, and the Republic of Korea) together account for 53 per cent of the world tonnage. Among the top 35 ship-owning countries and territories, 17 are in Asia, 14 in Europe, and 4 in the Americas (UNCTAD, 2013).

Figure 7. Spread of the control/ownership of vessels of over 1,000 gross tonnage between the 12 largest fleets and the rest of the world 2013. Source: compiled from UNCTAD, 2013.

2.5 Ship safety

Whether ships are carrying passengers or cargo, the main aim is that the ship should reach port safely at the end of the voyage. In the 1960s, concern about the numbers of collisions of ships, the damage that they could inflict on the environment, the risks to the lives of those on board and the economic effects of losses led to the development of various recommendations on methods of navigation in areas with high levels of shipping activity. In 1971, the IMO Assembly adopted the principle of compulsory measures for ships' routing under the SOLAS Convention, of which the scheme in the Dover Straits was the first (IMO, 2014c).

The IMO has now established some 152 ships' routing measures around the world. These include Traffic Separation Schemes (which require ships going in opposite directions to stay in designated lanes), Inshore Traffic Zones (designated areas landward of a traffic separation scheme for coastal traffic), Deep-Water Routes (routes which have been accurately surveyed for clearance of sea-bottom and submerged objects), and Areas To Be Avoided (areas in which either navigation is particularly hazardous or it is exceptionally important to avoid casualties and which should be avoided by all ships, or by certain classes of ships). In addition, a number of Governments and port authorities have established similar schemes, particularly in the approaches to major ports (UKHO, 2014). The importance of ships' routing measures can be seen from the straits linking the Black Sea and the Mediterranean. A 2004 study showed that the majority of the accidents in the period 1953 to 1994 were collisions between two or more ships; after the introduction of a traffic separation scheme in 1994, the majority of the accidents were groundings or strandings (Akten, 2004).

In addition to the ships' routing measures adopted by IMO, the IMO has designated, on the proposal of coastal States, Particularly Sensitive Sea Areas (PSSAs) in their exclusive economic zones, where associated measures to protect the environment can be approved. Fourteen such areas have so far been designated. Eight establish Areas to be Avoided (ATBA), six impose mandatory reporting requirements on some or all ships (MSR), four include Traffic Separation Schemes (TSS), two impose a ban on any ship anchoring in a specified area, and one imposes a mandatory deep-water route (DWR). In addition, two recommend the use of pilotage and two recommend the use of an established two-way route. Three of the areas (the Great Barrier Reef, Malpelo Island and the Paracas National Reserve) are linked to areas designated as World Heritage Sites (see Chapter 8 – Cultural Ecosystem Services from the Ocean). The 14 areas, the States proposing them, and the additional protective measures adopted are (in the order of their designation):

- (a) Great Barrier Reef (Australia, 1990) (for measures see (h) below);
- (b) Sabana-Camagüey Archipelago (Cuba, 1997, ATBA);
- (c) Malpelo Island (Colombia, 2002 – ATBA);
- (d) Marine area around the Florida Keys (United States, 2002 – ATBA, mandatory no-anchoring areas);
- (e) Wadden Sea (Denmark, Germany, Netherlands, 2002 – DWR);
- (f) Paracas National Reserve (Peru, 2003 – ATBA);
- (g) Western European Waters (Belgium, France, Ireland, Portugal, Spain and the United Kingdom – MSR);
- (h) Extension of the Great Barrier Reef PSSA to include the Torres Strait (Australia and Papua New Guinea, 2003 – MSR, two-way route, recommended pilotage);
- (i) Canary Islands (Spain, 2004 – ATBA, TSS, MSR, recommended routes);
- (j) Galapagos Archipelago (ATBA, MSR, recommended routes);
- (k) Baltic Sea (Denmark, Estonia, Finland, Germany, Latvia, Lithuania, Poland and Sweden, 2004 – TSS, DWR, ATBA, MSR);
- (l) Papahānaumokuākea Marine National Monument (USA, 2007 – ATBA, MSR for all USA ships and all other ships over 300 gross tonnage, recommended reporting for other ships);
- (m) Strait of Bonifacio (France and Italy, 2011 – MSR, recommendation on navigation);
- (n) Saba Bank (Caribbean Netherlands, 2012 – ATBA, mandatory no-anchoring area) (IMO, 2014d).

Work continues to improve the safety of navigation, including through on-going improvements to charts, electronic aids to navigation and other navigation services. Such improvements have played a significant part in achieving the reductions in shipping casualties described in this chapter (IMO, 2014e).

The combined effect of all these measures has been to achieve a steady reduction in the number of ships lost at sea, with environmental, social and economic benefits: less pollution of the sea, fewer lives lost and less disruption of trade. Over the long term, in 1912, the casualty rate was about 1 in 100 ships from a fleet of about 33,000 ships; in 2009, the casualty rate was about 1 in 670 ships from a fleet of about 100,000 (Allianz, 2012). The following graph (Figure 8) shows how the number of ships lost has decreased over the past decade to 2013. (However, more recently, casualties to ships carrying refugees may affect the picture).

Figure 8. Number of ships over 1,000 gross tonnage lost 2002 – 2013. Source: Allianz, 2014 (based on Lloyd’s List Intelligence Casualty Statistics).

As for the locations of these events, they are naturally concentrated on the main shipping lanes. As Table 4 shows, 30 per cent of the losses between 2002 and 2013 were in the waters off eastern Asia.

Table 4. Shipping losses over 1,000 gross tonnage by sea area

SEA AREA	2002 - 2013	2013
South-East Asian Seas (the waters off southern China, Viet Nam and the eastern coasts of the Malaysian peninsula and Thailand, the coasts of Brunei Darussalam and Sarawak (Malaysia) and around Indonesia and the Philippines and Singapore)	296	18
Eastern Mediterranean and the Black Sea	215	17
North-West Pacific (the waters off northern China, Japan, the Korean peninsula and the Pacific coast of the Russian Federation)	207	9
The North Sea, the English Channel, other waters around the Britain and Ireland, and the Bay of Biscay	135	8
The Persian Gulf and its approaches	96	6
South-West Atlantic	82	5
Western Mediterranean	73	4
Wider Caribbean	51	3
Western Indian Ocean	51	3

SEA AREA	2002 - 2013	2013
Bay of Bengal	50	3
Eastern seaboard of the United States	45	0
Other parts of the world	372	18
Total Losses worldwide	1,673	94

Adapted from Allianz, 2014 (based on Lloyd's List Intelligence Casualty Statistics).

In the late 1990s a series of disasters involving ships not covered by the IMO Conventions and their requirements prompted IMO to undertake action as part of their Integrated Technical Cooperation Programme to help States in various regions to develop codes to improve the standard of shipping in those regions. By 1999, States in Asia, the Caribbean and the Pacific agreed codes for non-Convention ships, which many States have incorporated into their legislation. Draft regulations have been developed for Africa, and the IMO has been assisting some States to use these as a basis for improving the safety of ships operating in their waters. Much work still remains to be done, because the infrastructure and skilled personnel needed to implement the regulations are often not available (Williams, 2001). Even where regional codes have been adopted, they do not apply to vessels under 15 – 24 metres (depending on the region). Concern therefore remains in many parts of the world (especially Africa) about improving the safety of small vessels – for example, a 2012 study showed that 70 per cent of the shipping incidents between 1998 and 2011 reported in South Africa involved small ships or fishing vessels (Mearns et al., 2012).

3. Socioeconomic aspects of shipping

3.1 Profitability of the world fleet

The profitability of ferries and the carriage of cargoes within a State (“cabotage”) will depend very heavily on local circumstances. Many States subsidize ferries to offshore islands from general taxation in order to remove the disadvantages which those living on such islands would otherwise suffer. Restrictions on which ships may carry out cabotage (which can be restricted to ships flying the national flag of the State within which the carriage takes place) can significantly affect the profitability of routes. States may also intervene to make cabotage more profitable in order to encourage cargo traffic to use sea routes rather than land routes, in order to reduce pressure on roads or the need to build or improve them.

The profitability of international traffic, particularly on intercontinental routes, is, on the other hand, very much a matter of the global shipping market. Long-distance cargo capacity is largely traded on a global market, which is focused on certain cities with well-established local shipbroking networks. Among these are Amsterdam, the Netherlands; Athens (Piraeus), Greece; Copenhagen, Denmark; Hong Kong, China;

London, United Kingdom of Great Britain and Northern Ireland; New York, United States; Oslo, Norway; Shanghai, China; and Tokyo, Japan. This market covers both ships operated principally by those who own them, and ships whose owners generally expect to charter them out to other firms to operate. Ships can easily switch between these categories, depending on the levels of supply and demand in the market. Since the level of activity in global shipping is closely linked to the level of global trade within the four main markets of oil and gas, the main bulk cargoes, containers and general cargo, the levels of supply and demand of shipping in the market will likewise fluctuate. Extended periods of growth in global trade encourage ship-owners to invest in new capacity – even more so if growth causes demand to outstrip supply significantly, as happened at some periods over the past two decades. 2001 to 2012 saw the longest sustained growth in the size of the world fleet in history, with record deliveries of new vessels year after year. Additions to capacity will also be caused by investment in new vessels which can operate more efficiently, usually because they are larger. The entry into service of such improved vessels will cause other vessels to be cascaded down the markets. Mismatches between increases in capacity and growth in global trade will lead to overcapacity and falls in freight rates and consequent drops in profitability. Likewise, if global demand drops because of economic recessions, the long lead-time for new shipping means that capacity will continue to grow from deliveries of vessels ordered at a time of growth, thus enhancing the effects of falls in demand (UNCTAD, 2013).

The drop in global trade from the 2008 global recession led to serious drops in freight rates, especially for container ships. For container ships, recovery in trade in 2011 did not immediately lead to better freight rates, in view of the large increases in new capacity. Measures such as slowing voyages (which both saves fuel and uses more capacity) and transferring capacity from east-west routes (where trade remained low) to north-south routes (where trade was growing) meant that in 2012 container freight rates recovered. For tankers carrying oil, gas and chemicals, the position has been similarly poor, with rates over 2009 – 2013 roughly half those of the peak of early 2008. For bulk carriage of coal, grain and minerals, rates over the same period have been only 10 per cent - 30 per cent of the peak 2008 rates. In 2012, a survey revealed that 21 carriers of the top 30 that publish financial results reported an overall operating loss of 239 million dollars in 2012, with only seven carriers turning in positive results (UNCTAD, 2013).

Overall, the pattern has been one of bigger ships offered by fewer companies. Although, in general, the level of service for cargo carriage by regular sailings, as shown by the UNCTAD Liner Shipping Connectivity Index, has improved over the past decade, the result of concentrating cargo in bigger vessels owned by bigger companies has been to reduce the level of competition. In 2004, 22 countries were served by three or fewer carriers: in 2013, 31 countries were facing this situation (UNCTAD, 2013). In 2013, three of the largest container shipping lines proposed collaboration in the scheduling of sailings and allocation of cargo to sailings, while retaining separate sales and pricing systems. These proposals were not accepted by all States and have now been dropped. However, in 2014, the shipping companies involved in those proposals and other companies formed two alliances. Some in the

shipping industry believe that further arrangements may be proposed (SCD, 2014, Lloyds List, 2014).

In recent years, passenger cruise ships have suffered some bad publicity, with the loss of the *Costa Concordia* and a number of other adverse events. However, all the major cruise lines have been reporting profits. Across the industry, profits per passenger were reported to grow by nearly 18 per cent between 2011 and 2013, from 157 dollars to 185 dollars (Statista, 2014).

4. Seafarers

4.1 Numbers of seafarers

Worldwide, there are just over 1.25 million seafarers. Only about 2 per cent of these are women, mainly in the ferry and cruise-ship sectors (ITF, 2014). Their origins are shown in Table 5.

Table 5. Broad Geographical Origins of Seafarers 2010.

Origin	Officers	per cent	Ratings	per cent
Africa / Latin America	50,000	8	112,000	15
Eastern Europe	127,000	20	109,000	15
Far East	184,000	30	275,000	37
Indian Sub-Continent	80,000	13	108,000	14
OECD Countries	184,000	29	143,000	19
Total - All National Groups	624,000	100	747,000	100

Source: BIMCO/ISF, 2010.

Although there are many uncertainties, a recent survey by the Baltic International Maritime Council Organization and the International Shipping Federation indicates that the industry will most probably face a continuing shortage of qualified crew (and particularly of officers) when shipping markets recover. There is also a high wastage rate of qualified crew leaving the industry, and this contributes to potential shortages (BIMCO/ISF, 2010).

4.2 Conditions of work for seafarers

Because ships and those who work on them are operating in a world market, and are frequently (and, in international shipping, usually) not operating within the State under whose flag they fall, international action to regulate the pay and conditions of seafarers has been a major concern of the International Labour Organization (ILO) since its foundation in 1919. In 2006, the ILO adopted the Maritime Labour Convention (MLC) as the “fourth pillar” of international maritime law (alongside SOLAS, the International Convention on Standards of Training, Certification and Watchkeeping for Seafarers, as amended (STCW), and MARPOL). The MLC embodies “all up-to-date standards of existing international maritime labour Conventions and Recommendations, as well as the fundamental principles to be found in other international labour Conventions”. The MLC entered into force on 20 August 2013 and, by June 2014, had been ratified by 61 States representing 80 per cent of global shipping tonnage (ILO, 2014).

The MLC continues and restates a unique system for setting recommended minimum wages for seafarers from all countries. A Subcommittee of the ILO Joint Maritime Commission (with representation of Governments, seafarers and ship-owners) has agreed on an increase in the minimum monthly basic wage figure for able seafarers to 592 dollars (7,104 dollars a year) from 1 January 2015 and to 614 dollars (7,368 dollars a year) from 1 January 2016 (ILO 2014)

The pay of officers is determined by the market. However, there are noticeable differences between pay rates, depending on the national origin of the officers concerned. A global survey in 2012 showed the following pattern of salaries (Table 6).

Table 6. Pay of ships’ officers in United States dollars a year

ORIGIN	JOB TYPE			
	Master Mariner	Chief Engineer	Chief Officer	Second Engineer
Asia	111,422	102,740	74,319	72,996
Eastern Europe	109,627	104,448	74,653	81,125
Western Europe	138,320	104,628	90,273	81,871

Source: compiled from Faststream, 2012

Because seafarers can find themselves in foreign ports without many of the support services available to land-based workers, the rights under the MLC on such issues as enforcing arrears of pay are very important. In addition, a survey based on 3,480 cases presented to the Legal Committee of the IMO strongly suggested that the rights of seafarers, as set out in the IMO/ILO “Guidelines on fair treatment of

seafarers in the event of a maritime accident”, are often subject to violation. Among the views expressed were that the survey showed a need to keep up pressure for better implementation of the Guidelines, and that seafarers were more exposed to criminal proceedings than many other workers (UNCTAD, 2013).

4.3 Safety of seafarers

There are difficulties in obtaining a clear picture of the deaths and injuries suffered by seafarers. In this context, it seems necessary also to consider deaths and injuries suffered by those working at sea in the fishing industry, since these have similar causes. In 1999, a study looking at 19 major shipping administrations over the period 1990 – 1994 concluded that casualties arising from disasters involving merchant vessels were grossly underreported, and in addition failed to address mortality from all other causes of death at sea (Nielsen, 1999). In 2013, when the Secretary-General of IMO launched the Accident Zero Campaign, he noted that the available statistics are neither accurate nor comprehensive, and suggested that there is a need for an official global statistical base (Sekimizu, 2013). The statistics quoted by the IMO Secretary-General showed the following pattern of deaths (Table 7) as far as they could be ascertained:

Table 7. Pattern of Deaths of Seafarers 2008 - 2012

Year	Deaths of seafarers
2008	1,942
2009	2,395
2010	1,501
2011	1,095
2012	1,051

Source: Sekimizu, 2013.

Of these, about 10 per cent were in the fishing sector, 40 per cent in domestic shipping and 50 per cent in other categories, including international shipping. Statistics on serious injuries to seafarers are even less easily established.

Over the past three decades, acts of piracy and armed robbery have re-emerged as serious risks to seafarers. Much attention has been focused on such attacks on shipping in waters off eastern Africa, but reports show that the problem is more widespread. In the last three years, action against attacks off eastern Africa appears to have had some success, but attacks elsewhere are also of concern - especially in the South China Sea area, the location of over half the incidents reported in 2013. The statistics cover reports of alleged piracy (outside the territorial sea) and armed robbery at sea in the territorial sea and port areas (Figure 9). Of the 132 attacks reported in 2013 in the South China Sea area, 70 per cent allegedly occurred while

the ship was in port. Worldwide, 17 per cent of the attacks were reported to involve actual violence against the crew (IMO, 2014a).

Figure 9. Reports of Alleged Acts of Piracy and Armed Robbery Committed or Attempted 1984 – 2013. Source: IMO, 2014a.

4.4 Safety of Passengers

There are several aspects to the safety of passengers on board passenger ships. The aspect on which most attention has been focused by the international community, since at least the *Titanic* disaster in 1912, is protection against incidents involving ships on international voyages. Although (as with deaths and injuries to seafarers) there are problems in establishing the relevant statistics for deaths of, and injuries to, passengers, there seems to be little doubt that the number of incidents involving passenger ships on international voyages, and the consequent harm to passengers, is small and has fallen steadily: 13 passenger vessels were lost in 2002 as compared to six in 2013 (Allianz, 2014). A second aspect of passenger safety is that of passenger ferries on domestic voyages. Although, again, statistics are limited, the IMO Secretary-General has drawn attention to the fact that in the 2½ years from January 2012 to June 2014, 2,932 lives were lost in domestic passenger ship accidents around the world. The third main aspect of passenger safety is the accidents and other events of a kind that have nothing to do with the failure of vessels: these cover not only medical emergencies, but also crimes committed by crew or other passengers, and people falling overboard. The size of modern cruise ships (with up to about 5,000 passengers and 2,500 crew) means that this kind of event is as likely to happen on a ship as in a small town. However, investigation and follow-up are a matter for the flag State of the vessel. Statistics on these aspects of passenger safety are not consistently collected. However, because of the large proportion of cruise trips that start in its territory or involve its citizens, the United States since 2010 has required reporting these incidents to the Federal Bureau of Investigation (FBI) for,

among others, cruises starting or ending in its ports. The reports show 130 reports of alleged serious crimes in 2011 – 2012 (Rockefeller, 2013).

5. Links to other industries

5.1 Shipbuilding

The steady growth in the numbers and size of vessels of all kinds resulted in record levels of ships being on order in 2008: the dead-weight tonnage (dwt) on order grew by between 50 per cent (general cargo) and 1000 per cent (bulk carriers) to a total of around 600 million dwt. The economic crisis of 2008 resulted in a rapid decline in new orders, and as a consequence many shipyards are thought likely to have to reduce employment. Over the decade from 2002 to 2012, there have been major changes in the location of shipbuilding: in 2012, China (41 per cent), Republic of Korea (33 per cent) and Japan (18 per cent) produced about 92 per cent of all new dwt tonnage; six years earlier in 2006, China had been producing only about 15 per cent, about the same as the European shipyards taken together. The Philippines also has a growing shipbuilding industry: 3 per cent of global dwt completed in 2012. Eastern Asia has thus become dominant in the global shipbuilding market (UNCTAD, 2013).

5.2 Ship-breaking

The ship-breaking industry has likewise become more concentrated. In 2012, 70 per cent of all gross tonnage reported as sold for demolition was sold to ship-breaking yards in Bangladesh, India and Pakistan; 22 per cent was sold to ship-breaking yards in China and 3 per cent to yards in Turkey, leaving only 5 per cent being sold to the rest of the world (UNCTAD, 2013). The ship-breaking industry has given rise to concerns about both the impact on the workers employed and the effects on the marine environment (see Chapter 20). An ILO expert group described it as very hazardous for the workers and presenting many threats to the environment, with major difficulties in enforcing regulations (ILO, 2003). The Hong Kong International Convention for the Safe and Environmentally Sound Recycling of Ships was adopted in 2009. To enter into force, this requires ratification by 15 States representing 40 per cent of the gross tonnage of the world fleet and the combined maximum annual ship recycling volume of these States constituting not less than 3 per cent of the gross tonnage of their combined fleet. However, at the end of 2014, only three States representing 1.98 per cent of world tonnage had ratified it (IMO, 2014b). From the start of 2015, the IMO will implement, in coordination with the Government of Bangladesh, a project aimed at enhancing the standards of health, safety and environmental compliance of ship recycling in Bangladesh.

5.3 Bunkers

Ships need to burn fuel to move, and there is therefore a substantial world-wide industry delivering ships' bunkers (as ships' fuel is named). Estimates of total

worldwide fuel consumption by ships vary: calculations in the IMO Greenhouse Gas study based on a bottom-up approach using data on ship movements from Automatic Identification Systems (AIS) show a total consumption of about 327 million tons per year in 2011, compared with a figure of 254 million tons a year based on top-down data on sales of bunkers (IMO 2014o). This compares with an estimate by the United States Energy Information Agency of around 164 million tons a year (EIA, 2014b). In 2010, this represented about 1.5 per cent of the world's total primary energy supply (OECD, 2014). Most of the bunkers are residual fuel oil – that is, the fuel oil that remains after lighter fractions have been removed for other uses. As a consequence, it often has high sulphur content and presents other problems (such as the need to heat it before it can be pumped to the engines). Restrictions are being introduced on bunkers, in order to combat air pollution from ships (see below). Much of the delivery of bunkers takes place in the larger ports, especially those situated near navigational choke-points. Singapore is the world's leading port for the supply of ships' bunkers (MPA, 2014).

5.4 Marine insurance

Alongside the maritime transport industry, a major industry has grown up to insure ships and their cargoes while they are in transit. This is an important component of maritime transport, since cargo owners, ship owners, crew and the rest of the world (including the marine environment) can easily be damaged by ship accidents. A means of ensuring compensation is essential. Many States require a valid insurance certificate as a precondition of entry to their ports: for example, this is a requirement in all European Economic Area States (EC, 2009). The annual premium income worldwide of the marine insurance industry was estimated at 28,930 million United States dollars (excluding the offshore energy industries, whose insurance is often included in marine insurance figures, because it is provided by the same firms). The premiums on cargoes and freight costs represented 18,139 million dollars (62.7 per cent) of this business, the ships themselves 8,563 million dollars (29.6 per cent), and 2,228 million dollars (7.7 per cent) the cost of insurance against causing damage to the marine environment. In addition to the commercial insurance of ships, cargoes, freight costs and environmental risks, many ships are entered into Protection and Indemnity Clubs (P & I Clubs). These are non-profit associations of ship owners, which cover their members against other risks not covered by the marine insurance policy. These clubs are financed by calls on members. In 2013, the total of calls from P & I Clubs was estimated at 3,630 million dollars (Seltmann, 2014).

An important element of these insurance arrangements is the inspection of ships by independent surveyors. These inspections are organized by Classification Societies, which also lay down construction standards for ships that are consistent with the legal requirements of the States with which the Classification Society works. Registration by a Flag State, as well as obtaining insurance, is normally conditional on a Classification Society issuing a certificate that the ship meets the standards laid down for its class. There are over 100 Classification Societies in the various parts of the world. The major Classification Societies formed, in 1961, the International Association of Classification Societies (IACS), which currently consists of 12 member

societies and has adopted common approaches to the task of classification through the development of unified rules, requirements and interpretations— for example, the Common Structural Rules for Tankers and Bulk Carriers 2006 (IACS, 2014).

6. Pathways by which shipping impacts on the marine environment and the nature of those impacts

Shipping's impacts on the marine environment can be divided into the catastrophic and the chronic. Catastrophic impacts on the marine environment result from disasters involving the ship, and may lead to its total loss: for example, collisions, fires, foundering and wrecks. Chronic impacts are those that result from the day-to-day operation of ships, without calling into question the ship's integrity or continued functioning (Donaldson, 1994). Both are important, and both are addressed by very similar methods, including by ensuring the safe construction of vessels and their safe operation through construction standards, safe navigation methods, and the proper training and deployment of the crew.

Figure 2 highlights the way in which major shipping routes pass through certain choke-points: among the more significant are the Malacca and Singapore Straits, the Strait of Hormuz, the Bab al Mandab at the entrance to the Red Sea, the Suez Canal, the straits linking the Black Sea and the Mediterranean, the Sound and the Belts at the entrance to the Baltic Sea, the English Channel and the Straits of Dover, and the Panama Canal. Concerns about chronic effects are therefore greatest in these areas, because it is there that those effects are most concentrated.

Catastrophic events produce the most serious impacts on the marine environment, as well as being very serious from the point of view of the crew and any passengers and in their economic impact. As explained above, the combined effect of efforts under a number of international conventions has been to reduce steadily the number of ship losses and other catastrophic events.

6.1 Combined impacts of catastrophic events and chronic inputs to the ocean from ships

For most of the major threats to the ocean from shipping, MARPOL provides the technical specifications for preventing and reducing the threats. It was adopted in 1973, adapted in 1978 to facilitate its entry into force, and entered into force for the provisions relating to oil and noxious liquids in bulk in 1983. Since then, it has developed over time (as explained below), both by strengthening the requirements and by bringing into force regulations relating to additional fields. Other international conventions also address threats to the marine environment arising from ships (see also below).

Effective implementation and enforcement of the requirements of these international conventions are crucial.

6.2 Oil

Oil spills from shipping have a wide range of impacts. Catastrophic discharges of large amounts of hydrocarbons will produce large oil slicks with consequentially massive impacts. Smaller slicks will have lesser impacts, but may be equally serious if they are repeated frequently. The impacts range from covering seabirds with oil (which can lead to death), through killing and tainting fish and shellfish and making the stock of fish farms unusable to covering beaches and rocky shores with oil (which can adversely affect tourism). In specific cases, problems can be caused for industries that rely on an intake of seawater (such as marine salt production, desalinization plants and coastal power stations) and coastal installations (such as marinas, ports and harbours) (ITOPF, 2014a). In summarising general experience with oil spills, the study on the environmental impact of the spill of 85,000 tons of crude oil in the 1993 *Braer* catastrophe (Ritchie et al., 1994) drew attention to three important features of major oil spills:

- (a) There is an initial, very serious impact, usually with extensive mortality of seabirds, marine mammals, fish and benthic biota and coastal pollution;
- (b) In many circumstances, however, marine ecosystems will recover relatively quickly from oil spills: crude oil loses most of its toxicity within a few days of being spilled at sea, mortality of marine biota declines rapidly thereafter, sub-lethal effects are of limited long-term significance and marine ecosystems recover well where there are nearby sources of replacement biota;
- (c) Nevertheless, the local circumstances of an oil spill will be very significant. The impact on seabirds, marine mammals and sessile biota will obviously be worse if the spill occurs in areas where they are present in large numbers at the season when the spill occurs – the location of breeding and nursery areas and migration routes and other regular concentrations being particularly important.

The ambient temperature is one of the local circumstances that are most significant for the duration of the impact and the timing of recovery. In warmer areas, the bacteria that break down hydrocarbons are more active, and the effects will disappear more quickly. In spite of the size (about 1 million tons) of the discharges (not including the airborne deposits from the burning of a further 67 million tons), the effect on the coasts of Kuwait and Saudi Arabia of the discharges from oil wells during the Gulf War in 1991 was largely disappearing within 18 months. These coasts had largely recovered within five years. However, oil appears to have persisted in salt marshes and at lower depths in the lower sediments as a result of their anaerobic condition (Readman et al., 1992; Jones et al., 1994; Otsuki et al., 1998; Barth, 2001). In colder areas, on the other hand, bacterial activity is much lower, and the effects of oil spills persist much longer. The impact of the *Exxon Valdez* disaster, in which 35,000 tons of oil were spilt in 1989, was still measurable 20 years later (EVOSTC, 2010).

Local circumstances will also determine the appropriate response to an oil spill. In relatively calm water, it is often appropriate to contain an oil spill with floating booms and use skimmers to retrieve as much oil as possible. With such equipment,

it is possible to recover a large proportion of the spill – two-thirds of the 934 tons spilt from the *Fu Shan Hai* in the Baltic in 2003 were recovered (HELCOM, 2010). The other major approach is the use of chemical dispersants. Opinion is divided on the appropriateness of using them: some States regard them as appropriate in many cases, depending on the meteorological circumstances, the local environment and the nature of the oil spill; other States regard them as unacceptable (for examples, see the different opinions in BONN, 2014).

The problem of pollution from oil was the starting point of MARPOL, and the rules to prevent it are in its Annex I. The Annex covers the construction of oil tankers, their operation, what discharges of oily water are permitted, the equipment that must be used and the record-keeping required about any discharges. These requirements have been strengthened over time. In particular, it requires the phasing out of single-hulled oil tankers by, at the latest, 2015.

MARPOL Annex I not only prohibits any discharge into the sea of oil or oily mixtures from any ships in the waters around Antarctica, but also provides for the designation of Special Areas, in which more stringent limits on the discharge of oily water apply. As a counterpart to the designation of Special Areas, coastal States in a Special Area must be parties to MARPOL and must provide appropriate reception facilities for oily waste (see also Chapter 18 - Ports). An important feature of Special Areas is that the maximum permitted level of oil in water discharged is 15 parts per million. In a number of States, the legal system considers that any visible slick on the sea surface must have been caused by a discharge above this level (for examples, see NSN, 2012). Special Areas have been designated, and are in force, in the Mediterranean Sea, the Baltic Sea, the Black Sea, the “Gulfs Area”⁴, the Antarctic Area (south of 60°S), North-West European Waters and Southern South African waters. Three further areas have been designated, but are not yet in force because the coastal States have not all notified IMO that adequate reception facilities are in place: the Red Sea, the Gulf of Aden and the Oman area of the Arabian Sea (IMO, 2014f).

In some parts of the world, special measures have been introduced to reduce oil pollution. Aerial surveillance, supplemented and guided more recently by the use of satellite surveillance, has been used in North-West Europe. Coupled with an effective programme of prosecutions of owners and masters of ships observed unlawfully discharging oil, this has led to decreases over the last two decades in the numbers of oil spills, both in absolute terms and in terms of numbers of oil spills observed per hour flown (BONN, 2013; HELCOM, 2014). In the Mediterranean, pilot projects of this kind have been undertaken (REMPEC, 2014). Canada also has set up similar surveillance programmes, using both aerial and satellite surveillance (Canada, 2011).

Over the past forty years, there have been substantial reductions in the scale of marine environmental problems from oil pollution. As Figure 10 shows, after the amount of oil transported by sea started to recover from the effects of the 1974 price increases, the amount transported (measured in ton/miles) has steadily

⁴ The “Gulfs Area” is the sea area between the Arabian Peninsula and the Asian mainland.

increased. At the same time, the number of recorded spills of more than 7 tons has steadily decreased. Forty-six per cent of the spills between 7 and 700 tons between 1970 and 2013 occurred as a result of collision or grounding and 26 per cent as a result of hull or equipment failure or fire or explosion. For spills of over 700 tons in that period, 63 per cent were the result of collision or grounding and 28 per cent of hull or equipment failure or fire or explosion. In both cases the remaining causes were unidentified (ITOPF, 2014a, UNCTAD, 2012).

Figure 10. Seaborne oil trade and number of tanker spills of more than 7 tons 1970 - 2012. Source: ITOPF, 2014b.

As Figure 11 shows, a similar decrease is observed in the amount of oil involved in these oil

spills.

Figure 11. Quantities of oil in spills of more than 7 tons in the years 1970 – 2013. (with notes of the major recent oil spills and their sizes). Source: ITOPF, 2014b.

Nevertheless, a significant problem remains, especially near major shipping routes. A study has shown that even low levels of oil fouling in Magellanic penguins appear to be sufficient to interfere with reproduction (Fowler et al., 1995). One way in which the extent of the remaining problem can be seen is from observations on shorelines of the proportion of the dead seabirds found there which have been contaminated by oil. Diving seabirds are very sensitive to oil pollution: once such a bird is polluted with oil, it is likely to die from hypothermia and/or inability to forage. In the MARPOL North-Western Europe Special Area, the proportion of common guillemots (*Uria aalge*) stranded near the major shipping routes in the southern North Sea was about 40 per cent in 2010, compared with about 4 per cent around the Orkney Islands (OSPAR, 2010). Similar reports have been made about the oiling of seabirds in other areas with high levels of shipping: in the MARPOL Southern South Africa Waters Special Area, studies note that, on the basis of the proportion of the population that has been affected, the African penguin is considered to have suffered more from oiling than any other seabird species globally (Wolfaardt, 2009; Garcia-Borboroglu et al., 2013). In the Straits of Malacca, there is a serious problem with illegal discharges of oil: during the five-year period from 2000 to 2005, there were 144 cases of oil spills into the sea; of this number, 108 cases were due to illegal discharges from ships (BOBLME, Malaysia, 2011). In the waters around south-eastern South America, used both by coastwise local shipping and large vessels travelling between the Atlantic and Pacific Oceans, a study showed that between 1980 and 1994 some 22,000 adult and some 20,000 juvenile Magellanic penguins

(*Spheniscus magellanicus*) were being killed each year by oil from discharges from ships passing through the foraging areas for their colonies on the coast (Grandini, 1994). Happily, the solution adopted in 1997 of requiring coastal shipping to follow routes further out to sea may have reduced this problem: over the years 2001 – 2007, the number of oiled penguins observed annually was around 100 (Argentina, 1998; Boersma, 2008). However, other reports are less optimistic (see Chapter 36B). Further north, on the Atlantic coast of Canada, there are also reports of substantial numbers of seabirds being killed by oil. A conservative estimate is put at 300,000 birds a year, with appreciable effects on the populations of species commonly suffering this fate (Canada, 2011).

Effective response to oil spills requires a good deal of organization and equipment. The international framework for this is provided by the 1990 International Convention on Oil Pollution Preparedness, Response and Co-operation (OPRC Convention). This entered into force in 1995, and 107 States are now parties. The IMO plays an important role in coordination and in providing training (IMO, 2014g). Coastal States have to bear the capital cost of establishing adequate response capability, but may be able to recover operational costs if and when that capacity is deployed to deal with an oil spill. Developing countries can have difficulties in mobilising the resources for investment in the necessary facilities (Moller et al., 2003).

Major oil spills can cause serious economic damage to a wide range of people and enterprises. After the 1967 *Torrey Canyon* disaster, many States sought to make it easier for those suffering economic damage to obtain reparation. The 1969 International Convention on Civil Liability for Oil Pollution Damage and the 1971 International Convention on the Establishment of an International Fund for Compensation for Oil Pollution aimed to achieve this. These Conventions were revised in 1992 and the revisions came into force in 1996. By July 2014, 115 States were parties to both the 1992 Conventions, and 24 States have become parties to a supplementary protocol providing for additional compensation if the damage exceeds the limits of the 1992 Convention. The economic effect of the Conventions is basically to transfer the economic consequences of an oil spill from the coastal State to the States in which undertakings receive cargoes of oil. This is done either through the insurance costs which the cargo carriers have to incur and include in the costs of the voyages or (to the extent that the damage exceeds the amount insured and the coastal State participates in the funds) through the contributions paid to the funds by those that receive oil cargoes and are located in the States parties.

6.3 Hazardous and noxious substances and other cargoes capable of causing harm

Oil is not the only ship's cargo capable of causing damage. Much depends on the quantities involved – large quantities of nearly any cargo can have an adverse impact, at least on the local environment. SOLAS and MARPOL require precautions against damage from a range of other cargoes, including through requiring compliance with the International Maritime Solid Bulk Cargoes Code, the International Maritime Dangerous Goods Code, the International Code for the Safe

Carriage of Grain in Bulk and the International Code for the Construction and Equipment of Ships carrying Dangerous Chemicals in Bulk.

Data on marine pollution incidents involving hazardous and noxious substances are scarce (FSI, 2012). A 2010 study looking at 312 reported incidents of this kind between 1965 and 2009, mainly in the North Atlantic, concluded that reports had become much more frequent since about 2000, with the advent of the internet. It found that about 33 per cent of the cases involved bad weather or structural damage, 30 per cent collision or grounding, 11 per cent fire or explosion and only 6 per cent failures in loading or unloading. Only about half the cases involved discharges into the sea. The three most common substances involved were iron ore, sulphuric acid and caustic soda (Cedre, 2010).

The increased use of containers means that a substantial amount of hazardous or noxious substances is being carried in containers. In 2010 a group of container owners set up a voluntary system to report incidents involving containers, such as fires and spillages, with a view to analysing the data to see if any patterns emerged which could be useful for risk reduction. The Container Notification Information System now covers about 60 per cent of all container slot capacity. Data on the number of incidents have not yet been published, but some preliminary conclusions have been announced: nearly 50 per cent of incidents involved containers where the contents had been mis-declared; 75 per cent of incidents involved hazardous or noxious cargoes; no particular global pattern of loading ports emerged from the incidents, but incidents appeared to be higher with containers packed in June, July and August (CINS, 2014).

Containers lost overboard are another source of potential pollution from hazardous and noxious substances. Some estimates have suggested that the numbers of such containers could be in the thousands annually. However, the World Shipping Council, based on a survey to which 70 per cent of the global container shipping capacity responded, estimated in 2011 that about 350 containers are lost overboard each year, excluding mass losses of 50 or more containers as a result of a major ship disaster. If those mass losses are included, the number of containers lost rises to about 650 a year out of about 100 million carried annually (WSC, 2011). On the other hand, it must be remembered that even one container lost overboard can have a lasting and widespread effect on the marine environment: a container holding 28,800 plastic yellow ducks, red beavers, blue turtles and green frogs was lost in 1992 in the middle of the Pacific. The toys have been washed up not only all around the Pacific, but also as far away as the Hebrides in the United Kingdom in 2003 (Ebbesmeyer, 2009).

Following on from the International Convention on Oil Pollution Preparedness, Response and Cooperation (OPRC), a protocol dealing with preparedness and response to incidents involving hazardous and noxious substances was adopted in 2000. This follows the same model as the OPRC Convention. It came into force in 2007, but so far only 33 States have become parties. Efforts to set up an international agreement to deal with compensation for liability and damage from hazardous and noxious ships' cargoes were started as long ago as 1984. A convention was agreed in 1996 but, despite further efforts, no scheme is yet in force

to provide international support where a hazardous or noxious cargo causes economic damage.

6.4 Sewage

The problems from the discharge of sewage (in the narrow sense of human and animal urine and faecal waste) from ships are the same as those for similar discharges from land, which are discussed in Chapter 20. Basically, the problems are the introduction of nutrients into the sea, and the introduction of waterborne pathogens. Away from land, the oceans are capable of assimilating and dealing with raw sewage through natural bacterial action. Therefore, the regulations in Annex IV to MARPOL prohibit the discharge of sewage into the sea within a specified distance of the nearest land, unless ships have in operation an approved sewage treatment plant. (IMO, 2014j).

In summary, discharge of sewage into the sea outside a Special Area is permitted:

- (a) When a ship has in operation an approved sewage treatment plant to meet the relevant operational requirements (these are broadly similar to the performance of an effective secondary sewage-treatment plant on land);
- (b) When a ship is discharging comminuted and disinfected sewage using an approved system at a distance of more than three nautical miles from the nearest land;
- (c) When a ship is discharging sewage which is not comminuted or disinfected at a distance of more than 12 nautical miles from the nearest land (MARPOL Annex IV as in force from 2005).

Because of the problems of eutrophication described in Chapter 20, the amendments to MARPOL Annex IV by IMO in 2011 introduces the Baltic Sea as a special area under Annex IV and adds new discharge requirements for passenger ships while in a special area. In effect, when adequate reception facilities are in place, passenger ships capable of carrying more than 12 passengers may only discharge sewage if nitrogen and phosphorus have been removed to specified standards. (MEPC, 2012).

“Grey water” (that is, waste water from baths, showers, sinks, laundries and kitchens) is not covered by MARPOL Annex IV. Some States (for example, the United States in respect of Alaska) have introduced controls over the discharge of sewage and grey water from larger passenger ships putting into their ports because the local conditions (in Alaska, particularly the water temperature) make the breakdown of any contaminants it may contain quite slow (EPA, 2014a). Furthermore, some States, particularly small island developing States, have difficulties in managing sewage discharged ashore from cruise ships and from the large numbers of such ships visiting their ports. These challenges for small island developing States are discussed further in Chapter 25.

6.5 Garbage

There is no doubt that a substantial part of the marine debris considered in Chapter 25 originates from ships. The damage to the environment from this marine debris is described in that chapter. This debris is constituted by waste from the normal operations of the ship that is thrown overboard. All the serious (and not entirely understood) consequences of marine debris described in that chapter therefore apply to this chronic form of discharge from ships. Because of the large numbers of passengers that they carry, cruise ships generate a high proportion of the garbage generated at sea – in 1995, the United States National Research Council estimated that cruise ships produced 24 per cent of the solid waste generated on board ships, although they represented only 1 per cent of the world fleet (NRC, 1995). Because of the scale of the challenge, most large cruise ships now incinerate on board each day a high proportion of the waste that they generate (75 to 85 per cent of garbage is generally incinerated on board on large ships (EPA, 2008)).

Annex V to MARPOL seeks to eliminate and reduce the amount of garbage being discharged into the sea from ships. Although the Annex is not a compulsory part of the requirements of MARPOL, 15 States, with combined merchant fleets constituting no less than 50% of the gross tonnage of the world's merchant shipping became parties to enable its entry into force on 31 December 1988. Experience showed that the requirements in the original version of Annex V were not adequately preventing ships' garbage from polluting the sea. United Nations General Assembly resolution 60/30 invited IMO to review the Annex. This was done and a revised version entered into force in 2013. Alongside this, IMO adopted guidelines to promote effective implementation. The revised Annex V prohibits generally the discharge of all garbage into the sea, with exceptions related to food waste, cargo residues, cleaning agents and additives and animal carcasses. It also provides for Special Areas where the exceptions are much more restricted. The Special Areas comprise the Mediterranean Sea, the Baltic Sea, the Black Sea, the Red Sea, the "Gulfs" area⁵, the North Sea, the Antarctic area (south of 60°S) and the Wider Caribbean Region (including the Gulf of Mexico and the Caribbean Sea) (IMO, 2014h).

Providing adequate waste reception facilities in ports and ensuring that those facilities are used is important. The provision of waste-reception facilities in ports is considered in Chapter 18. However, it should be noted here that small island developing States face major problems in establishing adequate port waste-reception facilities (Corbin, 2011). The greatest effort to promote use of waste-reception facilities has been in Europe, by requiring ships to deliver garbage on shore before leaving port, and removing any economic incentive to avoid doing so. Under this approach, with a few exceptions, all ships are required to deliver their garbage to the port waste-reception facility before leaving port, and the cost of such facilities is to be recovered from ships using the ports, with all ships (again with some exceptions) contributing substantially towards the cost of those facilities, whether or

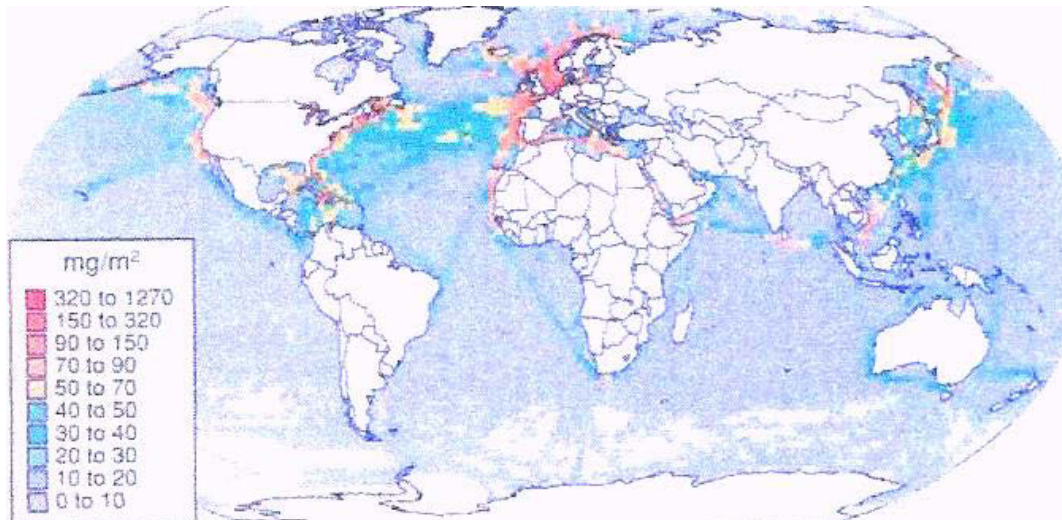

⁵ The sea area between the Arabian Peninsula and the mainland of Asia.

not they made use of them (European Union, 2000). This substantially removes any economic advantage from not using them. This has resulted in a significant (about 50 per cent) increase between 2005 and 2008 in the amount of garbage delivered on shore in European Union ports (EMSA, 2010).

As the OECD pointed out in its 2002 report: “Illegal discharge of wastes at sea often takes place away from shorelines and under cover of night. These two factors make it difficult for port and coastal States to detect acts of pollution, and/or positively identify the polluting vessel” (OECD, 2002). As said in Chapter 25, more information is needed.

6.6 *Air pollution*

Since the replacement of sail by steam and then diesel, ships have been making emissions to the air. By the early 1990s it was becoming apparent that, in some parts of the world, emissions of nitrogen oxides (NO_x) and sulphur oxides (SO_x) from ships were becoming a serious element in air pollution for coastal States with heavy shipping traffic in their coastal waters (OSPAR, 2000). Even short-term exposure to NO_x produces adverse respiratory effects, including airway inflammation, in healthy people and increased respiratory symptoms in people with asthma. It also reduces resistance to respiratory infections (Knelson et al., 1977; Lee, 1980; EPA, 2014b). Airborne NO_x is also a substantial source of nitrogen inputs into coastal waters, and can thus contribute to excessive levels of nutrients (OSPAR, 2010: see also Chapter 20). Exposure to SO_x likewise weakens resistance to respiratory infections, and is linked to higher rates of mortality in humans. It is also a contributor (with land-based emissions) to acid rain, which can harm forests and fresh waters (Greaver et al., 2012). SO_x emissions from ships have been worsening for decades, as a result of the increasing restrictions on the levels of sulphur in hydrocarbon fuels used on land: as restrictions have reduced the extent to which fuel oils with higher sulphur content can be used on land, so such fuel oils have become more attractive for use at sea, because there were no restrictions and the reduced demand on land lowered the price. NO_x and SO_x, together with volatile organic compounds (VOCs), can also react in sunlight to produce smog, which affects many major cities: for coastal cities, emissions from ships can contribute to this problem (EPA, 2014c). In addition, shipping was seen as a further source of chlorofluorocarbons and other substances which were contributing to the depletion of the ozone layer, and thus increasing ultraviolet radiation on the earth’s surface (GESAMP, 2001). Estimates in 1997 of total global NO_x emissions from shipping suggested that they were equivalent to 42 per cent of such emissions in North America and 74 per cent of those in European OECD countries, and that total global SO_x emissions from shipping were equivalent to 35 per cent of such emissions in North America and 53 per cent of such emissions in European OECD countries. The global emissions of both NO_x and SO_x were concentrated in the northern hemisphere (Corbett et al., 1997) – see Figure 12 for SO_x. Emissions from shipping have therefore been seen as a significant contributory source of air pollution in many parts of the world.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 12. Estimated annual emissions of SO_x from ships 1997. Source: Corbett et al., 1997.

In 1997 a new annex to MARPOL (Annex VI) was adopted to limit the main air pollutants contained in ships' exhausts, including NO_x and SO_x. It also prohibits deliberate emissions of ozone-depleting substances and regulates shipboard incineration and emissions of VOCs from tankers. Following its entry into force in 2005, it was revised in 2008 to reduce progressively up to 2020 (or, in the light of a review, 2025) global emissions of NO_x, SO_x and particulate matter, and to introduce emission control areas (ECAs) to reduce emissions of those air pollutants further in designated sea areas (IMO, 2014n). These requirements can be achieved either by using bunkers with lower sulphur content (which may have higher prices) or by installing exhaust scrubbers. Some shipping companies have announced fuel surcharges to meet extra costs which they attribute to the new requirements (Container Management, 2014).

6.7 Anti-fouling treatments

Ships have always been at risk of marine organisms (such as barnacles) taking up residence on their hulls. This increases the resistance of the hull in its passage through water, and thus slows its speed and increases the fuel requirement. With fuel being around half the operating cost of a vessel, this can be a significant extra cost. Historically, the response involved taking the ship out of water and scraping the hull. Because of the inconvenience and cost of this, various treatments developed, mostly involving the application copper sheeting or copper-based paints. In the 1960s, organic compounds of tin were developed, which were shown to be very effective when applied as paints to ships' hulls, with the tin compounds leaching into the water. The most effective was tributyl tin (TBT) (Santillo et al., 2001). By the late 1970s they were commonly used on commercial and recreational craft from developed countries. In the late 1970s and early 1980s, oyster (*Crassostrea gigas*) harvests in Arcachon Bay, France, failed. Subsequent research identified that TBT was the cause. At the same time, research in the United Kingdom showed that TBT was an endocrine disruptor in a marine whelk species (*Nucella lapillus*) causing

masculinisation (imposex) in females and widespread population decline. Bans on TBT on boats less than 25 metres long first started in the 1980s. In 1990, the IMO recommended that Governments should eliminate the use of antifouling paints containing TBT. This resolution was intended as a temporary restriction until the IMO could implement a more far-reaching measure. The International Convention on the Control of Harmful Anti-fouling Systems on Ships was adopted in 2001. This prohibited the use of organotin compounds as biocides in anti-fouling paints. This Convention came into force in 2008, and has been ratified by 69 States, representing 84.41 per cent of the gross tonnage of the world's merchant fleet (IMO, 2014j). There are the typical enforcement problems with this Convention. There is also a legacy problem in that dry docks and port berths may have deposits of old anti-fouling paint in the sediments on their bottoms. As and when this sediment has to be removed, disposal into the sea will be a problem, since it may remobilise the TBT remains.

6.8 Wrecks

The seabed is littered with the remains of shipwrecks, some dating as far back as the second millennium BCE. The main impact on the marine environment comes from more recent wrecks, since the introduction of fuel oil as the source of the motive force. Such more recent wrecks will usually contain bunkers, which will eventually leak, and become a new source of oil pollution of the sea. Likewise, cargoes may present dangers of pollution from oil or hazardous substances. There are a number of other problems: first, and depending on its location, a wreck may constitute a hazard to navigation. Secondly, substantial costs are likely to be involved in the location, marking and removal of hazardous wrecks. The Nairobi International Convention on the Removal of Wrecks, 2007, aims to resolve these and related issues. It sets out rules on how to determine whether a wreck presents a hazard, makes the owner of the ship liable for costs of removal and marking (subject to the rules on limits for liability for marine damage) and requires compulsory insurance to cover such costs for ships registered in, or other ships entering or leaving, States parties to the Convention. The Convention will enter into force in 2015. So far there are 12 contracting States, representing 13.84 per cent of the gross tonnage of the world's merchant fleet (Bray et al, 2007; IMO, 2014).

6.9 Invasive species

Invasive non-native species are a major and growing cause of biodiversity loss. They can cause health problems, damage infrastructure and facilities, disrupt capture fisheries and aquaculture and destroy habitats and ecosystems. In some cases, the transport by shipping is clear. For example, in 1991 and 1992, the bacterium that causes cholera (*Vibrio cholerae*) was found in ballast water from five cargo ships in ports in the United States along the Gulf of Mexico (McCarthy, 1994). In other cases, it can be inferred. There are two main ways in which ocean shipping transports invasive species: as attachments to hulls, and in ballast water that has been taken up and discharged by ballasting operations during the stages of a voyage.

So far, the International Union for the Conservation of Nature (IUCN) has identified 84 non-native invasive marine species which have appeared in marine habitats outside their natural distribution (GISD, 2014). A separate review (Molnar et al, 2008), using a wide range of reports (not all peer-reviewed), identified 329 marine invasive species, with at least one species documented in 194 marine eco-regions (84 per cent of the 232 marine eco-regions worldwide used in the review). The main groups of species listed were crustaceans (59 species), molluscs (54), algae (46), fish (38), annelids (worms) (31), plants (19), and cnidarians (sea-anemones, jellyfish, etc) (17). The review found 205 species with detailed shipping pathway information. Of these, 39 per cent are thought to have been, or likely to have been, transported only by fouling of ships' hulls, 31 per cent in ballast water, and 31 per cent by one or other of these routes. Some regional reviews have also identified high numbers of non-native species: for example, 120 in the Baltic Sea and over 300 in the Mediterranean (Zaiko et al., 2011).

Another review of reports of cases of invasive species (Williams et al, 2008) found several estimates of economic damage in the range of millions of US dollars to the localities where the invasive species had been studied. Figure 13 shows a summary of the scale of transfers between origins and destinations (Nelleman, 2008).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 13. Major pathways and origins of invasive species infestations in the marine environment. Source: Nelleman et al, 2008.

The scale of these problems led to international efforts to address the pathways through ships' ballast water and biofouling. In 1991 the IMO Marine Environment Protection Committee (MEPC) adopted guidelines for preventing the introduction of unwanted organisms and pathogens from ships' ballast water and sediment discharges. In 1993, the IMO Assembly followed this up by asking the MEPC to review the guidelines with a view to developing an international convention and, in

1997 invited States to use the guidelines to address this problem. More than fourteen years of negotiations were needed to develop the 2004 International Convention for the Control and Management of Ships' Ballast Water and Sediments (the BWM Convention). The Convention will require all ships to implement a Ballast Water and Sediments Management Plan. All ships will have to carry a Ballast Water Record Book and will be required to carry out ballast water management procedures to a given standard. States parties can take additional measures subject to specified criteria and guidelines. The MEPC completed the work of developing the guidelines in 2008. The basic requirements of the BWM Convention are the ballast water exchange standard and the ballast water performance standard. Ships performing ballast water exchange must do so with an efficiency of 95 per cent volumetric exchange of ballast water. Ships using a ballast water management system must meet a performance standard based on agreed numbers of organisms per unit of volume. The BWM Convention requires acceptance by 30 States representing 35 per cent of the gross tonnage of the world merchant fleet before it can enter into force. By November 2014, 43 States representing 32.54 per cent of the tonnage of the world merchant fleet had accepted it. It therefore seems likely to enter into force fairly soon (IMO, 2014j, IMO, 2014k).

The Guidelines for the control and management of ships' biofouling to minimize the transfer of invasive aquatic species (Biofouling Guidelines) were adopted in July 2011. The Biofouling Guidelines are intended to provide a globally consistent approach to the management of aquatic organisms on ships' hulls, and represent a decisive step towards reducing the transfer of invasive aquatic species by ships. In addition, biofouling management can improve a ship's hydrodynamic performance and, therefore, be an effective tool in enhancing energy efficiency and reducing air emissions. In October 2012, the IMO supplemented the Biofouling Guidelines with Guidance for minimizing the transfer of invasive aquatic species as biofouling (hull fouling) for recreational craft, less than 24 metres in length.

6.10 Noise

The marine environment is subject to a wide array of human-made noise from activities such as commercial shipping, oil and gas exploration and the use of various types of sonar. This human activity is an important component of oceanic background noise and can dominate in coastal waters and shallow seas. Long-term measurements of ocean ambient sound indicate that low frequency anthropogenic noise has been increased, primarily due to commercial shipping, both as a result of increases in the amount of shipping and as a result of developments in vessel design (particularly of propellers), which have not prioritised noise reduction. Shipping noise is centred in the 20 to 200 Hz frequency band. Noise at these low frequencies propagates efficiently in the sea, and can therefore affect marine biota over long distances. Baleen whales use the same frequency band for some of their communication signals. A variety of other marine animals are known to be affected by anthropogenic noise in the ocean. Negative impacts for least 55 marine species (cetaceans, fish, marine turtles and invertebrates) have been reported in scientific studies. The effects can range from mild behavioural responses to complete avoidance of the affected area. A 1993 study concluded that "low-frequency noise

levels increased by more than 10 dB in many parts of the world between 1950 and 1975,” corresponding to about 0.55 dB per year. A 2002 study indicated an increase of approximately 10 dB over 33 years (about 0.3 dB per year). Subsequent measurements up to 2007 confirmed this but suggest that, in some places at least, the subsequent rate of increase has slowed or stopped. It is generally agreed that anthropogenic noise can be an important stressor for marine life and is widely regarded as a global issue that needs addressing (NRC, 2003, Tyack 2008, Andrew et al., 2011, UNEP 2012).

6.11 Enforcement

The effectiveness of the internationally agreed rules to protect the marine environment from the adverse effects of shipping depends to a large extent on the extent of enforcement. There are important economic aspects to the ways in which this enforcement is carried out. The United Nations Convention on the Law of the Sea (UNCLOS) gives flag States, coastal States and port States a range of powers to enforce internationally agreed rules and standards. For port-State control, ports are often competing with their neighbours. This makes it economically important for the port-States to be certain that their enforcement actions are not disadvantaging the competitive positions of their ports. Port-State inspection is, therefore, carried out in many regions in accordance with memorandums of understanding between the States of the region. Memorandums of understanding (MoU) have been set up covering most ocean regions: Europe and the north Atlantic (Paris MoU – 27 States); Asia and the Pacific (Tokyo MoU – 19 States and territories); Latin America (Acuerdo de Viña del Mar – 15 States); Caribbean (Caribbean MoU – 14 States and territories); West and Central Africa (Abuja MoU – 14 States); the Black Sea region (Black Sea MoU – 6 States); the Mediterranean (Mediterranean MoU – 10 States); the Indian Ocean (Indian Ocean MoU – 17 States); and the Riyadh MoU (part of the Persian Gulf – 6 States). These port-State inspection organizations publish details of the results of their inspections, which can have economic significance for ship operators, since cargo consignors tend not to want to use shipping lines which have a poor performance.

Attention to the implementation of international rules and standards demands qualified inspectors to undertake the various controls. Most port-State control inspectors have qualified through service on board ships. A demand for more inspectors may well be in competition for the same pool of staff, which (as noted above) may be itself inadequate for the primary task of crewing ships if the steady growth in shipping activity continues.

7. Significant environmental, economic and/or social aspects in relation to shipping (including information gaps and capacity-building gaps)

This section summarises the most significant elements from the foregoing sections.

Shipping is a vital component of the world economy. As the world economy has become increasingly globalized, the role of shipping has become more important. The economic crisis of 2008 produced some reductions in the levels of shipping, but those have recovered and growth has resumed, though not at quite the previous rate. Shipping has provided means for many States rich in primary resources to export those resources, and for many States that are developing their economies to export their products. Gradually, the balance of the tonnage of goods loaded in developed and in developing countries is becoming more equal. Increasing human wealth will therefore continue to be a driver in increasing the scale of shipping that is needed.

The pressures that shipping imposes on the environment are significant and widespread. In total they represent a significant contribution to the cumulative pressures that humans are imposing on the rest of the marine environment, and that is affecting the harvest from the sea and the maintenance of biodiversity. The pressures are particularly concentrated at certain choke points where shipping routes crowd through narrow sea-passages, e.g., straits or canals. Those pressures are also diverse – some result from shipping disasters, and some are chronic (oil discharges, loss of containers, garbage, sewage, air pollution, noise, anti-fouling treatments of hulls, transport of invasive species). Over the past 40 years, global rules and standards have been developed to regulate most of these. Steps are now being taken to make the enforcement of these rules and standards more uniform throughout the world.

However, there is still a significant number of States and territories that have not been able to become parties to the various international conventions and agreements that embody these rules and standards. These States and territories need to build the capacities which will enable them to commit themselves to implementing these rules and standards. The necessary skilled staff and facilities will also be needed to implement those rules and standards. Although the IMO and other international organizations have programmes to support such capacity-building, there are still gaps.

There are signs that, at least in some regions, the implementation of these global rules and standards and other local measures is helping to improve the status of the marine environment. The overall number of ships lost at sea has continued to decrease, and in some areas oil discharges seem to have declined. But there is a continuing growth in shipping. Unless the everyday pressures generated by shipping can be steadily reduced, the continuing growth in shipping will lead to increased pressure on the ocean. Even if all ships can meet the standards of the best, increased numbers and tonnage of shipping will eventually increase the pressures on the environment.

However, in many parts of the world, coastal States do not have adequate plans to respond to maritime casualties. Such plans often require substantial investment in plant and equipment and the training of personnel. The resources for such investment are sometimes lacking.

From the social aspect of shipping, it is noteworthy that Africa and South America are underrepresented in the labour force. The divergence between the genders is

even more noteworthy, with only an estimated 2 per cent of the maritime labour force being female. It is also noteworthy that there are significant differences in the levels of pay of ships' officers depending on their national origin.

Current reports suggest that there is an adequate labour force to provide the crews of the current levels of shipping. If (as is expected) the amount of world shipping continues to grow, crew shortages may develop. Skilled staff will also be needed to enforce the internationally agreed rules and standards, and this demand may be competing with those for ships' crews.

The entry into force of the 2006 Maritime Labour Convention in 2013 was a major step forward in ensuring the provision of decent working and living conditions for seafarers. Capacities will need to be built for its enforcement.

There is a gap in the information available on deaths of, and injuries to, seafarers. This information is essential for ensuring that they have decent working conditions and for reducing the numbers of seafarers' deaths and injuries. Likewise, the information available on the deaths of, and injuries to, passengers does not appear to be adequate to support policy development in this field, although such information as is available does not suggest that this is a major problem.

Chapter 18. Ports

Group of Experts: Alan Simcock (Lead member)

1. Introduction

Ports are the nodes of the world's maritime transport system. Every voyage of a ship must begin and end at a port. Their size and distribution will therefore both reflect and contribute to the pattern of maritime transport described in Chapter 17 (Shipping). Since the maritime transport system is part of a much larger global transport system, including road, rail, river and canal transport and the interchanges between all the modes, the factors that determine the location and growth (and decline) of ports are manifold, and go well beyond an assessment of the marine environment. These non-marine factors (such as land and river transport connections, location of population and industry and size of domestic markets) will determine, to a large extent, the development of ports and, therefore, the way in which they affect the marine environment. Nodes, however, can become bottlenecks, restricting the free flow of trade. Before the economic crisis of 2008, there were fears that port capacity could limit the development of world trade (UNCTAD, 2008). That problem has receded with the widespread economic slow-down, but could easily re-appear. This would lead to increased pressure for new port developments.

Just as containerization has transformed general cargo shipping from the mid-20th century onwards, so it has also transformed the nature of the ports that container ships use. In the past, ports relied on large numbers of relatively unskilled dockworkers to do the physical work of loading and unloading general cargo, often on a basis of casual labour, with no security of regular work. Containerization and parallel improvements in the handling of bulk cargoes have transformed this situation. Ports now require smaller numbers of much more skilled workers, and even more investment in handling equipment.

2. Scale and magnitude of port activity

Ports can be classified in several different ways. Some ports are dedicated to a single function (such as the handling of oil). Others are general, handling a variety of trades. Some are private, used for the traffic of one trader (or a small number of traders). Others are general, open to shipping in general. Some are designed for bulk traffic, both dry and liquid. Others are for general cargo, which today usually implies containers. And some ports are a mix of these various categories. (This chapter does not deal with marinas and other harbours for recreational vessels: those are covered in Chapter 27 (Tourism and recreation)).

Dry bulk traffic covers the five major bulk trades (iron ore, coal, grain, bauxite/alumina and phosphate rock), together amounting to 2,786 million tons in 2013, and the minor bulk trades (soymeal, oilseed/meal, rice, fertilizers, metals, minerals, steel and forest products), together amounting to 2,300 million tons in 2013. The main tanker bulk traffic (crude oil, petroleum products, and liquefied natural gas) amounted to 2,904 million tons. There is also a much smaller market in bulk tanker carriage of chemicals (UNCTAD, 2013).

The location of ports for handling bulk traffic is usually determined by the location of their sources of supply and demand. A new oil field may well demand the creation of a completely new port, as happened with the creation of Sullom Voe in the Shetland Islands in the United Kingdom in the 1970s at the beginning of the exploitation of North Sea oil and gas (Zetland, 1974). A large iron and steel works may be linked to the creation of new port facilities to receive imports of iron ore, as is happening at Zhanjiang in China (Baosteel, 2008). As a result of geographical or historical factors, some ports for bulk traffic can have awkward conjunctions in their location. For example, in Australia, the coal mines in Queensland need more port outlets, but the likely locations for ports are near the Great Barrier Reef, which gives rise to difficult decisions (Saturday Paper, 2014). In the United Kingdom, the Milford Haven oil terminal grew up gradually over many years in the safe natural harbour of Milford Haven. It is currently the United Kingdom's largest oil port, with a throughput of hydrocarbons in bulk of 40 million tons a year. However, the United Kingdom's first marine nature reserve, Skomer Island, is near the mouth of the harbour (Donaldson, 1994; DfT, 2014).

The containerization of general cargo, the consequent reduction of trans-shipment costs and the use of ever larger ships has changed the nature of the demand for general cargo ports over the past half century. Instead of relatively small ships moving directly from the origin to the destination of the cargo, thus minimising the then expensive trans-shipment costs, there is now a hierarchy of ports, with cargoes passing through entrepôts where they are trans-shipped. Rotterdam, in the Netherlands, is a good example of such an entrepôt, with many other North Sea ports receiving the trans-shipped goods. (Haralambides, 2002). The proportion of worldwide total container movements that involve trans-shipment is gradually increasing (25 per cent in 2000: 28 per cent in 2012 (Notteboom et al., 2014)). The nature of this hierarchy shows that there is a major equatorial shipping route linking major ports, with supporting north-south and transoceanic routes. The "trans-shipment markets" identified are the zones within which ports are competing with each other for the long-haul business, which will be trans-shipped for delivery to its final destination by ship, road or rail (Rodrigue, 2010, figure 13). Containerized general cargo amounted to 1.6 billion tons in 2012 – an estimated 52 per cent of global seaborne trade in terms of value (UNCTAD, 2013). The imbalances in containerized exports and imports, the liberalization of trade regulation and transit facilitation are resulting in a growth of containerization of trades previously handled as bulk. Since more containerized imports arrive in some ports than there are exports from those ports to fill the containers, the shipping costs for the return or onward journey using the surplus containers are low. This acts as a form of subsidy on the use of such containers, and thus attracts business from the bulk trades. For

example, between 2008, when grain trading was deregulated in Australia, and 2013, the country's containerized wheat export shipments increased tenfold (UNCTAD, 2013).

The world's busiest container port is Shanghai in China, with 33.62 million TEU movements in 2013. Table 1 sets out the numbers of container movements for each of the further five container ports with the heaviest traffic. Outside these areas, there are of course other very large and busy ports – for example (with millions of TEU movements in 2013): Los Angeles, California, USA (7.87), Long Beach, California, USA (6.73) and New York/New Jersey, USA (5.47). In total, the world's 50 busiest container ports in 2013 were spread as follows:

- (a) Twenty-four in the west Pacific (ten in China; three in Japan; two each in Indonesia and Malaysia; and one each in Hong Kong, China, the Philippines, the Republic of Korea, Singapore, Taiwan Province of China, Thailand and Viet Nam);
- (b) Four in the eastern Pacific (two in the United States of America and one each in Canada and Panama);
- (c) Seven in the Indian Ocean (two in the United Arab Emirates and one each in India, Oman, Saudi Arabia, Sri Lanka and South Africa);
- (d) Eleven in the eastern Atlantic and adjacent seas (two each in Germany and Spain and one each in Belgium, Egypt, Italy, Malta, the Netherlands, Turkey and the United Kingdom); and
- (e) Four in the western Atlantic (two in the United States and one each in Brazil and Panama) (WSC, 2014).

Table 1. The world's busiest container ports in the five major transshipment markets – 2013.

PORT	COUNTRY	TEU MOVEMENTS 2013 (MILLIONS)
<i>World's busiest container port</i>		
Shanghai	China	33.62
<i>North-East Asia</i>		
Busan	Republic of Korea	17.69
Qingdao	China	15.52
Tianjin	China	13.01
Dalian	China	10.86
Keihin ports (Kawasaki, Tokyo, Yokohama)	Japan	8.37
<i>Central East Asia</i>		
Hong Kong	China	22.35
Ningbo-Zhoushan	China	17.33

PORT	COUNTRY	TEU MOVEMENTS 2013 (MILLIONS)
Guangzhou	China	15.31
Kaohsiung	Taiwan Province of China	9.94
Xiamen (<i>formerly known as Amoy</i>)	China	8.01
<i>South-East Asia</i>		
Singapore	Singapore	32.60
Port Kelang	Malaysia	10.35
Tanjung Pelepas	Malaysia	7.63
Tanjung Priok	Indonesia	6.59
Laem Chang	Thailand	6.04
<i>Middle East and Indian Sub-Continent</i>		
Jebel Ali, Dubai	United Arab Emirates	13.64
Jeddah	Saudi Arabia	4.56
Colombo	Sri Lanka	4.31
Jawaharlal Nehru Port (<i>near Mumbai</i>)	India	4.12

3. Socioeconomic aspects of ports

The arrival of containerization of general cargo and the increased mechanization of the handling of bulk cargoes has transformed employment in the dock industry. It has reduced the amount of human physical effort, increased the amount of work done by machinery and reduced substantially the risks of death and injury to dockworkers. As a result, it has also decreased substantially the number of dockworkers required. Negotiations over the change have therefore often been difficult, particularly in the early years of the introduction of containerization. The change has now spread worldwide, and few ports still rely on the handling of general cargo parcel by parcel. However, statistics at global level on the effects of the change are not available (ILO, 2002).

The economic effects on port operations have been no less thoroughgoing. Three main strands of change have been noticeable:

- (a) As the economics of ship operation have created pressures for ever larger ships, both for bulk carriage of cargoes and for containers (see Chapter 17 – Shipping), so pressures have developed on ports to create the facilities to handle these larger ships. These pressures have required ports to invest in deeper-water facilities, bigger cranes and navigational improvements in order to accommodate the larger ships. These have all required substantial investment;
- (b) The general liberalization of the terms of world trade and consequent growth in shipping have led to ports being placed more and more in competition with each other. Coupled with the development of hierarchies among ports in container traffic, where large ships are used for long voyages between hubs, and the containers are then re-distributed in smaller ships on shorter voyages, this has led to the need for ports to work together to offer shipping lines and (through them) shippers a comprehensive service. At the same time, in many parts of the world there has been a substantial transfer of the operation of ports (and, in some cases, the ownership of the land and equipment of the ports) from the public sector to the private sector. The combined effect of these various trends has been the creation of large commercial

groupings of ports around the world. Some of these groupings have sprung from a successful operator of a specific port: the Port of Singapore Authority is the leading example of this type of development, with interests in 25 terminals around the world. Others have sprung from major shipping lines: APM Terminals is controlled by the major Danish maritime shipping enterprise A P Møller Mærsk, and has interests in 71 ports around the world. Another starting point for assembling a chain of ports has been sovereign wealth funds: for example, Dubai Ports World has interests in more than 65 terminals around the world. The final major type of port grouping is represented by Hutchison Port Holdings, part of the Hutchison Whampoa group, which developed from a dock-operating company in Hong Kong; it has interests in 52 ports. These four groups alone therefore have major interests in over 200 ports worldwide. There are a number of smaller similar chains, largely with a regional focus: these include SSA Marine in North America and Eurogate in Europe (privately-owned companies), Hanjin and Evergreen (linked to ocean carriers) and Ports America (owned by financial holding companies) (Rodrigue, 2010). In many countries, however, ports remain under the control of government agencies or chambers of commerce, or are independent public agencies;

- (c) The larger sizes of ships have intensified the pressures to handle them in port in the shortest possible time. Ship owners want their capital to be earning money on voyages as much as possible, and therefore dislike the ships being tied up in port – or, even more, waiting at sea until they can get into a port berth. This, coupled with the more stringent requirements arising from growing trade volumes, global value chains, increasingly time-sensitive trade and lean supply chains, has led to increased competition between ports, intensified the pressure on ports to service ships and handle their cargo the shortest possible time and produced an intense focus on the efficiency of ports.

One important aspect of the economics of port operation is security against theft and disruption. In 2002, the International Maritime Organization adopted a new chapter in the International Convention on the Safety of Life at Sea (SOLAS) and promulgated the International Ship and Port Facility Security (ISPS) Code to improve ship and port security. This is supported by the joint IMO/International Labour Organization code of practice on security in ports. These instruments provide a consistent baseline worldwide, by clarifying the desirable division of responsibilities for issues such as access control, cargo and ship stores control, and facility monitoring to prevent unauthorized persons and materials from gaining access to the port. The ISPS Code came into force in 2004. Gaps still remain in some areas to implement these arrangements (IMO, 2015).

3.1 Efficiency

In 2012, the Organization for Economic Cooperation and Development (OECD) published a study on port efficiency that it had commissioned (Merk and Dang,

2012). This study sought to compare the efficiency of ports around the world, in the different fields of containers, grain, iron ore and oil, looking at proxies for the inputs of each type of port to the handling of cargoes and the throughput achieved, measured in terms of the dead-weight tonnage (dwt) passing through the port. For container ports, the study concluded that, with the exception of Rotterdam in the Netherlands, the most efficient ports were mostly located in Asia. The most efficient container ports were not necessarily the largest ports. Among most efficient ports are some of the largest global container ports (for example, Hong Kong, China; Singapore; and Shenzhen and Shanghai in China) (handling from 20 to 60 million dwt per port per month), but also medium to small size ports. For bulk oil ports, it concluded that, with the exception of Galveston, Texas, in the United States and (again) Rotterdam in the Netherlands, the most efficient oil ports are mostly located in the ROPME/RECOFI area¹, but not all ports in that region are operating efficiently. In this case, size does matter: the most efficient terminals are largely those with the largest throughput. In the case of bulk coal ports, the study concluded that a group of coal ports in Australia and China were clearly more efficient than nearly all the rest of the sample, although Velsen/IJmuiden in the Netherlands, Banjamarsin in India and Puerto Bolivar in Colombia were equally good. In the case of iron-ore and grain ports, the study concluded that, in both cases, larger ports were more efficient. It also concluded that, for grain ports, the least efficient terminals tend to be found in developed OECD countries. It should be noted, however, that the methodology of the study inevitably tends to rate a port as less efficient if, for historical reasons, its past investment has provided more facilities than is required for current levels of traffic.

It is instructive to compare the results of this study with the ranking published by the World Bank of the quality of the infrastructure of ports in different countries. This is based on a questionnaire to members of the World Economic Forum, which has been running for some 30 years. Recent rounds of the survey have included around 13,000 respondents from around 130 countries. Although subjective, the views expressed are likely to influence trade and investment decisions. The classification runs from 7 (efficient by international standards) to 1 (extremely underdeveloped). In 2012, the best-regarded ports were those in the Netherlands and Singapore, both being ranked at 6.8. Table 2 shows the countries whose ports are regarded as being in categories 6 and 5.

¹ Regional Organization for the Protection of the Marine Environment (ROPME) Members: Bahrain, Iran (Islamic Republic of), Iraq, Kuwait, Oman, Qatar, Saudi Arabia, and the United Arab Emirates. Table 2. Quality of Port Infrastructure

Category 6:	Bahrain, Belgium, Finland ↓, Germany ↓, Hong Kong, China ↓, Iceland, Netherlands↑, Panama↑, Singapore, United Arab Emirates↑.
Category 5:	Australia↑, Barbados↑, Canada↑, Chile ↓, Cyprus ↓, Denmark ↓, Estonia, France ↓, Ireland↑, Jamaica ↓, Japan, Lithuania↑, Malaysia, Malta↑, Namibia, New Zealand, Norway ↓, Oman↑, Portugal, Qatar↑, Republic of Korea↑, Saudi Arabia↑, Seychelles, Slovenia, Spain↑, Suriname↑, Sweden, United Kingdom↑, United States of America↓.
<i>Those countries marked ↑ had a higher ranking, and those marked ↓ a lower ranking, in 2012 than in 2009.</i>	

Source: World Bank, 2012.

The message from both these sources is that well-equipped and well-managed ports can be found in all parts of the world – as can less well-equipped and less well-managed ports. Given the importance of port effectiveness for world trade, improving capacities both in the planning and construction of ports and in their management could have beneficial effects. The facilities for the provision of accurate and timely navigational information to ships using ports is an important element of the equipment for the efficiency and effectiveness of ports, particularly in view of the adverse impacts on the marine environment from ships' casualties.

3.2 Charging

Charges for the use of ports raise some important issues. First, there is how to charge for services rendered. The normal recommendation of economists is that charges should only be levied if a service is delivered: economic theory argues against cross-subsidization between services. In the case of ports, however, there is a strong argument that ships' operators should not normally be able to opt out of paying for port waste-reception facilities. If they can opt out, they have an economic incentive not to pay for the disposal of their waste and to retain it on board until they can throw it into the sea, thereby aggravating the problem of marine debris. The European Union has adopted legislation requiring its ports generally to apply the rule of no separate charge for waste-reception facilities (EU, 2000). Whatever form a charge takes, it is important that the money is applied towards the environmentally sustainable disposal of the waste (see Chapter 17).

Secondly, there is the question of how far the port operator should be expected to cover the costs of providing the port. This applies both landward and seaward. In the landward direction, it is important that ports have adequate road, rail or inland-waterway connections to the port's hinterland. Otherwise, any efficiency gains in the port are cancelled out by the inefficiencies of transport into the hinterland. This can be very important for the economic viability of the port, since competitors may be able to offer a better deal overall. There is then the question of how far the costs of such adequate connections should be financed from the port charges rather than from government revenues or charges on the users of the connections. Decisions on this can only be taken for each port in the light of the policies of its possible competitors.

A parallel situation arises in the seaward direction, where there is often a need for dredging to maintain the access channels. In some countries, port operators have pressed governments to fund all or part of the costs of deepening and widening navigation channels, since they find themselves faced with competition from neighbouring ports which have natural deep-water harbours.

3.3 Landlocked countries

Because of the large proportion of international trade that is transported by sea (see Chapter 17 – Shipping), landlocked countries have particular difficulties from their lack of seaports. The 31 landlocked developing countries (LLDCs), 16 of which are among the least-developed countries (LDCs), face serious challenges to their growth and development, derived in substantial part from their problems in accessing maritime transport. In general, LLDCs face a 45 per cent higher ratio of freight charges to total value of exports and imports than the average of the developing countries through which their exports and imports must transit (LLDCs, 2011). This is a further aspect of capacity-building gaps to improve the efficiency of ports in the transit countries.

4. Impacts on the marine environment from port operations

The direct impacts on the marine ecosystem from ports take three main forms: first, the concentration of shipping, secondly, the demand for coastal space and, thirdly, the need for deep water. Chapter 26 (Land/sea interaction) considers other impacts that result from the transformations caused to the shoreline by the creation of ports and harbours.

4.1 Concentration of shipping

The concentration of shipping is generally an inevitable result of a successful port. Where a port takes part in a general market for port services, the more successful the port is, the greater are the size and number of the ships that it will serve. This means that discharges and emissions from the ships will be higher and have a more concentrated effect on the marine environment around the port. Even if each individual ship maintains the best practicable level of control over its impact, increasing levels of shipping to and from a port will result in increasing overall impacts, unless the best practicable means of control can be improved. Chapter 17 (Shipping) discusses the impacts from ships, particularly chronic oil discharges, garbage, sewage, anti-fouling treatments, air pollution and noise. All these can be controlled, but that control is more in the hands of the ships' masters and owners than in the hands of the port authority. Port authorities and governments can, however, influence these aspects through their charging policies and their enforcement of international standards. Because many ports have competition from their neighbours, effective action is likely to require agreement at a regional level.

For this reason, the regional memorandums of understanding on port-state control have an important role in managing the impact of ports on the marine environment. Other effects, such as the turbidity caused by ships' propellers disturbing sediments, are more site-specific, and can to some extent be controlled by port navigation rules. Nevertheless, such turbidity (and the subsequent re-settlement of sediment) can have adverse impacts on sensitive habitats, such as corals and sea-grass beds (Jones, 2011).

In all these cases, port authorities and port operators have some important roles to play in managing the impacts of ships. Adequate waste-reception (and especially for cruise ships) sewage-reception facilities are important for preventing marine debris and eutrophication problems. Likewise, adequate land-based electricity supplies ("cold ironing") for ships that need to run equipment while in port (especially refrigerator ships) are essential to reduce air pollution, since otherwise they must run the ships' generators while they are in port.

The IMO has set up a system whereby ships' operators can report inadequacies in port reception facilities. This can be found at <https://gisis.imo.org/Public/PRF/ReportedCases.aspx>. It enables ships to report the problems that they have encountered and port authorities to offer (if they wish) explanations for such shortcomings and information on steps that are being taken to resolve them. Since the beginning of 2005, 279 inadequacies have been reported. States have responded in only 76 cases (although there are several where the port State had not been notified).

4.2 Coastal space

The demand for coastal space in ports is tied up with the growth in container traffic. Space is needed next to the berths for the containers to be off-loaded. In step with the development of container traffic, there has therefore been a substantial growth in the land needed for container ports. Rodrigue (2010, in figure 3) shows the current scale of coastal space occupied by container ports. These are particularly demanding of coastal space because they have to have level space to hold the containers until they can be forwarded into the hinterland: bulk cargoes are normally transferred directly to less space-demanding storage.

Further growth in port throughput will inevitably result in further demand for container storage space at ports. This demand is rarely going to be able to be met from land that is not part of the coast, because around most ports this land is already committed to other forms of development (such as housing or industry) which are also essential for the growth of the port. As discussed in Chapter 26 (Land/sea physical interaction), this demand has therefore often been met by land reclamation – often from mangroves or salt marshes (for the pressures on which see Chapters 48 (Mangroves) and 49 (Salt marshes)). These pressures are likely to continue. There is therefore a need for further investigation on how ports can handle increasing numbers of containers without increasing their demands for coastal space.

4.3 *Deep water*

The third pressure generated by ports is for deep water access channels. This normally means that dredging is used to deepen and widen the channels through sedimentary deposits, although in some cases it can involve blasting a channel through rock or (in rare cases) through coral reefs. Lack of available dredging services may constrain what can be done to provide deep-water access, and thus affect a port's competitiveness. Dredging can also affect the hydrodynamics of an estuary with consequences for adjacent beaches and seabed stability over broad areas (Pattiaratchi and Harris, 2002). Where dredging is used on areas not previously dredged, the impact on the bottom-dwelling flora and fauna may have to be balanced against the advantages of the improved access for ships. Where blasting is the only method available for providing the necessary deep-water access, the judgement is even more difficult, because it may mean the destruction of ecosystems based on a rocky or coral reef substrate. The quantities of material to be lifted by dredging can be immense (see Chapter 24 – Disposal of solid waste) and difficult judgements may have to be made about where the disposal should take place (Brodie, 2014). Where the dredging has to be done in the estuary of a river with a history of heavy industrial development, even more difficult judgements may have to be made about whether the dredged material should be re-introduced to the sea at all, given the risk of remobilising hazardous substances that have been sequestered in the sediments (see again Chapter 24 – Disposal of solid waste). The effects of elevated turbidity from dredging operations can have negative impacts on seagrasses (Erftemeijer and Lewis, 2006) and other benthic communities (Newell et al., 1998).

5. Integrating environmental, social and economic aspects

Port development is a special case of the issues raised by integrated coastal-zone management. Economically, it is always of high importance for the coastal State (and for the landlocked States that depend on transit through the coastal State). The pressures from ports will grow in step with the growth in international trade between coastal States, except to the extent that it is possible to improve the performance of ships and port installations. Port development also focuses together a large bundle of difficult trade-offs: increased benefits from trade, increased impacts from shipping, increased demand for coastal space and increased demand for creating or maintaining access channels. The growth in port throughput will therefore nearly always be accompanied by increased pressures on the environment. Social effects will be less pressing, because the changes needed as a result of the changeover to containerization are now largely in the past, and the social adjustments have been made. They will, however, need to be taken into consideration for those ports that have not yet joined the global consensus on containerization. A careful review of the different interests will therefore always be essential if port development is to be sustainable.

6. Information and capacity-building gaps

6.1 Knowledge gaps

Since ports constitute a significant economic sector, much information is available about them and their operations. What seems to be lacking is systematic information bringing together worldwide the operational aspects of ports and their impacts on the local marine environment, and their contribution to economic activity.

6.2 Capacity-building

Since the operation of a port can significantly affect both the successful operation of ships and the economic performance of the countries it serves, some ports need capacity-building in the operational skills needed for successful port operation. This is particularly important for ports that are serving as transit ports for landlocked countries, since the landlocked countries rely on the quality of port management in the transit country or countries, and are not in a position to insist on improvements.

It is important to develop (and then maintain) the capacities of port States both to implement the International Ship and Port Facility Security Code and related instruments and to carry out port-State inspections of ships, so as to enforce the internationally agreed standards for ships. Capacities to provide ships with good, real-time information on local navigational issues are also important.

Since the delivery to shore of garbage from ships in general is an important element of combating marine debris problems, ports which do not have adequate and easily used port waste-reception facilities need to have their capacities in this field improved. The same applies to sewage-reception facilities for cruise ships in relation to eutrophication problems.

Where ports which need dredging to maintain or improve navigation adjoin bays, rivers or estuaries with a history of industrial discharges, there is a need for them to have the capacity to examine the dredged material to decide whether it can safely be re-deposited in the sea.

Chapter 19. Submarine Cables and Pipelines

Group of Experts: Alan Simcock (Lead member)

1. Submarine communications cables

1.1 *Introduction to submarine communications cables*

In the last 25 years, submarine cables have become a dominant element in the world's economy. It is not too much to say that, without them, it is hard to see how the present world economy could function. The Internet is essential to nearly all forms of international trade: 95 per cent of intercontinental, and a large proportion of other international, internet traffic travels by means of submarine cables. This is particularly significant in the financial sphere: for example, the SWIFT (Society for Worldwide Interbank Financial Telecommunication) system was transmitting financial data between 208 countries via submarine cables in 2010. As long ago as 2004, up to 7.4 trillion United States dollars were transferred or traded on a daily basis by cables (Rauscher, 2010). The last segment of international internet traffic that depended mainly on satellite communications was along the East coast of Africa: that was transferred to submarine cable with the opening of three submarine cables along the East coast of Africa in 2009-2012 (Terabit, 2014). Submarine cables have advantages over satellite links in reliability, signal speed, capacity and cost: the average unit cost per Mb/s capacity based on 2008 prices was 740,000 dollars for satellite transmission, but only 14,500 dollars for submarine cable transmission (Detecon, 2013).

Submarine telegraph traffic by cable began between England and France in 1850-1851. The first long-term successful transatlantic cable was laid between Newfoundland, Canada, and Ireland in 1866. The early cables consisted of copper wire insulated by gutta percha, and protected by an armoured outer casing. The crucial development that enabled the modern systems was the development of fibre-optic cables: glass fibres conveying signals by light rather than electric current. The first submarine fibre-optic cable was laid in 1986 between England and Belgium; the first transatlantic fibre-optic cable was laid in 1988 between France, the United Kingdom and the United States. It was just at that time that the Internet was beginning to take shape, and the development of the global fibre-optic network and the Internet proceeded hand in hand. The modern Internet would not have been possible without the vastly greater communications possibilities offered by fibre-optic cables (Carter et al., 2009). Over the 25 years from 1988 to 2013, an average of 2,250 million dollars a year was invested in laying 50,000 kilometres of cable a year. However, this includes a great burst in the development of the global fibre-optic network that took place in 2000-2002, in conjunction with the massive interest in investment in companies based on the Internet: the so-called dot-com bubble. At the peak, in 2001, 12,000 million dollars were invested in submarine cables in one year. After the dot-com bubble burst in 2002, the cable-laying industry contracted severely, but by 2008 had recovered to what has since been a steady growth

(Terabit, 2014). Figures 1 and 2 show diagrammatically the transatlantic and transpacific submarine communications cables that exist. More detailed diagrammatic maps showing submarine cables in the Caribbean, the Mediterranean, North-West Europe, South and East Asia, and Sub-Saharan Africa can be found here: <http://submarine-cable-map-2014.telegeography.com/>.

Two Arctic submarine communications cables are reported to be planned, linking Tokyo and London: one will go around the north of the Eurasian continent, the other around the north of the American continent through the North-West passage; both would service Arctic communities *en route*. In 2012, both were planned to be in service by 2016. The link by the American route is said to be under construction but is not now expected to be complete until 2016. The link around the Eurasian route is reported to be stalled (Hecht, 2012; Arctic Fibre, 2014; Telegeography, 2013; APM, 2015).

Deployed international bandwidth (in other words, the total capacity of the world's international cables) increased at a compound annual growth rate of 57 per cent between 2007 and 2011. It reached 67 Terabits per second (Tbps) in 2011, which was six times the bandwidth in use in 2007 (11.1 Tbps). It has increased steadily since then and was estimated to be increasing to about 145 Tbps in 2014 (Detecon, 2013). Submarine cable bandwidth is somewhat lower, as shown in Table 1. The investment necessary to support this steady stream of investment is provided through consortia. The precise balance of the different interests varies from case to case, but the major players are nearly always national telecommunications operators, internet service providers and private-sector equity investors. Governments are rarely involved, except through government-owned national telecommunications operators (Terabit, 2014; Detecon, 2013).

Table 1. Activated Capacity on Major Undersea Routes (Tbps), 2007-2013

1.2 Magnitude of the impact of submarine cables on the marine environment

In 2007, the total route length of submarine fibre-optic cables was about 1 million route kilometres (Carter et al., 2009). This has now extended to about 1.3 million route kilometres, given the extensions reported in the 2014 Submarine Cable Report (Terabit, 2014). Although these are great lengths, the breadth of the impact on the marine environment is much, much less: the diameter of the fibre-optic cables on the abyssal plain is about 17-20 millimetres – that is, the width of a typical garden hose. On the continental shelf, the width of the cable has to be greater – about 28-50 millimetres – to allow for the extra armour to protect it from impacts and abrasion in these more dynamic waters and the greater threats from shipping and bottom trawling (Carter et al., 2009).

The cable is normally buried in the seabed if the water depth is less than 1,000-1,500 metres and the seabed is not rocky or composed of highly mobile sand. This is to protect the cable against other users of the sea, such as bottom trawling. Known areas where mineral extraction or other uses are likely to disturb the seabed are avoided. In greater water depths, the cable is normally simply laid on the seabed (Carter et al., 2009). Where a cable is buried, this is normally done by a plough towed by the cable ship that cuts a furrow into which the cable is fed. In a soft to firm sedimentary seabed, the furrow will usually be about 300 millimetres wide and completely covered over after the plough has passed. On other substrates, the furrow may not completely refill. The plough is supported on skids, and the total width of the strip disturbed may be between two and eight metres, depending on the type of plough used. Various techniques have been used to minimise disturbance in specially sensitive areas: on the Frisian coast in Germany, a specially designed vibrating plough was used to bury a cable through salt marshes (recovery was monitored and the salt-marsh vegetation was re-established in one to two years and fully recovered within five years); in Australia, cables crossing seagrass beds were placed in narrow slit trenches (400 millimetres wide), which were later replanted with seagrass removed from the route prior to installation; in the Puget Sound in Washington State in the USA, cables were installed in conduits drilled under a seagrass bed. Mangroves are reported to have recovered within two to seven months, and physical disturbance of sandy coasts subject to high-energy wave and tide action is reported to be removed within days or weeks. Where burial has not been possible, it has sometimes been necessary to impose exclusion zones and to monitor such zones (as between the North and South Islands of New Zealand (Carter et al., 2009)).

Further disturbance will occur if a cable failure occurs. Areas of cable failure are likely to have already been disturbed by the activity that caused the cable failure. Normally, the cable will have to be brought to the surface for repair. This will involve the use of a grapnel dragged across the seabed, unless a remotely operated robot submarine can be used. Reburial of the cable may involve agitating the sediment in which it has been buried. This disturbance will mobilise the sediment over a strip up to 5 metres wide. Fibre-optic cables have a design life of 20-25 years, after which the cable will need to be lifted and replaced, with a recurrence of the disturbance, although there is also the possibility of leaving them in place for use for purposes of scientific research (Carter et al., 2009; Burnett et al., 2014).

Evaluating the impact on marine animals and plants of this disturbance is not easy, since the area affected, though long, is narrow. In general, the verdict is that the seabed around a buried cable will have returned to its normal situation within at most four years. In waters over 1,000-1,500 metres deep (where burial is unusual), no significant disturbance of the marine environment has been noted, although any repairs will disturb the plants and animals that may grow on the cable. Such growth is common on exposed cables in shallow calm water, but is limited in water depths greater than 2000 metres, where biodiversity and macrofaunal abundance are much reduced (Carter et al., 2009). Some noise disturbance may be caused by the process of laying cables, but this is not significantly more than would be caused by ordinary shipping (OSPAR, 2008).

1.3 *Threats to communications cables from the marine environment*

Soon after transoceanic communications cables were laid, problems were experienced from impacts of the marine environment on the cables: specifically, submarine earthquakes and landslides breaking the cables (Milne, 1897). However, around 70 per cent of all cable failures are associated with external impacts caused by fishing and shipping in water depths of less than 200 metres (Carter et al., 2009).

Nevertheless, the risks of damage through catastrophic geological events (including those triggered by storms) are real, and some aspects of such risks are probably growing (see the discussion of the effects of climate change on storms in Chapter 5). The most recent major events have been near the Taiwan Province of China. On 26 December 2006, an earthquake occurred at the south end of the island. This triggered multiple submarine landslides. The landslides and subsequent turbidity currents travelled over 330 kilometres and caused 19 breaks in seven cable systems. Damage was located in water depths to 4,000 metres. The cable repair works involved 11 repair vessels and took 49 days. The result was a major disruption of services in the whole region: the internet connections for China, Japan, Philippines, Singapore and Viet Nam were seriously impaired. Banking, airline bookings, email and other services were either stopped or delayed and financial markets and general commerce were disrupted (Detecon, 2013; Carter et al., 2014).

Three years later, Typhoon Morakot hit the island of Taiwan Province of China, on 7 August 2009. Three metres of rain fell on the central mountains, causing much erosion. The sediment carried into sea caused several submarine landslides which broke a number of cables. The level of disruption was shorter and less serious than in 2006. This case is particularly significant, however, because it was the result of an extreme weather event. Given the consensus that climate change is causing the poleward migration of storms, areas that have previously been spared this kind of event are more likely in future to suffer from such storms. This is likely to increase the chances of submarine landslides, since an instability will be introduced into areas where it has not previously been generated (Carter et al., 2012).

The seas off East Asia present a combination of a very dense network of submarine communications cables (see the diagrammatic map in <http://submarine-cable-map-2014.telegeography.com/>) and an area of unstable geology. The scale of disruption that might be caused, either by a geological incident or by a vessel, can be envisaged by considering the Straits of Malacca. Fourteen of the 37 main submarine cables in the Western Pacific run through this narrow strait. These cables represent virtually the entire data connection between Asia, India, the Middle East and Europe. In addition, it is one of the busiest shipping routes worldwide. This drastically increases the likelihood of disruptions by anchors and other manmade hazards. Such disruptions unfortunately do happen regularly (Detecon, 2013). This, and the situation on the Isthmus of Suez, is one of the main attractions in a submarine cable route from the Pacific to the Atlantic around the north of either the American or the Eurasian continent. There is further a risk from deliberate human interference, but statistically this is a rare event (Burnett et al., 2014).

The International Cable Protection Committee Ltd. (ICPC) is a non-profit organization

that facilitates the exchange of technical, legal and environmental information concerning submarine cable installation, maintenance and protection. It has over 150 members representing telecommunication and power companies, government agencies and scientific organizations from more than 50 countries, and encourages cooperation with other users of the seabed. It is thus the main forum in which issues about the protection of these submarine cable connections, vital to global commerce, are being discussed.

1.4 Information and capacity-building gaps

A large body of knowledge already exists about the construction and operation of submarine communication cables, including how to survey environmentally acceptable routes and allow for the submarine geology. Coastal States need access to these skills to decide on safe locations and to take account of areas of potential geological change and disruption, or (at least) to negotiate successfully with commercial undertakings planning to install cables.

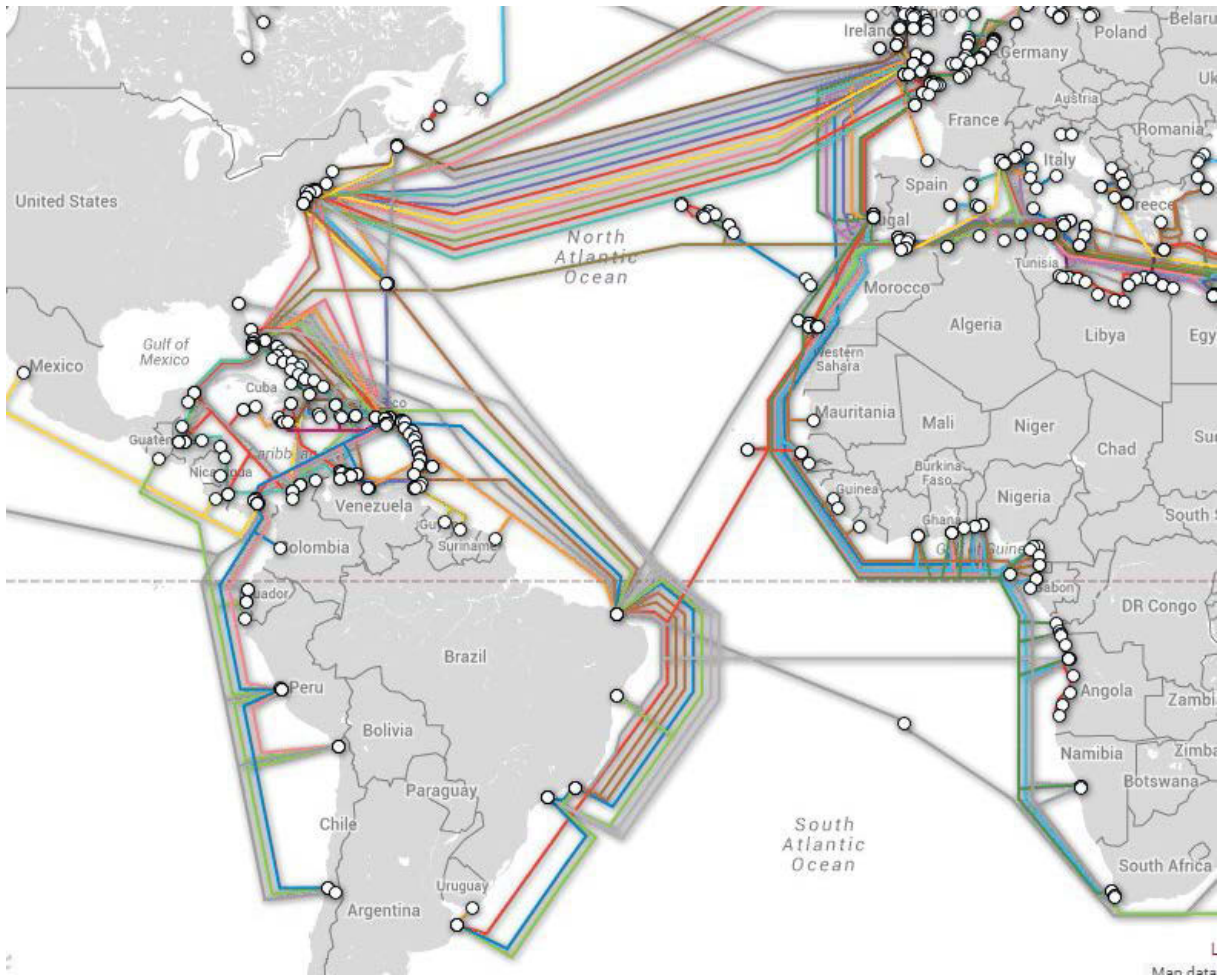

As with many other uses of the marine environment that involve uses of the seabed within their jurisdictions that may prevent or limit other legitimate uses of the sea, States need to have the capacities, in taking decisions on submarine cables, for resolving the conflicting demands of these uses with the other parties involved.

2. Submarine power cables

2.1 The nature and magnitude of submarine power cables

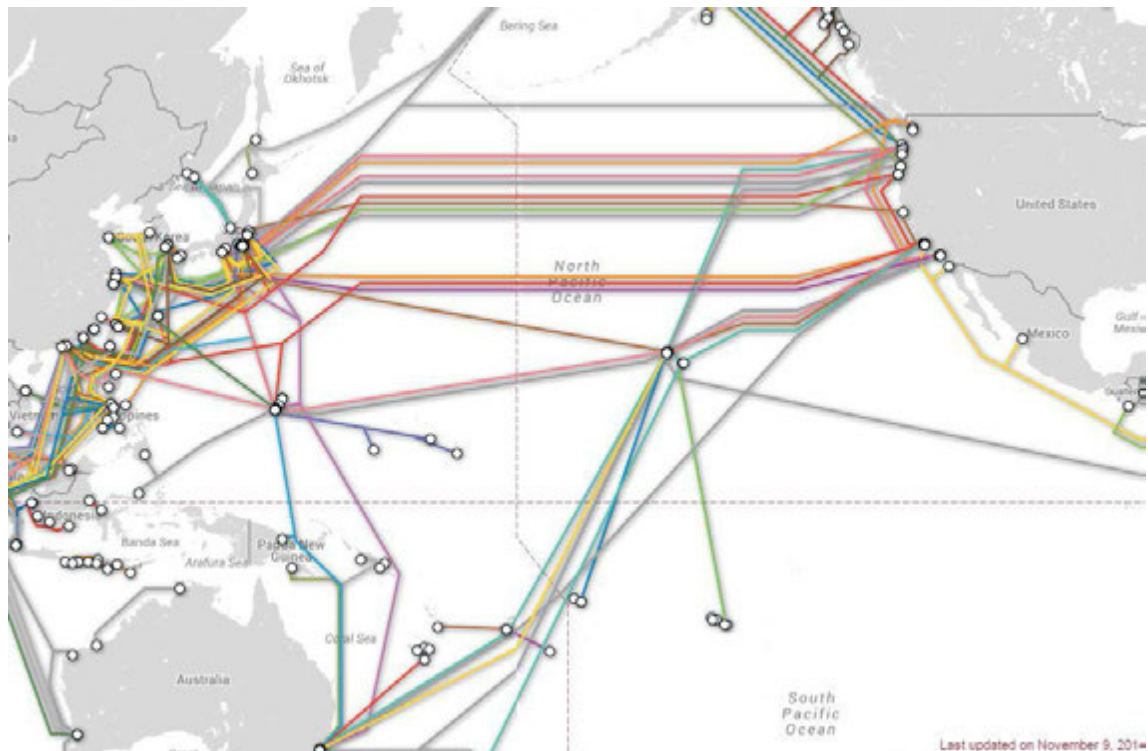

The number and extent of submarine cables carrying power rather than communications are much less significant, both in terms of their impact on the marine environment and in their importance to the world economy. They are essentially of only local interest.

Most of the world's submarine power cables are found in the waters around Europe. The cables fall into one of two classes, depending on whether the electricity is carried as direct current (DC) or alternating current (AC). The choice depends on several factors, including the length of the submarine cable and the transmission capacity needed: DC cables are preferred for longer distances and higher transmission capacities. DC cables can be either monopolar (when the current returns through the sea water) or bipolar (when the cable has two components with opposite polarities). Because monopolar DC cables tend to produce electrolysis, they are now rarely used for major projects.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Diagrammatic map of transpacific submarine cables. Source: Telegeography, 2014.

The AC cables include those between the mainland of Germany and its island of Heligoland, between Italy and its island of Sicily, between Spain and Morocco, between Sweden and the Danish island of Bornholm and, outside Europe, between the islands of Cebu, Negros and Panay in the Philippines. The DC cables include cables linking the Danish islands of Lolland, Falster and Zealand to Germany, Denmark to Norway, Denmark to Sweden, Estonia to Finland, Finland to Sweden, France to the United Kingdom, Germany to Sweden, the Italian mainland to its island of Sardinia and to the French island of Corsica, the Netherlands to Norway (at 580 kilometres, this is the longest submarine power cable in the world), the Netherlands to the United Kingdom, Northern Ireland to Scotland in the United Kingdom of Great Britain and Northern Ireland and the mainland of Sweden to its island of Gotland. Outside Europe, there are DC cables linking the mainland of Australia to its island of Tasmania, the mainland of Canada to its Vancouver Island, Honshu to Shikoku in Japan, the North Island to the South Island in New Zealand and Leyte to Luzon in the Philippines.¹ As can be seen, all these cables (with the exception of the Netherlands/Norway cable) cross fairly narrow stretches of water. They play a locally important part in managing electricity supply, enabling surpluses in one country or area to be transferred to another, or to enable an island to benefit from the economies of scale in power generation through a link to power stations serving

¹ This list has been compiled from a variety of sources.

a much bigger area. The links between Denmark, Norway and Sweden play an important role in the common power policy of those three States.

2.2 Environmental impacts of submarine power cables

The disturbance of the marine environment caused by the installation of a power cable will usually be larger than that for a communications cable, simply because the cable will be larger, in order to carry the current. However, neither the physical disturbance nor the associated noise is likely to have more than a temporary effect.

The other two aspects that have given rise to concern are heat and electromagnetic fields. There are few empirical studies of heat emitted from submarine power cables. AC cables are theoretically likely to emit more heat than DC cables. Calculations for the cable from the Australian mainland through the Bass Strait to Tasmania suggested that the external surface temperature of the cable would reach about 30°C-35°C. The seabed surface temperature directly overlying the cable was expected to rise by a few degrees Celsius at a burial depth of 1.2 metres. Readings taken at a Danish wind farm in 2005 showed that, for a 132 kV cable, the highest temperature recorded closest to the cable between March and September was 17.7°C. German authorities have set a precautionary standard for new cables such that the cables should not raise the temperature at a depth of 20 cm in the seabed by more than 2°C. This can be achieved by burying the cables at an appropriate depth (OSPAR, 2008).

Concerns have been raised about the effects of the electromagnetic fields generated by the electric current flowing along submarine power cables, since some fish and marine mammals have been shown to be sensitive to either electric fields or magnetic fields. The World Health Organization, however, concluded in 2005 that "...none of the studies performed to date to assess the impact of undersea cables on migratory fish (e.g. salmon and eels) and [on] all the relatively immobile fauna inhabiting the sea floor (e.g. molluscs), have found any substantial behavioural or biological impact" (WHO, 2005). A literature survey in 2006 reached a similar conclusion (Acres, 2006), and nothing had emerged by the 2010 European Union report on the implementation of the EU Marine Strategy Directive to cast doubt on those conclusions (Tasker et al., 2010).

2.3 Knowledge and capacity-building gaps

As with communications cables, coastal States need to have access to the skills to locate submarine power cables in a safe and environmentally acceptable way, and to evaluate the economic and social benefits of introducing such links.

3. Submarine Pipelines

3.1 The nature and magnitude of submarine pipelines

Submarine pipelines are used for transporting three main substances: gas, oil and

water. Submarine gas and oil pipelines fall into three groups: intra-field pipelines, which are used to bring the oil or gas from well-heads to a point within the operating field for collection, processing and onward transport; export pipelines, which transport the gas and oil to land; and transport pipelines, which have no necessary connection with the operating field, but transport gas or oil between two places on land. The last category is often included with the export pipelines. The intra-field and export pipelines are discussed in Chapter 21 as part of the processes of extracting the oil and gas. This section is concerned only with the transport pipelines. In general, what is said about submarine pipelines in Chapter 21 applies to gas and oil transport pipelines.

Submarine transport pipelines are used mainly for the transport of gas and are located predominantly around the Mediterranean and the Baltic and North Seas. Many have been created since 2000. In the Mediterranean, the earliest gas pipeline was the Trans-Mediterranean Pipeline, built in 1983 to link Algeria and the Italian mainland, via Sicily. This was followed in 1996 by the Maghreb-Europe Pipeline to link Morocco and Spain across the Strait of Gibraltar. Subsequent Mediterranean pipelines are: the Greenstream Pipeline, built in 2004 between Libya and Sicily, the interconnector built in 2007 between Greece and Turkey, the link completed in 2008 between Arish in Egypt and Ashkelon in Israel (which has been out of service since 2012), and the Medgaz Pipeline built in 2011 between Algeria and Spain. Further north, a link was built between Scotland and Northern Ireland in the United Kingdom in 1996. An interconnector was built between Belgium and the United Kingdom in 1998. The Balgazand/Bacton Line (BBL) connected the Netherlands and the United Kingdom in 2006. Finally, the Nord Stream Pipeline was completed in 2011 and 2012 through the Baltic, between Vyborg in the Russian Federation and Kiel in Germany. This is the longest gas transport pipeline in the world (1,222 kilometres in length). Issues about its environmental impact bulked large in the negotiations leading to its construction, and particular problems were encountered over munitions dumped in the Baltic at the end of the Second World War (see Chapter 24 (Solid waste disposal)).² There are also a number of gas pipelines linking Norwegian gas production to its export markets. The Norwegian upstream gas transportation system has been developed from the 1970s, and continues to develop, to cater for the transportation of natural gas produced on the Norwegian continental shelf. Norwegian domestic consumption of natural gas is limited. Almost all the gas produced is exported (101,000 million standard cubic metres) to European gas markets through landing terminals in Belgium, France, Germany and the United Kingdom. The pipeline network in 2014 forms a 7,980-kilometre integrated transportation system, transporting gas from nearly 60 offshore fields and three large gas processing plants on the Norwegian mainland, to European gas markets. The latest main addition to the system is the Langeled Pipeline, opened in 2007, which goes from the onshore processing plant in Norway for the Ormen Lange gas field to the United Kingdom, via a riser platform at the Sleipner field.

Outside Western Europe and the Mediterranean, there is a gas pipeline linking the Russian Federation and Turkey across the South-Eastern corner of the Black Sea, and

² This list has been compiled from a variety of sources.

one linking the island of Sakhalin to the mainland of the Russian Federation in the North-West Pacific. Oil transport pipelines exist between Indonesia and Singapore across the Strait of Malacca, and in China, linking the island of Hainan to Hong Kong.³ Generally, these submarine transport pipelines have been built and financed by oil and gas operators (including national oil and gas companies), sometimes in consortiums with national gas distribution undertakings.

3.2 Environmental impacts of oil and gas pipelines

The environmental impacts of intra-field and export submarine pipelines are discussed in Chapter 21 (Offshore hydrocarbon industries). The impacts of oil and gas submarine transport pipelines are essentially the same.

3.3 Submarine water pipelines

Because of the high cost and maintenance difficulties, submarine pipelines are only used to supply small islands close to continents or larger islands where the natural water supplies of the islands are insufficient for their needs. The supply of water to Singapore from Malaysia is the only significant international example (PUB, 2014). Domestic examples include: China (where Xiamen Island receives some of its water from the mainland through 2.3 kilometres of submarine pipelines), Fiji (where several small islands with tourism resorts are supplied through submarine pipelines), Malaysia (where Penang receives some of its water supply from the Malaysian mainland through 3.5 kilometres of submarine pipelines), the Seychelles (where five small islands are supplied through submarine pipelines of up to 5 kilometres in length) and, most significantly, in Hong Kong, China (where water is supplied to some of the islands, including the densely populated Hong Kong Island, from the Chinese mainland, through 1.3 kilometres of submarine pipelines) (UNESCO, 1991).

3.4 Knowledge and capacity-building gaps

For oil and gas transport pipelines, the requirements are likely to arise from the overall planning of the exploitation of hydrocarbon reserves and the provision of gas services. The comments in Chapter 21 on this subject are therefore relevant.

For submarine water pipelines, the essential questions will be linked to the planning and implementation of freshwater supply services. Questions of access to information and the necessary skills need to be addressed in that context. As with the laying of submarine communication cables, in taking decisions on submarine water pipelines within their jurisdictions, States need to have the capacities for resolving the conflicting demands of these uses.

Chapter 20. Coastal, Riverine and Atmospheric Inputs from Land

Contributors: Alan Simcock (Lead member and Convenor), Benjamin Halpern, Ramalingam Kirubakaran, Md. M. Maruf Hossain, Marcos Polette, Emma Smith, Juying Wang (Co-lead member).

Commentators: Arsonina Bera, Mark Costello, Robert Duce, Ralf Ebinghaus, Jim Kelley, Thomas Malone, Jacques Rasoanaina.

Some material originally prepared for Chapter 36F (Open Ocean Deep Sea) and Chapter 51 (Seamounts and other submarine features potentially threatened by disturbance) has been incorporated into parts of this Chapter. The contributors to those chapters were Jeroen Ingels, Malcolm R. Clark, Michael Vecchione, Jose Angel A. Perez, Lisa A. Levin, Imants G. Priede, Tracey Sutton, Ashley A. Rowden, Craig R. Smith, Moriaki Yasuhara, Andrew K. Sweetman, Thomas Soltwedel, Ricardo Santos, Bhavani E. Narayanaswamy, Henry A. Ruhl, Katsunori Fujikura, Linda Amaral Zettler, Daniel O. B. Jones, Andrew R. Gates, Paul Snelgrove, J. Anthony Koslow, Peter Auster, Odd Aksel Bergstad, J. Murray Roberts, Alex Rogers, Michael Vecchione.

1. Introduction

The movement of materials from land to sea is an inevitable part of the hydrological cycle and of all geological processes. Nevertheless, human activities have both concentrated and increased these flows as a result of the creation of large human settlements, the development of industrial processes and the intensification of agriculture. Until the 1960s, many took the view that the oceans were capable of assimilating everything that humans wanted to discharge into the oceans. In the 1960s, this view came to be seen as out-dated (UNESCO, 1968). Following the 1972 Stockholm Conference on the Human Environment, many steps were taken to address issues of marine pollution. During the preparations for the United Nations Conference on Environment and Development (“the first Earth Summit”), held in Rio de Janeiro, Brazil, in 1992, there was general agreement that, in spite of what had been done, a major initiative was needed to address the problems of land-based inputs to the oceans. As a result, Agenda 21 (the non-binding action plan from the 1992 Earth Summit) invited the United Nations Environment Programme (“UNEP”) to convene an intergovernmental meeting on protection of the marine environment from land-based activities (Agenda 21, 1992). In October 1995, the Global Programme of Action for the Protection of the Marine Environment from Land-Based Activities (GPA) was adopted in Washington, DC. First among the priorities of this Programme was improving the management of waste-water: this concerned not only waste-water containing human wastes, but also waste-water from industrial processes. In addition, a wide range of other source categories also creating

problems for the marine environment was identified (UNEP, 1995). The Programme reflected the experience of over twenty years' work by governments, both individually and through regional seas organizations, to address these problems. Subsequent intergovernmental reviews of the implementation of the GPA show that progress is being made in many parts of the world, but only slowly.

In evaluating the impacts of contamination on the marine environment, there are significant difficulties in comparing the situations in different areas. For many aspects of contamination, evaluating the levels of contamination requires chemical analysis of the amounts of the contaminants in samples of water, biota and/or sediments. Unless there is careful control of the sampling methods and analytical techniques in all the cases to be compared, it is difficult to achieve scientifically and statistically valid comparisons. Lack of clear and practical comparisons creates problems in setting priorities. For example, a fairly recent review of available evidence in the Wider Caribbean concluded that, among the 30 pollution studies examined, analyses varied in terms of sampling schemes, parameters and analytical techniques, and data were presented in ways which made comparison all but impossible – whether data were in terms of dry weight or wet weight, what sediment fraction was analyzed, and whether data were presented in absolute terms or as a percentage of lipids (Fernandez et al., 2007). Such differences make meaningful comparisons of the available data very difficult. For this reason, this chapter does not attempt to give detailed figures on concentrations of contaminants. The Global Environment Facility is supporting the Transboundary Waters Assessment Programme (TWAP), to enable priorities between different areas to be established.

The main issues relating to inputs to the oceans and seas from land-based sources can be categorized for the purposes of this chapter under the headings of: hazardous substances (including the effects of desalinization plants), endocrine disruptors, oil, nutrients and waterborne pathogens, and radioactive substances.

In all cases, consideration has to be given to the variety of means by which the movement of the substances from land to water takes place. The main distinction is between waterborne and airborne inputs. Waterborne inputs can either be direct (through a pipeline from the source directly into the sea, by run-off from land directly into the sea or by seepage of groundwater directly into the sea) or riverine (through runoff or leaching from land to a watercourse or by a direct discharge into a watercourse, and the subsequent flow from such watercourses into the sea). Waterborne inputs are much more readily measured, and for that reason have so far attracted more attention. There is increasing evidence that airborne inputs are more significant than has hitherto been thought, not only for heavy metals and other hazardous substances but also for nitrogen (GESAMP, 2009; Duce et al., 2008).

2. Hazardous Substances

2.1 Which substances are hazardous?

A wide range of substances can adversely affect marine ecosystems and people. The adverse effects can range from straightforward fatal poisoning to inducing cancers, weakening immune systems so that diseases develop more easily, reducing reproductive performance and inducing mutations in offspring. A first requirement for controlling the input of hazardous substances into the marine environment, whether from point or diffuse sources or through the atmosphere is therefore to establish what substances show sufficient grounds for concern that regulatory action is needed. Lists of substances identified as hazardous can never be closed: new substances are constantly being developed, and new uses are likewise constantly being found for a wide range of elements and compounds.

International effort to define substances hazardous to the marine environment began in relation to dumping of waste at sea (see Chapter 24). In this context, the Convention for the Prevention of Marine Pollution by Dumping from Ships and Aircraft of 15 February 1972 (Oslo Convention) and the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter of 13 November 1972 (London Convention) established the first internationally agreed lists of substances whose introduction into the marine environment should be controlled. In both Conventions, a ban on dumping was agreed for similar “black lists”. These included, among other items, substances such as toxic organohalogen compounds, agreed carcinogenic substances and mercury and cadmium and their compounds. Controls were agreed on dumping for similar “grey lists”, which included, among other items, arsenic, lead, copper and zinc and their compounds, organosilicon compounds, cyanides, fluorides and pesticides not in the “black list” (Oslo Convention 1972; IMO, 1972). When attention was thereafter given to dealing with discharges and emissions from land, these “black” and “grey” lists were adapted and used by many national and international authorities concerned with the marine environment for the initial work in the field of regulation of land-based inputs of hazardous substances.

Over the past 40 years, regulatory authorities have added further categories to be controlled. In 1976 the United States Environment Protection Agency produced a list of “toxic pollutants” and an explanatory list of “priority pollutants” (EPA, 1976; EPA, 2003). An important contribution to the more general debate on the approach to control of hazardous substances was made in 1993, when the Great Lakes Commission proposed the virtual elimination of discharges of substances which are toxic and persistent (IJC, 1993). The most extensive exercise that has focused specifically on the marine environment was undertaken from 1998 by the OSPAR Commission for the Protection of the Marine Environment of the North-East Atlantic to implement its long-term strategy of eliminating discharges, emissions and losses of hazardous substances which could reach and affect the marine environment. For this purpose, “hazardous substances” were defined as substances that are toxic, persistent and liable to bioaccumulate (bioaccumulation occurs when a substance taken in by an organism is not excreted, but builds up in the organism), or which give

rise to an equivalent level of concern (OSPAR, 1998). This required a definition of thresholds of toxicity, persistence and bioaccumulativity. These agreed levels were applied to the more than 11,000 substances listed in the Nordic Substances Database with experimental data. The resulting list of substances of possible concern was then analysed in 2001-2004 to see which substances were only found as intermediates in closed systems, or were not being produced or used, and were therefore unlikely to affect marine ecosystems. After these had been discounted, the resulting list of chemicals for priority action was used to see what action was needed to meet the cessation target (OSPAR, 2010). The European Union, through its Regulation, Evaluation, Authorization and Restriction of Chemicals (REACH) Regulation (EU, 2006), is addressing all “persistent, bioaccumulative and toxic” (PBT) and “very persistent and very bioaccumulative” (vPvB) substances that are in substantial (more than 1 ton/year) use in its area, or proposed to be introduced. China has developed its Catalogue of Toxic Chemicals Prohibited or Strictly Controlled (China, 2014). Other organizations, such as the Arctic Monitoring and Assessment Programme, have developed similar lists (Macdonald et al., 1996).

Although there is substantial overlap between the various lists of substances where action is considered to be needed to protect the marine environment, there are variations. These result from differences in evaluation of the level of risk. Different methods of evaluation, and different choices of cut-off levels for toxicity, persistence and bioaccumulativity can lead to differing views. Different judgements are made on the extent to which precautions by users can sufficiently guard against the risks to the environment. Different views are taken on the reasonable practicability of the use of acceptable substitutes: what is regarded in some jurisdictions as acceptable (because, for example, its use can be managed acceptably) is regarded in others as unacceptable. Sometimes (as with chlordane) international action can help change what is regarded as reasonably practical. The result is that there is no single agreed list of hazardous substances that are of concern: substances that are regarded as acceptable in one area are banned in another.

Table 1 shows the principal substances which the range of authorities mentioned in the previous paragraph have regarded as hazardous to the marine environment, and on which action is being taken in all or some parts of the world to control inputs of them to the sea from land.

Table 1. Background information on substances classified by the authorities mentioned in the text as presenting hazardous characteristics and therefore justifying action.

SUBSTANCES	SOURCES AND MAIN USES ¹	PRODUCTION AND RELATED DEVELOPMENTS
† = Persistent Organic Pollutant (POP) under the Stockholm Convention on Persistent Organic Pollutants 2001; †? = Substance under consideration for listing as a POP) under the Stockholm Convention	* = diffuse sources, where the pathways will be mainly from leaching (especially from land-fill waste disposal), emissions to air and/or runoff	
Heavy metals		
Cadmium	Large combustion plants; electroplating; incinerators; paints*; batteries*	World production of cadmium is fairly stable (around 20,000 tons/year) between 2001 and 2011 ²
Copper	Mining; electric wiring and machinery*; pesticides*	World production of copper increased 15% to 16.2 million tons/year during 2001-2011 ²
Lead and organic lead compounds	Roofing*; fuel for internal combustion engines*; paint*; PVC stabilizer*	The phasing out of lead in vehicle fuel has significantly reduced inputs of lead to the seas. Emissions in Europe have decreased by 92% during 1990-2003, with similar decreases in North America ³ . World production of lead has, however, risen 53% to 4.75 million tons/year during 2001-2011 ² . Over half of this is in Australia and China.
Mercury and organic mercury compounds	Large combustion plants; electrolysis chlor-alkali plants; primitive gold-refining*	World production of mercury is relatively stable, fluctuating between 1,120 and 2,280 tons/year during 2001-2011 ² . A substantial stock-pile is, however, emerging as mercury-cell chlor-alkali plants change technology. A global Convention was adopted at Minamata, Japan, in 2013 to control trade in, and the use of, and plants discharging or emitting it. The Convention is not yet in force.
Zinc	Large combustion plants; surface-treatment of sheet metal*; cosmetics*	World production of zinc has risen by 38 % to 12.6 million tons during 2001-2011, over half in Australia, China and Peru.
Organohalogenes		
Brominated diphenyls (BDPs) (hexa-BDP†) and BDP ethers (BDEs)(tetra-BDE†, penta-BDE†, hexa-BDE†, hepta-BDE and deca-BDEs)	Fire retardants in automobiles; plastics and textiles*	World production is about 40,000 tons/year. All BDEs are now controlled in a number of countries. Production and use of hexa-BDP and tetra-, penta-, hexa- and hepta-BDEs are to be eliminated under the Stockholm Convention ⁴ .
Hexabromobiphenyl†,	Fire retardant*	No current production or use is known.
Hexabromocyclododecane	Fire retardant in plastic foam*	At its peak in the 1970s, production was about

¹ <http://chm.pops.int/TheConvention/ThePOPs/tabid/673/Default.aspx> and associated risk assessments, together with the relevant OSPAR Background Papers

⁴ Stockholm Convention on Persistent Organic Pollutants, United Nations *Treaty Series*, vol. 2256, No. 40214.

SUBSTANCES	SOURCES AND MAIN USES ¹	PRODUCTION AND RELATED DEVELOPMENTS
(HBCDD) †?		6,000 tons /year. No production is now reported.
Hexachlorobutadiene†?	Fumigant*; transformer, hydraulic or heat transfer liquid*; viticulture pesticide*	Production and use have ceased in Europe.
Perfluorooctanyl sulphonic acid and its salts (PFOS)† and perfluorooctanesulfonyl fluoride (POSF-F)†	Electronic components*; fire-fighting foams*; insecticide*; stain repellent for carpets*; fat repellent in food-packaging	Production and use to be eliminated under Stockholm Convention, subject to specific exemptions.
Polychlorinated biphenyls (PCBs)†	Heat exchange fluids*; electric transformers and capacitors*; paint additives*; carbonless copy paper*; plastics*	Production and use to be eliminated under the Stockholm Convention. Such a prohibition has been in force since about 1990 in many States, but residues often remain.
Polychlorinated dibenzodioxins (PCDDs)† and polychlorinated dibenzofurans (PCDFs)†	Incomplete combustion of material containing organic substances and chlorine; emissions from polyvinylchloride (PVC) plants.	Emissions to be minimised under the Stockholm Convention
Polychlorinated naphthalenes†?	Wood preservatives*, additives to paints and engine oils*, cable insulation*; in capacitors*	
Short chained chlorinated paraffins (SCCPs)†?	Lubricants in metal working; leather treatment; production of rubber and plastics	SCCPs are produced in Brazil, China, India, Japan, Russia, Slovakia and the United States. Use in Europe and North America has dropped by about 75% since peaks in the 1990s.
Vinyl chloride	Mainly used in the production of polyvinylchloride (PVC);	
<i>Pesticides/biocides</i>		
Aldrin†, Dieldrin†, Endrin† (Aldrin rapidly converts to Dieldrin)	Insecticides*. Endrin also used in rodent control*.	Production and use to be eliminated under the Stockholm Convention, subject to some transitional exemptions.
Atrazine and Simazine	Herbicide (used extensively in maize and sugarcane agriculture to control weeds)*	Production and use have been phased out in some countries (where it has largely been replaced by less persistent herbicides. Still produced and used in some other countries, where controls on use are seen as sufficient to keep it out of the water environment.

SUBSTANCES	SOURCES AND MAIN USES ¹	PRODUCTION AND RELATED DEVELOPMENTS
Chlordane†	Insecticide, particularly for termites	Production and use to be eliminated under the Stockholm Convention. The Global Environment Facility in 2006 provided USD 14 million for a programme to enable China to achieve this.
Chlordecone†	Insecticide, particularly used in banana culture	No current production or use is known.
Dichlorodiphenyltrichloroethane (DDT)†	Originally use widely as a broad-spectrum insecticide, now almost exclusively for controlling insect disease-vectors*	Production and use controlled under the Stockholm Convention. 18 Convention Parties have registered to continue to use DDT for disease-vector control, of which 5 reported no use in their last report. One Party (the Gambia) reported use, but had not registered.
Dicofol	Pesticide, especially for mites on tomatoes and melons*	Some countries have phased out the use of dicofol. It is still used in Brazil, China, India and Israel. Produced by chemically modifying DDT.
Endosulfan†	Pesticide*	Production and use to be eliminated under the Stockholm Convention, subject to specific exemptions.
Heptachlor	Insecticide, especially for soil insects and termites*	Production and use to be eliminated under the Stockholm Convention.
Hexachlorobenzene	Fungicide*	Production and use to be eliminated under the Stockholm Convention.
Lindane (γ -hexachlorocyclohexane (HCH)†, including α -HCH† and β -HCH† isomers (produced in large quantities as by-products to γ -HCH)	Insecticide*	Production and use to be eliminated under the Stockholm Convention, subject to exception for use against head-lice and scabies. Production and use have largely already ceased, but stockpiles of α - and β -HCH exist.
Methoxychlor	Insecticide for use on both animals and plants*	Phased out in the European Union and the United States. Information is lacking on production and use elsewhere.
Mirex†	Insecticide, particularly for termites*; fire retardant*	Production and use to be eliminated under the Stockholm Convention. The Global Environment Facility in 2006 provided US\$14 million for a programme to enable China to achieve this.
Pentachlorophenol (PCP) and its salts and esters†?	General pesticide, now widely restricted to use as a fungicide and wood preservative*	PCP is being considered under the Stockholm Convention because it transforms into pentachloroanisole (PCA) which is seen as a problem. PCP has been phased out in the European Union.
Pentachlorobenzene†	Used to make PCBs less viscous*; in dyestuff carriers*; as a fungicide*; as a flame retardant*	No current intentional production or use is known; probably still produced as a by-product in imperfect incineration.
Toxaphene†	Insecticide, particularly used for cotton and soya-bean culture*	Production and use is to be eliminated under the Stockholm Convention.
Aromatics		
Polycyclic aromatic hydrocarbons (PAHs)	Incinerators; large combustion plants; Söderberg-process aluminium-smelting plants; coke plants; imperfect combustion of wood and fossil fuels	Reductions in PAH emissions are being achieved by tighter regulation of vehicles, combustion plants and incinerators, technology changes in aluminium-smelting plants and (in some areas)

SUBSTANCES	SOURCES AND MAIN USES ¹	PRODUCTION AND RELATED DEVELOPMENTS
	(including vehicles)*; coal-tar surface treatments (including creosote)*	elimination of the use of some surface-treatment processes.

Particularly important are:

- (a) **Heavy metals:** All heavy metals occur naturally and, because of natural weathering processes and the immunity of natural elements to destruction, are found at measurable levels even in waters generally regarded generally as pristine. Some heavy metals (such as cadmium, mercury and lead) are always highly toxic. Others (especially copper and zinc) are essential trace elements in diet or intake for many biota. Some heavy metals, especially copper and arsenic, have been used extensively in the past for plant protection purposes, resulting in widespread additional dispersal and higher concentrations in some areas. In excessive amounts, however, even these can interfere with the absorption of other essential trace elements and, at high levels, become toxic. At lower levels, they also appear capable of affecting the immune systems of biota (Coles et al., 1995; Kakuschka et al., 2007) or their reproductive success (Leland et al., 1978);
- (b) **Persistent organic pollutants (POPs):** In contrast, POPs are man-made. They are organic compounds (that is, compounds involving carbon, most often combined with hydrogen and/or with chlorine, bromine or other halogens) that resist degradation in the environment through chemical, biological or other processes. Many were developed as biocides (insecticides, herbicides, etc.) since about 1910-1930. Others are used in manufacturing processes or in electrical appliances. From the 1960s, concerns developed about their effects on immune systems and reproductive success, and about their carcinogenic effects. As a consequence of the call in the GPA in 1995, subsequently endorsed by the UNEP Governing Council, the Stockholm Convention on Persistent Organic Pollutants was adopted on 22 May 2001⁵ and now provides a global mechanism for controlling the production and use of POPs. Initially, agreement was reached in 2004 that production and use of 12 POPs should be banned or strictly controlled. Since then a further 10 POPs have been brought under the Convention's controls;
- (c) **Polycyclic aromatic hydrocarbons (PAHs):** PAHs are complex compounds of hydrogen and carbon (and, in some cases, other elements such as nitrogen, oxygen or sulphur). They occur naturally, and are also typically created by imperfect combustion processes. Many, but not all, are carcinogenic and/or affect reproductive success;

It is important to note that the category of hazardous substances is not closed. New substances are constantly being developed, and new uses are constantly being found for a wide range of elements and compounds. The questions whether these substances and elements are toxic, persistent and bioaccumulative and whether

⁵ 2256 United Nations *Treaty Series* 119.

their uses present risks to the marine environment need to be kept under continual review. Substances where such questions arise are sometimes referred to as “contaminants of emerging concern” (see, for example, Yuan et al., 2013).

Knowledge of the extent of the presence of hazardous substances in the marine environment is patchy. Some issues, such as the presence in the marine environment of contamination from heavy metals and lindane, have been studied for over 30 years in some areas and, to a lesser extent, have also been studied quite widely around the world. Other issues have only been looked at more recently, and a number have only been examined from the point of view of laboratory tests of substances on marine biota, without monitoring for the presence of the substances in the sea itself or its biota and sediments.

Some hazardous substances reach the marine environment in inflows of water, others are airborne. Waterborne contaminants tend to be found mainly near the inflows, and thus concentrated in estuarial and coastal waters, particularly where they are adsorbed onto particles in the water and settle as sediments. Airborne contaminants are carried much further out to sea, and therefore are found more generally. For some hazardous substances, sampling around the world’s continents has shown that they are present in all continents (for example, dioxins and furans (which are most often airborne) have been found in butter samples from all continents, though to a lesser extent in the southern hemisphere (Weiss et al., 2005). Where hazardous substances have been spread worldwide largely by air transport, it can be assumed that they have also reached the ocean. It is known that some POPs have been concentrated on the higher latitudes of northern hemisphere land-masses by a process of volatilization from land and redeposition – sometimes described a “multi-hop” process, as compared with “one-hop” contaminants that are carried in one step to their final destination.

3. Point Sources

The most obvious threats to the marine environment from hazardous substances come from point sources. Such point sources can be either discharges into rivers which ultimately reach the sea, or direct discharges through pipelines into the sea. There can be cases (usually volcanic eruptions) in which natural processes result in the introduction of naturally occurring hazardous substances into the ocean. However, many point sources are large industrial plants which provide a concentrated source from which the hazardous substances pass into the marine environment. Waste-water treatment plants can also be regarded as point sources, since they can concentrate hazardous substances from a substantial area and funnel them to a single discharge point. Historically, it was the impact of such point sources on inland waters that first gave rise to concern. In England, effective legislation was introduced as early as 1875 (Rivers (Prevention of Pollution) Act 1875). Similar legislation followed in other industrialized countries. Because of the then current belief in the almost infinite absorptive capacity of the sea, general measures on discharges and emissions reaching and affecting the sea were not

adopted until the 1970s. Initially the measures were “end of the pipe” methods of removing contaminants from discharges and emissions. Gradually, the emphasis has moved more to “clean technology”, where the contaminants are not used in, or not generated by, the process. Among the most significant point sources in respect of hazardous substances are the following:

- (a) **Large combustion plants:** Since fossil fuels naturally contain other minerals, such as heavy metals, their combustion releases those elements. Since the gases from combustion are released to the air, large combustion plants are a significant source for airborne transport of contaminants to the ocean. Many large combustion plants do not have sufficient scrubbers to clean the flue gases. Such plants are particularly significant for emissions of mercury: all forms of coal-burning account for 24 per cent of the total global estimated annual anthropogenic releases of 1,960 tons (estimate range: 304 to 678 tons) (UNEP, 2013a based on a 2010 inventory). This estimate differs in absolute amount and relative proportion of the total emissions from an earlier one in 2008 based on a 2005 inventory: in 2008 all forms of coal-burning were estimated to be in the range of 1,230 to 2,890 tons, and to constitute the largest sector emitting mercury; the change is due to revised estimates of emissions from domestic heating (revised downwards from 2008 to 2013), and emissions from artisanal gold refining (revised upwards from 2008 to 2013, and thus estimated in 2013 to be the largest mercury-emitting sector). If the 2005 inventory figures are compared with the 2010 inventory figures and the same methodology used is considered, and the estimates employ the same 2010 methodology, the emissions in 2010 from coal combustion in power generation and industrial uses combined are the same as, or perhaps slightly higher than, in 2005. The fact that emissions from this sector are not higher, even though new coal-fired power plants are being built, rests on the improving combustion efficiency and emissions controls in most parts of the world (UNEP, 2008; UNEP, 2013a). Emissions of mercury from large combustion plants should eventually be controlled by the actions required under the Minamata Convention on Mercury of 10 October 2013 (Minamata Convention). Coal-fired power stations are also significant sources of cadmium, zinc and PAHs. Cement production is another form of large combustion plant which can emit heavy metals both from the fuel and from the raw materials: in 2013, mercury emissions from this sector were estimated on the basis of the 2010 inventory at 173 tons (estimate range 65.5 – 646 tons) (EU BREF, 2013; UNEP, 2013a).

Between 2001 and 2012, the proportion of the total amount of electricity generated by coal-fired power stations declined or remained stable in much of the world (Africa, Europe and Central Asia, North and South America, South Asia). It can therefore be expected that emissions of mercury from such power stations reaching the ocean will stabilise or decline. The proportion, however, grew steadily in East Asia – from 51 per cent to 63 per cent (although China’s proportion of coal-derived electricity remained stable at around 80 per cent). Unless even greater efforts are made to control emissions of hazardous substances from coal-fired power stations, the levels of contaminants reaching

the ocean from this source in that part of the world are likely to increase (World Bank, 2014).

The pattern of development in cement production is different from that of coal-fired power generation: except in Europe, there has been significant growth over the past decade: 33 per cent in the Americas, 66 per cent in Oceania, over 200 per cent in Africa and over 250 per cent in Asia. This increase in production appears to have been accompanied by marked improvements in the quality of control of emissions: for one of the most significant, mercury, the UNEP 2013 estimate of mercury emissions from this sector was lower than the 2008 estimate (173 tons as against 189 tons) (UNEP, 2008; UNEP, 2013a).

Figure 1 World Cement Production 2001-12. Source: European Cement Association, 2014.

(b) **Chemical industries:** Chemical industries can give rise to a wide range of contaminant emissions and discharges: the products themselves may present problems – as can be seen from the list of substances in Table 1 – and other hazardous substances can be released either in the production process or as part of the waste stream. Where efforts have been focused on combating pollutant discharges and emissions, chemical plants have usually been high on the list of targets. For traditional technologies, the focus has to be on removing pollutants from the waste streams and preventing leaks during the process. Increasingly, however, the focus is on new technologies which do not present the same pollution problems as the traditional technologies (for example, the membrane process in chlor-alkali production and the “no-chlorine” processes in paper and pulp production).

The world of chemical production is, moreover, changing fast. Measuring the overall situation is not easy, because of the wide range of products that come under the umbrella of the chemical industries. One measure that can be used to indicate the scale of change in the chemical industries, however, is the value of the goods produced. In real terms, the statistics of such product values will show changes in the level of activity of the chemical industries in different countries. Such statistics will, of course, hide changes in chemical industries where bulk production of basic chemicals is replaced by production of

specialist chemicals of higher intrinsic value. Nevertheless, they can give an overall view of the way in which the world's chemical industries are changing (see Appendix to this chapter):

- (i) Between 2003 and 2012, the value of the total world output of chemicals rose by 12 per cent in real terms;
- (ii) In 2003, 60 per cent by value of the world output of chemicals was in North America and Europe. By 2012, this had dropped to 40 per cent;
- (iii) In contrast, the proportion by value of world chemical production in Asia and the Pacific rose from 29 per cent to 49 per cent, in spite of a reduction of 24 per cent in the value of Japanese chemical products. The value of Chinese chemical products in real terms rose by 293 per cent between 2003 and 2012 (to 29 per cent of total world production), that of Singapore by 74 per cent, that of India by 56 per cent, and that of the Republic of Korea by 32 per cent.

Figure 2 World Chemical Production by value in 2003 and 2012. Source: Appendix to this chapter.

There has therefore been a significant change in the potential for the impact of chemical industries on the marine environment, with a change of focus from the Atlantic Ocean basin to the Pacific Ocean basin.

Certain types of chemical plants merit specific mention: chlor-alkali plants, polyvinyl chloride (PVC) plants and titanium-dioxide plants.

- (c) **Chlor-alkali plants:** Chlorine and caustic soda are basic requirements for many chemical industries. Since 1892, they have been produced by electrolysis of brine. The (original) mercury-cell process uses a layer of mercury as the cathode, which is constantly withdrawn and reacted with water. The resulting water discharges, unless purified, have a high mercury content. This original process is increasingly being replaced, initially by the diaphragm process (which used an asbestos diaphragm) and now by the membrane process, neither of which use mercury. One hundred mercury-cell process plants still exist in 44 countries. Existing plans will result in this number diminishing to 55 plants in 25 countries by 2020 (UNEP, 2013b).
- (d) **Polyvinyl chloride plants:** PVC plants use various processes to convert vinyl chloride monomer into the plastic PVC which has manifold uses throughout the world. Global production in 2009 was around 30 million tons, representing a growth of 50 per cent since 1995. The world's production capacity is

significantly higher (around 48 million tons/year), but the economic recession reduced use of this capacity (Deloitte, 2011). Production levels are expected to recover quickly and to continue to grow. Capacity in China has grown particularly rapidly, from about 375,000 tons in 2001 to nearly 16,000,000 tons in 2008.

The adverse environmental impact from PVC plants consists mainly of the emission of dioxins and furans and the risks from the emission of vinyl chloride monomer (VCM), a known carcinogen. Although the immediate threats are to the vicinity of the plants, there is evidence that all these emissions can reach the marine environment (OSPAR, 2000).

In China, there is an additional problem in that the large majority of PVC plants in that country develop the PVC by an acetylene-based process starting from coal, in contrast to plants in the rest of the world which mainly use an ethylene-based process starting from oil. The production of the acetylene from coal requires a catalyst, which is currently mercury chloride (although research is in hand to develop a mercury-free alternative). About 574-803 tons/year of mercury are used (2009 figures), of which about 368-514 tons are lost in waste (China, 2010). It is not clear how much of this reaches the sea.

Figure 3. China: PVC production capacity and output (in 10,000 tons). Source: Chlor-Alkali Industry Association in China, 2010.

- (e) **Titanium dioxide (TiO_2) plants:** TiO_2 is used as a very white pigment, mainly in paint, plastics and paper. Different production processes are used for the two main mineral sources (ilmenite and rutile), but both produce large amounts of acid waste. In Europe in the 1970s, much of this was disposed of into the sea, either by pipeline or dumping. This gave rise to concern about effects on fish (Vethaak et al., 1991). Improved waste management methods, mainly through recycling the acid or its use in other products, have now largely removed these problems in Europe. Estimated production of TiO_2 is about 1.4 million tons/year each in Europe and the United States, and about 2.3 million tons/year in China, where production is growing rapidly (USGS, 2013).
- (f) **Mining:** Mining is a significant part of the economy in a number of States, and everywhere is a basic source of supply to manufacturing industry. In 2010, eight States were responsible for over 70 per cent by value of global

production from mining: Australia (15.6 per cent), China (15.0 per cent), Brazil (10.2 per cent), Chile (6.8 per cent), the Russian Federation (6.2 per cent), South Africa (5.9 per cent), India (5.6 per cent) and the United States (5.0 per cent). Mining formed over a tenth of Gross Domestic Product (GDP) in Papua New Guinea (33.4 per cent), Zambia (23.8 per cent), Chile (14.7 per cent), Ghana (12.7 per cent) and Peru (12.0 per cent) (ICMM, 2012).

From the point of view of the aquatic environment, the main concern about mining is the disposal of waste. Large amounts of pulverized rock mixed with water (“tailings”) are produced, which have to be stored or disposed of. Except that some mines remove cyanide (used in extracting metals), tailings are not treated before disposal. They therefore contain a large range of potentially hazardous substances. They can also cause problems through siltation and smothering of biota, particularly in the sea. Concerns about the consequent problems for the sea go back 600 years in south-west England (Worth, 1953). Tailings are most often stored on land behind dams. Catastrophic collapses of tailings dams can release toxic materials into watercourses and thence to the sea. Twenty-six tailing-dam failures in 15 countries have been noted between 2000 and 2014 (WISE, 2014). Not all of these will have affected the sea, but the 1996 event at Marinduque, in the Philippines, clearly had effects on the marine environment, making the sea much more acid, with elevated heavy-metal levels, as well as smothering a substantial area of the seabed (USGS, 2000). In some cases, tailings are also disposed of directly into rivers and into the sea. In 2012, there were 12 mines (1 in Indonesia, 5 in Norway, 4 in Papua-New Guinea, 1 in Turkey and 1 in the United Kingdom) practising disposal direct into the sea (IMO, 2012). In all cases the aim was to have a pipeline taking the waste well below the bulk of marine life in the water column. However, the tailings smother a large area of seabed, and are capable (depending on the local geology) of introducing substantial amounts of heavy metals into the marine environment.

- (e) **Smelting:** The smelting of metals, both ferrous and non-ferrous, can result in the emission of heavy metals to the atmosphere, which may then be deposited in coastal catchments and transported to the sea by watercourses, or deposited direct onto the sea by wet or dry deposition. For example, around 70 per cent of the emissions of lead to the atmosphere in Australia in 2003/04 were from non-ferrous metal processing (though not generally adversely affecting the marine environment). Ferrous-metal production also leads to emissions of lead to air: in Europe in 2000, it was estimated that lead emissions from iron and steel production was about half as much again as that from non-ferrous metal production. There is no recent estimate of the amount of global emissions of lead to air, but in 1983 it was estimated at 87,000-113,000 tons (this will have reduced substantially since with the reduction in use of leaded petrol/gasoline) (UNEP, 2010). When properly managed, metal smelting can have very limited adverse effects on the marine environment. However, production of many metals is increasing rapidly (see, for example, the figures in Table 1 for heavy metals). Likewise, the production of iron and steel is also increasing rapidly: pig-iron production increased by 85 per cent between 2001

and 2011 to 1,158 million tons/year (BGS, 2012). In particular, pig-iron production in China over the same period rose by over 300 per cent, so that it is now over half the annual world production. Even if the levels of emissions per ton of production are kept steady at the present level, the total load will increase in proportion.

Aluminium presents a special case. The primary form of production is by electrolysis. The Söderberg process became the predominant method. The carbon anode used in this process is consumed at a rate of about 0.5 ton for every ton of aluminium produced (ALCOA, 2014). Much of this carbon used to be emitted as polycyclic aromatic hydrocarbons (PAHs). Over time, better controls on PAH emission have been introduced, and more importantly, the Söderberg-process aluminium-smelting plants are being phased out – only about 7 per cent of global aluminium production is now by that process. From 2005 to 2010, world primary aluminium production increased by almost 30 per cent to 41.6 million tons (over one-third of which is in China, which has no Söderberg plants), but PAH emissions to air were reduced by 50 per cent per ton of aluminium produced (IAI, 2013);

- (f) **Paper industry:** Paper mills can give rise to a variety of environmental concerns. In relation to hazardous substances, the problems arise mainly from bleaching the pulp, a process needed for the production of most paper. During the period before the 1970s-1980s, the pulp and paper industry was the source of inputs giving rise to concern: polychlorinated dioxins and furans (PCDDs and PCDFs) were detected in effluents of pulp mills, resulting from the long-established use of chlorine in bleaching. It has proved possible to reduce this problem substantially by a mix of measures: principally by replacing elemental chlorine with chlorine dioxide and other oxygen-containing substances and by introducing closed systems and recycling the bleach-plant effluent. New processes have also been introduced: the Elemental-Chlorine-Free (ECF) and the Totally-Chlorine-Free (TCF) processes, which avoid the by-products of the chlorine bleaching process (EU BREF, 2001).

The paper industry has seen substantial growth in the period 2001-2012: worldwide production has increased by 23 per cent to just over 400 million tons. This growth has not been uniform: production in Canada and the United States has declined, while production levels in Africa, Europe, Oceania and the Russian Federation have remained more or less stable. The growth has been in Asia and Latin America, where production has increased over this period by 76 per cent and 34 per cent, respectively; production in China alone has grown by nearly 220 per cent to 103 million tons in 2012 (see Table 1 in Appendix to this chapter). Even if levels of contaminants per ton of production are kept at previous levels, growth on this scale will substantially increase the total load of contaminants finding its way to the sea. There is evidence (Zhuang, 2005) that the expansion of Chinese paper-making capacity has been accompanied by improved environmental management, but data to show the total effect do not seem to have been collated.

- (g) **Incinerators:** Increasingly, significant amounts of domestic and municipal waste consist of plastics containing chlorine. Much of this waste is disposed of through incineration. Where this happens in uncontrolled open-air burning, there is a substantial risk of the formation of dioxins and furans: almost any combination of carbon, hydrogen, oxygen and chlorine can yield some polychlorinated dioxins/furans under the wrong conditions (Altwicker et al., 1990). Even where the incineration takes place in purpose-built incinerators, a risk of such formation remains, especially where controls do not ensure that appropriate temperatures are reached during combustion or where devices to scrub or filter the flue gases are not installed or not properly maintained and operated. The same problem arises where incineration is used to dispose of wastes from industries that produce waste containing hazardous substances: if incineration is not properly done, both the hazardous substances in the waste and other newly created hazardous substances may be emitted.
- (h) **Fertilizer production:** The production of phosphate fertilizer produces substantial amounts of waste from the rock that has to be processed. Heavy metals, especially cadmium, are found in this waste, and reach the sea either from direct discharges or, in some cases, by leaching from land-based waste storage. Total world fertilizer production has risen by 23 per cent between 2002 and 2011, rising even more in South America (89 per cent) and East Asia (78 per cent). Production in Africa represents a fifth of the total world production, and concern has been raised about the impacts of some of the discharges (Gnandi et al., 2006).
- (i) **Desalination:** Desalination is very important in some parts of the world where fresh water is in short supply (see chapter 28). Desalination plants require massive intakes from the sea (capacity in the north and central Red Sea, for example, is over 1,750 megalitres⁶ a day (PERSGA, 2006), and in the Persian Gulf, it is over 10,900 megalitres a day (Sale et al., 2011)) and produce substantial discharges. The potential contaminants are found in discharges of heated, concentrated brine and of chemicals added to improve performance and to prevent corrosion (chlorine, copper and antiscalants). The effects of the brine discharge are mostly local (within tens of metres of the discharge), and are quickly diluted and dispersed, but in extreme cases they can be traced for several kilometres (Roberts et al., 2010). They are particularly significant in areas with high tidal ranges where the discharge is above the high-tide mark, where they can affect biota in the inter-tidal zone. Chlorine concentrations in discharges in the Red Sea average 0.25 ppm (standard swimming-pool chlorination is 1.0-3.0 ppm), and so local biocidal effects are possible. Copper concentrations in the discharges of a typical desalination plant are around 15 ppb, significantly above generally accepted criteria for satisfactory water-quality. In Red Sea desalination plants, about 9 tons of antiscalants a day are used and discharged. They have a relatively low toxicity and are diluted rapidly, and are therefore judged unlikely to pose a significant threat, but there

⁶ A megalitre is equivalent to one million litres or one thousand cubic metres.

is limited information on them. In general, the conclusion of a review of articles studying these problems was that discharge site selection is the primary factor that determines the extent of ecological impacts of desalination plants (Roberts et al., 2010). Overall, the Regional Organization for the Conservation of the Environment of the Red Sea and Gulf of Aden (PERSGA) determined in 2006 that desalination was not a threat to the Red Sea (PERSGA, 2006). No overall assessment of effects in the Persian Gulf appears to have been made (Sale et al., 2011).

4. Diffuse Sources

There are manifold diffuse sources of hazardous substances that can reach and affect the ocean. The main pathways are through surface water runoff in watercourses (both from liquid discharges and from leaching), groundwater discharges, and wet and dry deposition of emissions to the atmosphere. The most significant processes are waste disposal, routine combustion processes, abrasion, use of biocides and accidents. All of these affect both land and sea, and there is nothing special about the methods to control these processes for the purpose of protecting the marine environment. It is, however, necessary to ensure that marine aspects of the impact of all hazardous substances are specifically considered in decision-making on control measures, because the effects of some hazardous substances are significantly greater (or different) than in freshwater or land environments. Other compounds released from diffuse sources that have been suggested for consideration include pharmaceuticals (both human and veterinary) and cosmetic ingredients (such as musk xylene). Evaluation of such substances has not yet shown general agreement that there are significant problems which need action, although some regulatory bodies are keeping some of these substances under observation.

4.1 Waste disposal

Adverse effects on the marine environment from waste disposal can arise from a wide range of processes. Leaching from land-fills into which waste has been deposited is probably the major source. This can be significant for brominated flame retardants (PBDEs and related substances (see entry in Table 1)). Industrial liquid waste will often enter into municipal waste water treatment systems – these can be regarded as point sources, but at the same time they usually collect waste water from a large area. The waste entering municipal waste water treatment systems also includes runoff from accidents involving the spilling of hazardous substances. A large number of hazardous substances will form part of materials in waste streams. Among the heavy metals, lead and cadmium are particularly significant given their widespread use in batteries: 80 per cent of all lead used in OECD countries is used in batteries (ILZG, 2014). Although there is a strong economic interest in recycling such lead (and lead is the most recycled non-ferrous metal), there is a substantial risk that it will eventually leach to the ocean from badly managed waste streams. The same

applies to other heavy metals (such as cadmium) which are also used in batteries and electronic equipment.

Plastics containing chlorine compounds (such as PVC) form a significant part of waste streams in most countries. These therefore also present problems for the marine environment if disposal is not properly managed, because inadequately controlled combustion can result in the release of hazardous substances to the marine environment.

The Global Alliance on Health and Pollution (which includes, among others, UNEP, UNDP, UNIDO and the World Bank) has developed an international register of over 2,000 sites in middle- and low-income countries (as defined by the World Bank) where pollution problems are occurring (<http://www.pollutionproject.org/about-tsip/>). A large number of these sites are in the immediate coastal zone. Although this exercise has been focused on implications for human health, the extent to which the problems at these sites consist of uncontrolled releases of hazardous substances gives an indication of the extent to which badly managed waste-disposal sites and other sites with toxic deposits can present a problem for the ocean. In more developed countries, there are also problems from sites with toxic deposits, but remediation efforts appear to have been implemented in many of these cases (Ericson et al., 2013).

4.2 Use of Pesticides

The purpose of pesticides is that they are spread into the environment in order to control the pest against which they are aimed. If the pesticides are applied improperly, if surplus pesticides are not adequately disposed of, or if the chemicals involved have a sufficiently high degree of persistence before they degrade, they will eventually reach the marine environment. As shown above, action has been taken to remove from use many of the pesticides that give rise to most concern about their impact on the marine environment because of their toxicity, persistence and bioaccumulativity. However, even where such pesticides have been removed from the market, stocks often remain, and residues from past use persist in the soil and watercourse sediments that can make their way to the sea. In some cases, the judgement has been made that controls on the use of the pesticide will be sufficient to guard against harm to the oceans (see above on atrazine). In all these cases, therefore, there is a strong case for continued monitoring to check that bans are working and that usage conditions are being observed.

4.3 Routine combustion processes

Some hazardous substances, especially polycyclic aromatic hydrocarbons (PAHs), can be created by relatively common combustion processes, such as wood-burning stoves (Oanh et al., 1999). Uncontrolled burning of waste, such as rubber tyres, is another such source. Such emissions can be limited by better design of stoves and by better management of waste disposal. However, effective control of all such sources is unlikely to be practicable.

4.4 Abrasion

Some hazardous substances are used in products such as vehicle tyres and paint, where eventual abrasion is likely to free them into the environment, as the tyres are worn down or the paint peels off. Significant progress was made in reducing this kind of contaminant with the replacement of white lead paint by paint based on titanium dioxide (Waters, 2011). Substitution of this kind is the most effective way of resolving this kind of problem.

4.5 Small-scale gold-mining

A traditional, but crude, refining process for recovering gold from ore uses mercury to create an amalgam with the gold and subsequently vaporizes the mercury to leave high-quality gold. The vaporized mercury becomes an airborne contaminant, and can reach and affect the ocean. Artisanal gold-mining has been estimated to account for about 25 per cent of global gold production (Donkor et al., 2006). The predominant refining process in artisanal gold-mining is the mercury-amalgam process. It is judged to be the sector with the largest source of mercury emissions to the air (UNEP, 2008). The Minamata Convention on Mercury (2013) requires States bound by the Convention which have artisanal and small-scale gold mining to reduce and, where possible eliminate the use and environmental releases of mercury from such mining and processing.

4.6 Accidents

Wherever hazardous substances are produced, stored or transported, there is scope for accidental releases. There is no effective global source for statistics of accidents involving hazardous substances (ILO, 2007). In several countries, systems have been established to provide for the location, design and inspection of premises where hazardous substances are produced or stored and of vehicles carrying them, and for response to, and investigation of, significant accidents that do occur (for example, the European Union Seveso Directive (EU, 1996)).

5. Regional View of the Impact of Hazardous Substances on the Ocean

The lack of data makes it impossible to develop a general assessment of the relative impacts of hazardous substances on the ocean in the different parts of the world. In some areas, regional or national efforts have produced time-series of observations that enable trends to be established. But even here, the need to work through a number of institutions often means that clear comparisons between the absolute situation in different areas is not possible: different measuring techniques may be used; significantly different ranges of varieties of chemicals may be observed; and

there is often an absence of any ring-testing to validate the accuracy of different institutions.

5.1 *Open ocean generally*

Observations of the presence of heavy metals and other hazardous substances in the open ocean⁷ are very limited, including areas around islands and archipelagos in the open ocean. Few specific studies of pollution in the open ocean have been conducted. What information is available is concentrated on the north Atlantic. The Indian Ocean and the southern parts of the Atlantic and Pacific Oceans have hardly been assessed.

For hazardous substances, the most significant route for impacts on the open ocean is transport through the atmosphere: hazardous substances can be carried either as aerosols (that is, microscopically fine particles of solids or liquids suspended in the air) or as gases (particularly in the case of mercury). The substances can remain suspended for long periods, and thus travel long distances. However, available evidence does not show that heavy metals in the open ocean are at levels causing adverse effects on humans or biota – with the exception of mercury. The load of mercury in the atmosphere has approximately tripled in the last two centuries. This has led to a probable doubling of inputs to the ocean. However, evidence also exists that, in some open-ocean areas such as near Bermuda, levels of mercury in the sea have decreased from the early 1970s to 2000. Nevertheless, there is good evidence that some fish concentrate mercury in their flesh to levels which give rise to risks for humans who eat a lot of such fish. Mercury concentrations in midwater fishes are several-fold higher than in epipelagic fishes at the same trophic level. Mercury levels in deep-sea fishes, such as morids and grenadiers, are substantially higher than in shelf-dwelling fishes, such as cod; notably long-lived fishes on seamounts, such as orange roughy and black cardinalfish, have mercury levels near or at the levels normally regarded as permissible for human consumption (0.5 ppm). Human activities have also led to higher levels of airborne inputs of lead and cadmium, but in these cases there is no evidence yet of toxic effects ((Monteiro et al., 1996; Koslow, 2007; GESAMP, 2009).

For persistent organic pollutants (POPs), there is no doubt about their ability to be carried long distances through the atmosphere – this was one of the major reasons for the concerns that led to the Stockholm Convention. Although the effects of deposition of POPs on land have been extensively studied, information specifically on the levels of deposition of these substances in the open ocean and their possible effects is very limited (GESAMP, 2009). Estimates suggest that concentration of POPs may be an order of magnitude higher in deep-sea than in near-surface-dwelling fishes, and the deep sea has been referred to as their ultimate global sink (Froescheis et al., 2000; Mormede and Davies, 2003).

⁷ As explained in Chapter 1, “open ocean” in this Assessment refers to the water column of deep-water areas that are beyond (that is, seawards of) the geomorphic continental shelf. It is the pelagic zone that lies in deep water (generally >200 m water depth).

5.2 Arctic Ocean

In the Arctic, downward trends are reported in concentrations of the POPs controlled by the Stockholm Convention. Levels in marine mammals, some seabirds and polar bears are still high enough to cause adverse effects on their immune systems and reproductive success, but this is not the case for fish. Of the heavy metals, lead concentrations in biota were assessed as low in 1997 and since then they have been found to be decreasing. Mercury has been found at relatively high levels in whales, but the presence of selenium is also high enough to neutralize any detrimental effects. Parts of northern Canada have substantial natural levels of cadmium. The runoff from these deposits is reflected in the marine biota. Local pollution from heavy metals and some POPs is found around some mines, especially on the Kola Peninsula (Russian Federation) and some military installations, such as the Distant Early Warning System stations in northern Canada. In addition, one report suggests that 12 million drums of unknown, but potentially polluting, contents have been left in the Russian Federation: remediation is under way (AMAP, 1997; AMAP, 2009). Nevertheless, atmospheric transport and transport by ocean currents of pollutants are still significant issues for the Arctic (Stemmler et al., 2010; Ma et al., 2015).

5.3 Atlantic Ocean and Adjoining Seas

5.3.1 North-East Atlantic Ocean, North Sea, Celtic Seas

The North-East Atlantic is one of the most thoroughly assessed areas of the ocean: two comprehensive assessments were carried out in 2000 and 2010 (OSPAR, 2010). It is also an area where major efforts have been made since 1975 to reduce inputs of hazardous substances. Assessments are made of each of the contaminants studied, rather than attempting to combine them in a single indicator.

Statistically robust results show major reductions in the amounts of heavy metals being introduced into the marine environment in this area (Green et al., 2003). This is also demonstrated from monitoring by the OSPAR Commission (see Table 2).

Table 2 Percentage change in inputs of some heavy metals into North Sea and Celtic Seas 1990-2006.

Area	Cadmium - riverine input	Cadmium - direct discharges	Lead - riverine inputs	Lead – direct discharges	Mercury – riverine inputs	Mercury - direct discharges
North Sea	-20%	-75%	-50%	-80%	-75%	-70%
Celtic Seas	-60%	-95%	No trend	-90%	-85%	-95%

Source: OSPAR, 2010

A large part of these reductions was achieved in the 1990s: progress since 1998 has been slower. Concentrations in some areas, such as around the industrial estuaries of the Rhine (the Netherlands), the Seine (France) and the Tyne, Tees and Thames (United Kingdom), as well as in certain industrialized estuaries in Norway (Inner Sjørfjord) and Spain (Ría de Pontevedra) and the inner German Bight, are still at levels giving rise to risk of pollution effects. High concentrations of cadmium found in fish and shellfish around Iceland seem to be linked to volcanic activity, such as the eruption of the Eyjafjallajökull volcano in Iceland in 2010 (OSPAR, 2010).

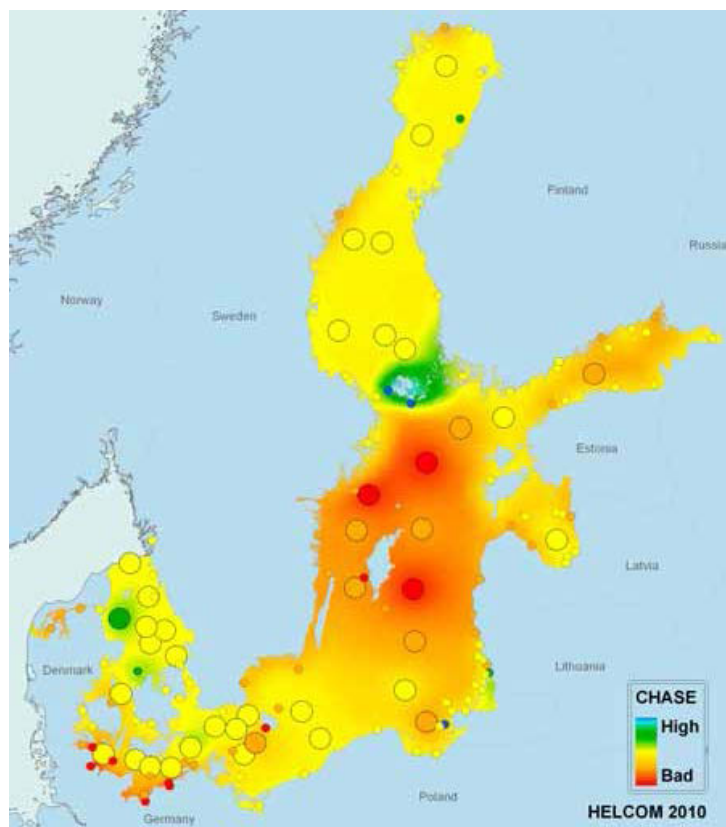

Trends in concentrations of PAHs in fish and shellfish are predominantly downward, especially in the Celtic Sea but, in many estuaries and urbanized and industrialized locations, they are still at levels which pose pollution risks. In many locations in coastal waters, concentrations of at least one polychlorinated biphenyl (PCB) congener pose a risk of causing pollution effects. Similar concern has arisen over the exposure to perfluorinated compounds, particularly perfluorinated octanoic sulfonate (PFOS). Over 25 years after being banned, PCBs are thought to be possibly causing adverse biological impacts in some areas: the Faroese authorities (Denmark) have initiated a risk management process for the human consumption of pilot-whale meat (a traditional food source in the Faroe Islands) because of the presence of POPs.

Observations show that concentrations in fish and shellfish of the pesticide lindane (which has been banned since the early 1980s) are decreasing generally. However, concentrations in some localities are still of concern. These probably represent past use on nearby land. The more recent cessation of the use of other pesticides classed as hazardous substances is seen as likely to achieve similar results.

5.3.2 Baltic Sea

The Baltic Sea is an enclosed water-body with very limited water exchange with the North Sea and the North-East Atlantic. Periodically major inflows occur, bringing in substantial amounts of new water with high salinity from the North Sea. These inflows were fairly frequent until about 1980, but thereafter became infrequent, occurring in 1993, 1997, 2003, 2011 and 2014. The large quantity of freshwater from the Baltic catchments, together with the limited exchange with the North Sea, allows the build-up of hazardous substances in the basins of the Baltic Sea. Like the North-East Atlantic, the Baltic has a long-standing practice of assessment of the state of the marine environment. The Helsinki Commission has developed a multimetric indicator-based assessment tool. This has been used to integrate the status of contamination by individual chemicals and biological effects at specific sites or areas into a single status value termed the “Contamination Ratio” (CR). This CR is the ratio of the current status (the measurement of the concentration of a substance or biological effect) and a threshold level or quality criterion for that particular substance or biological effect. The CRs of all substances or indicators are grouped under four different ecological objectives (contaminant concentrations in the environment generally, contaminant concentrations in fish, biological effects on wildlife and levels of radioactivity) and integrated to yield a status classification (“high”, “good”, “moderate”, “poor” or “bad”) for each ecological objective. The ecological objective receiving the lowest status classification serves as the overall

classification of the assessed site or area, giving the classification of the “hazardous substances status” of that site or area. The criteria used are not all uniform, but may include nationally set criteria. Therefore the results are not strictly comparable between assessment units. The overall picture is shown in the adjacent map, based on assessments at 144 sites, where “high” indicates good conditions and “bad” bad conditions of the marine environment with respect to hazardous substances (HELCOM, 2010a; HELCOM, 2010b).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 4. Baltic Sea: Combined Hazardous Substances Contamination Index. Source: HELCOM, 2010a.

Overall, there has been a steady and substantial improvement in the quality of the Baltic in respect of hazardous substances over the past two decades. This is due partly to the focus of the Baltic States in tackling the hotspots of pollution that were identified, and partly to the closure during this period of a number of the more polluting plants in countries in economic transition, as a result of economic circumstances. In the countries in economic transition, the former large installations have been superseded by a larger number of small and medium-sized enterprises, which makes the task of adequate regulation more difficult. There is, nevertheless, much further progress to be made before the goals set by the Helsinki Commission are reached.

5.3.3 Mediterranean Sea

The Barcelona Commission has carried out assessments of many aspects of the state of the Mediterranean over the last four decades. Nevertheless, there are major gaps

in the data available for assessment: much more is known about contaminants in the sea off the northern coasts of the Mediterranean than about those off the southern and eastern coasts. Major sources of discharges and emissions of heavy metals are seen as the cement industry, electricity generation, metal mining and smelting, and fertilizer production. Many waste-water treatment plants are also seen as a problem. Based upon the available information, high concentrations of heavy metals (especially lead and/or mercury) in sediments and shellfish (blue mussel (*Mytilus galloprovincialis*)) are found around Barcelona, Cartagena and Malaga (Spain), Marseilles/Fos and Toulon (France), the Gulf of Genoa, the Po delta, the Gulf of Trieste and around Naples (Italy), the coast of Croatia, Vlora Bay (Albania), around Athens, Thessaloniki and Kavala (Greece), around Izmir (Turkey) (though subsequent Turkish Government tests have found nothing that would require action to be taken), Haifa Bay (Israel), the Nile delta (Egypt) and the coastal lagoons of Bizerta and Tunis (Tunisia). Insufficient data were available for robust trend analysis, but the limited analysis possible showed a general pattern of stable to declining trends, although in some places there were slightly increasing trends (UNEP, 2012).

In the past, high levels of POPs have been measured in top predators in the Mediterranean. More recently, a study of data from 1971-2005 has concluded that the contamination of sediments by POPs is mainly associated with major urban areas, the mouths of major rivers, major ports and coastal lagoons, and that there has been a general decline in such concentrations. A 2011 study identified the areas of the mouth of the River Ebro and Barcelona (Spain), the mouth of the Rhône and Marseilles (France), the coast from Nice (France) to Livorno (Italy), the area around Genoa (Italy), the coast of Croatia and the port of Piraeus (Greece) as showing elevated levels of PCBs. Most of these locations, together with the Bay of Naples, the coast of the Marche and the Gulf of Trieste (Italy), the area around Dürres and Vloa Bay (Albania), the Ambracian, Saronic and Thermaic Gulfs (Greece), the area around Izmir (Turkey), the Bay of Tunis (Tunisia) and the Bay of Algiers (Algeria) also showed moderate to high levels of chlorinated pesticides. Again, data were insufficient for trend analysis (UNEP, 2012). Turkish authorities have subsequently indicated that there have been no findings which would have required measures to be taken.

5.3.4 Black Sea

Contamination by pesticides and heavy metals has not been judged to be a basin-wide problem by the Black Sea Commission. Elevated concentrations of heavy metals in bottom sediments and biota near river mouths, hot-spots and ports are decreasing. Pesticides are mostly introduced through rivers and streams discharging from agricultural areas. However, as a result of economic change, the use of these substances has decreased considerably and no longer presents a major hazard, except where their use was very intensive in the past. Elevated concentrations of HCH (mainly lindane) have been found along the coastal areas influenced by the Danube River: some sites near the Danube Delta were found to be among the highest levels of HCH recorded globally. In 2002, evidence was found of DDT and its breakdown products, probably from inappropriate storage of expired pesticides (Black Sea Commission, 2008; Heileman et al., 2008c).

5.3.5 North-West Atlantic

As in the Arctic, the problems of airborne transport of POPs found in the Arctic are also of concern in Labrador and Newfoundland. The main influence further south in Canada is the outflow of the St Lawrence River, which drains a large part of the heavily populated interior of Canada and the United States. The work derived from the efforts of the Canada/United States International Joint Commission (on shared water bodies) has done much to reduce the hazardous-substance content of this outflow. Similarly much has been done in Canada to address the problems posed by coastal industries, especially paper and pulp mills. As a result, hazardous substances are not seen as a priority for the Canadian Atlantic (Janowicz et al., 2006). Nevertheless, some problems remain, particularly in the Saguenay Fjord, where mercury and other metals were found in beluga whales at levels sufficient to cause concern. Cultured and wild scallops have been found to contain cadmium above the levels acceptable for human consumption, although its main source seems to be of natural origin (Dufour et al., 2007).

In the United States, the National Coastal Condition Reports (NCCR) (of which the latest NCCR IV was completed at the end of 2012, though based on data from 2003-2006 (EPA, 2012)) have been prepared regularly since 2000. They consider indices of water quality, sediment quality, benthic quality, coastal habitats and fish-tissue contaminants. They examine the coastal waters (estuaries and embayments) and also look at some of the waters further offshore. The sediment-quality index and the fish-tissue contaminants are the most relevant to the question of contamination by hazardous substances, although the benthic index (which looks at the structure of the benthos and the extent to which it is affected by pollution) can also be illuminating. The sediment-quality index is based on measurements of toxicity, amounts of contaminants (heavy metals, PAHs and PCBs) and total organic carbon content in samples taken from a range of stations, which number thousands across the country. The fish-tissue contaminants index is based on samples of fish for human consumption of species appropriate to the region. The indices for the sampling stations within a region are used to classify the region as “good”, “fair” or “poor”, according to the proportions of sampling stations within different bands of the indices.

The United States divides its Atlantic coast into two regions: the North-East region (Maine to Virginia, including Chesapeake Bay), and the South-East region (North Carolina to Florida). The North-East region is the most heavily populated part of the United States, and the overall condition of its coastal waters is judged to be “fair”. The positions on the sediment-quality index (overall “fair”) and the fish-tissue contaminant index (overall “fair to poor”) are shown in the pie charts below. The problem zones for both sediments and fish-tissue contaminants are principally in Great Bay (New Hampshire)^{DDT, Hg}, Narragansett Bay (Rhode Island), Long Island Sound, the New York/New Jersey harbour area^{DDT, Hg}, the Upper Delaware Estuary and the western tributaries of Chesapeake Bay. The impaired ratings for the large majority of these sites were due to the presence of PCBs. Advice was also issued at various dates during 2006 against eating fish caught along about 84 per cent of the length of the coast of the North-East region – mainly because of the presence of

PCBs. Those marked ^{DDT} also showed, above the thresholds, moderate to high levels of DDT and those marked ^{Hg} showed moderate levels of mercury. The NCCR also considered whether trends could be detected over the period from 2001 to 2006. No overall statistically valid trends were noted, but a significant reduction was observed in the areas judged as “poor” on the element of the presence of contaminants from Narragasset Bay to the Delaware River.

Figure 5. United States North-East Region Sediment and Fish-Tissue Contaminants Indices. Source: EPA, 2012.

In Chesapeake Bay, where a combination of problems of toxic contaminants and eutrophication resulted in 2009 in a special programme involving the Federal Government and the five States, the most recent report shows that for PCBs and mercury, many locations in the catchment have an impaired ecological status, largely stemming from concentrations in sediments and in fish tissue (where human consumption often has to be discouraged). A limited number of locations have severe problems from dioxins/furans, PAHs, some chlorinated pesticides (aldrin, chlordane, dieldrin, DDT/DDE, heptachlor epoxide, mirex), and some metals (aluminium, chromium, iron, lead, manganese, zinc). For other products (atrazine, some pharmaceuticals, some household and cosmetic products, some brominated flame retardants and biogenic hormones), it was not possible to assess where severe impacts were occurring, but it is known that that the substances have potential for adverse, sub-lethal ecological effects (EPA et al., 2012).

The NCCR also looked at the condition of the Mid-Atlantic Bight: that is, the seas between Cape Cod and Cape Hatteras out to the edge of the continental shelf. None of the contaminants for which tests are made for the sediment-quality index or the fish-tissue contaminants index was found in excess of their corresponding Effects Range Medium (ERM) values (values probably causing harmful effects). Only three chemicals (arsenic, nickel, and total DDT) exceeded their corresponding Effects

Range Low (ERL) values (values possibly causing harmful effects), and these lower-threshold exceedances occurred at only a few sites. This implies that, on the same basis as for waters closer to the shore, this sea area should be regarded as in a “good” condition.

The overall condition of the South-East region (North Carolina to Florida) was judged to be fair. The sediment-quality index was judged to be “fair to poor” and the fish-tissue contaminants index was rated “good”. No statistically significant trends were observed for the period 2001-2006. Conditions in the bight between Cape Hatteras and the south of Florida were also examined. Three metals (arsenic, cadmium, and silver) were found at concentrations between ERL and ERM values at 9 of the 50 offshore sampling sites, but no sites had more than one ERM value exceeded. Nevertheless, advice was in force in the whole area against eating king mackerel (*Scomberomorus cavalla*), because of mercury contamination.

A separate study – the National Mussel Watch – looked over a 20-year period (1986 – 2005) at levels of contamination by hazardous substances in mussels and oysters along the coast. For the Atlantic coast, this has shown in general no significant trends in contamination by heavy metals, but some locations show a decreasing trend. It has shown no significant trend in cadmium contamination in Chesapeake Bay, in spite of major efforts at reduction, and has shown significant increasing trends in mercury and lead at a few locations in the zones where problems were identified by the NCCR. Nevertheless, it has shown significant decreasing trends in contamination by POPs all along the Atlantic coast of the United States (Kimbrough et al., 2009; Mussel Watch, 2011).

5.3.6 Wider Caribbean

Information on hazardous substances in the Wider Caribbean (that is, the Gulf of Mexico, the Caribbean Sea and the Atlantic immediately east of the Leeward and Windward Islands) is mixed: for the United States and its dependencies, the same type of information is available as for the Atlantic coast; elsewhere, there is no systematic record.

The overall condition of the United States Gulf coast is judged to be “fair”. The sediment-quality index was judged to be “fair to poor” and the fish-tissue contaminants index was rated “good”. The areas rated “poor” on the sediment-quality index lay mainly around the Florida Keys, the coasts of Alabama and Mississippi, Galveston (Texas) and the Texas coast south of Corpus Christi. No statistically significant trends were observed for the period 2001-2006, but a substantial reduction in areas failing the test for the presence of contaminants was found. Nevertheless, in 2006 advice was in force along the whole of the United States Gulf Coast against the eating of king mackerel (*Scomberomorus cavalla*), because of mercury contamination (EPA, 2012). The Mussel Watch has likewise shown some locations with decreasing trends in heavy-metal contamination and a general decreasing trend in contamination by POPs (Mussel Watch, 2011).

There is no recent, comprehensive compilation and analysis of inputs of hazardous substances to the remainder of the Wider Caribbean (Fernandez et al., 2007), although specific areas are known where problems of this kind are found (Cartagena

Bay, Colombia; Puerto Limon, Costa Rica; Havana Bay, Cuba; Kingston Harbour, Jamaica; and some locations in Puerto Rico). These largely result from the discharge of untreated waste-water from local industries. Mining also presents significant problems, particularly mining of bauxite in Guyana, Jamaica and Suriname and (to a lesser extent) in the Dominican Republic and Haiti (GEF, 1998; EPA, 2012). Heavy and increasing usage of agricultural pesticides is reported from the mainland countries of Central America, and from Jamaica and Cuba (UNEP-UCR/CEP, 2010). In addition, chlordecone (an agricultural pesticide, the use of which was prohibited from 1993) gave rise to concern in fish and seafood from Martinique in 2003 (Bocquenéa and Franco, 2005). The presence of the same chemical in seafood was still preventing it being marketed in 2013 (*Le Monde*, 2013).

5.3.7 North Atlantic open ocean

The OSPAR Quality Status Report 2000 (OSPAR, 2000) examined the situation in the open ocean of the Atlantic (beyond the 200-m isobath) east of 42°W longitude. This showed limited information about the state of the marine environment in this area. No later comprehensive survey has been made. The conclusions on contamination by hazardous substances were that:

- (a) Airborne inputs of hazardous substances from land were very significant: probably equal to the effects of waterborne inputs reaching the deep Atlantic;
- (b) Anthropogenic inputs to the North Atlantic were higher than those to other deep ocean areas, representing up to 25 per cent of the total estimated global deposition rates for a range of substances;
- (c) Nevertheless, the level of concern for the area about contamination by hazardous substances was rated as low.

5.3.8 South-East Atlantic

The coastal waters of the South-East Atlantic are dominated by three currents: from north to south, the Canaries Current, the Guinea Current and the Benguela Current. These three areas have been adopted for the tasks of addressing the problems of the marine environment. Little detailed information is available about land-based sources of pollution in these areas. What is clear is that the main problems are “hot spots” in the proximity of the principal coastal cities: Abidjan (Côte d’Ivoire), Accra (Ghana), Cape Town (South Africa), Casablanca and Rabat (Morocco), Dakar (Senegal), Douala (Cameroon), Lagos and Port Harcourt (Nigeria), Luanda (Angola) and Walvis Bay (Namibia). Most of the industries operating in the region are located in or around these coastal areas and discharge untreated effluents directly into sewers, canals, streams and rivers that end up in the ocean. Outside the immediate areas of discharge, however, the effects are limited by the strong marine current (Heileman, 2008b).

Nevertheless, some specific problems are more than local. Mercury emissions from artisanal gold-mining in West Africa are a general problem. This gold production is an important part of the national economies of several States in the area, but significant levels of mercury have been found in many West African rivers, and

therefore present risks to the marine environment (Donkor et al., 2006). Other mining activities also present significant threats. For example, phosphate mining at Hahatoé-Kpogamé in Togo results in discharges of tailings and other waste with high levels of cadmium and lead being found in fish and crustaceans (Gnandi et al., 2006).

Samples from the Korle (Accra, Ghana), Ebrié (Abidjan, Côte d'Ivoire) and Lagos (Nigeria) lagoons, show heavy metals in the sediments up to three (Cd), six (Hg) and eight (Pb) times more than those from uncontaminated areas, and in shellfish at or above WHO standards for Cu, Pb and Zn (GCLMEP, 2003).

5.3.9 South-West Atlantic

Although there are studies of several locations along the coast of Brazil, there does not appear to be a comprehensive study of the levels of heavy metals or POPs for the coastal sea of Brazil as a whole. It is clear that there are many untreated direct and riverine discharges from coastal cities which produce significant local effects: São Paulo, with a population of over 11 million and a concentration of petrochemical and fertilizer industries, and Rio de Janeiro, with over 6 million inhabitants, are the most significant, but there are other examples, such as Rio Grande. The River Amazon also has a major effect on the northern part of the area. The diffuse sources contributing to this effect include agricultural pesticides and mercury from small-scale gold mining (Heileman, 2008a, Heileman, 2008c; Heileman and Gasalla, 2008; Niencheski et al., 2006).

The situation is much the same further south: there are hot-spots associated with major coastal cities, but no overall survey. The River Plate is a major influence, since it drains areas with a high concentration of potentially polluting industries, and is assessed as highly polluted. Apart from that, the most serious area is around Bahia Blanca, where the general level of contamination has been assessed as moderate (Marchovecchio, 2009). However, the San Matias Gulf has also been identified as having relatively high levels of cadmium and lead (Heileman, 2008e).

5.3.10 South Atlantic open ocean

Very limited information is available on levels of contaminants in the central South Atlantic. Nevertheless, samples of skipjack tuna, tested for brominated flame retardants as a marker for widely dispersed POPs, show levels that are lower than in the open ocean of the Pacific (Ueno et al., 2004).

5.4 Indian Ocean

No comprehensive studies or time series of the incidence of hazardous substances in the Indian Ocean exist, although there are a number of local, one-off studies.

5.4.1 Western Indian Ocean

In general, the areas of both the Agulhas Current (the waters off the coasts of eastern South Africa and Mozambique and around the Comoros, Madagascar, Mauritius, Réunion (France) and the Seychelles) and the Somali Current (the waters off the coasts of the Federal Republic of Somalia, Kenya and the United Republic of Tanzania) are not heavily polluted with heavy metals or POPs (Heileman et al.,

2008b). Nevertheless, some top predators (yellowfin tuna) are reported to show high concentrations of HCB and lindane by comparison with the same species elsewhere, although levels of PCBs and DDTs are not so high. The residues of PCBs, DDTs, lindane and HCB were higher than those measured in 1999 (Machado Torres et al., 2009).

However, relatively severe localized problems are found near major cities and industrialized areas in all the countries. The main industries that contribute towards chemical contamination in this region include: manufacturing, textiles, tanneries, paper and pulp mills, breweries, chemical, cement, and sugar and fertilizer factories. Coastal solid-waste dumps add to the problems. The intensive use of agrochemicals, such as DDT, aldrin and toxaphene, has been common throughout the region. Inappropriate utilization, storage and dumping of agrochemicals are a growing concern. Direct discharge of wastes from fertilizer factories is a severe problem in the region (Heileman et al., 2008a). Mozambique has instituted a legal and institutional framework for the management and treatment of municipal and industrial waste, including the development of sanitation infrastructure (landfills, industrial and wastewater treatment plants).

5.4.2 Red Sea, including the Gulf of Suez and the Gulf of Aqaba, and the Gulf of Aden

Slow water turnover makes the Red Sea particularly vulnerable to pollution build-up. Pollution is severe in localized areas around industrial zones and facilities, including especially the Gulfs of Suez and Aqaba and near the port of Aden. The installations include phosphate mines, desalination plants, chemical industrial installations and oil production and transportation facilities. In 2003, elevated levels of some heavy metals were found near Suez, in the Sharm al Maya Bay in Egypt (PERSGA, 2006; EEA, 2003).

5.4.3 Persian Gulf

Major manufacturing industries operate in the coastal States of the Persian Gulf, based largely on the raw materials from oil and gas extraction, producing fertilizers, chemicals, petrochemicals, minerals and plastics. The demand for fresh food has also led to intensive agriculture and the use of pesticides. All these activities have resulted in waste-water and runoff taking heavy metals and other hazardous substances into the semi-enclosed sea of this area (Sale et al., 2011).

5.4.4 Arabian Sea and waters west of India, the Maldives and Sri Lanka

Overall, pollution from hazardous substances in the northern Arabian Sea has been assessed as severe in several coastal hotspots, but in general it has been evaluated as moderate. The major issues in these hotspots are heavy metals from industrial installations. Other hotspots are found at the mouths of some major rivers (for example, the Tigris, Euphrates, Karun, Hileh and Mand rivers). Other hotspots involving PAHs have been recorded in coastal areas receiving effluents from highly industrialized zones. In waters off Pakistan, chlorinated pesticides are more prominent. Since persistent organic pesticides are not to be marketed in the States bordering the Arabian Sea, these findings likely result from the remains of historic use (Heileman et al., 2008a).

Along the coasts of India the picture is mixed. High concentrations have been noted, for example, off the Maharashtra coast. Near Mumbai, sample fish have also been shown to have concentrations of lead, cadmium and mercury above levels that are generally regarded as fit for human consumption (Heileman et al., 2008a; Deshpande et al., 2009). Around the Alang-Sosiya ship-breaking yards in Gujarat, India (which employ 40,000 people), on the basis of samples taken in 2001, particularly high levels, above approved limits of heavy metals in sediments, have been reported (Janil et al., 2011). On the other hand, along the Gujarat coast, the concentrations of mercury in sediments have decreased to below the limits of detection, reflecting the decrease in its concentrations in land-based effluents. Along the Maharashtra coast, mercury levels in sediments have declined and are currently about 0.1µg/g. Along the Karnataka coast, observations have been made off Mangalore and Karwar. At both locations, concentrations of mercury in sediments have shown decreasing trends. Along the Kerala coast, concentrations of mercury were low at all sampling locations, and exhibited declining trends (NIOT, 2014).

In Sri Lanka, most industrial plants are concentrated near Colombo. They lack wastewater treatment capacity, and textile and metal-finishing plants are discharging significant quantities of some heavy metals. The Lunawa coastal lagoon has been ruined by such discharges (BOBLME, Sri Lanka, 2011).

5.4.5 Waters east of India, the Maldives and Sri Lanka (Bay of Bengal, Andaman Sea, Malacca Strait)

The dominant influence in the north of this area is the River Ganges, the second-largest hydrological system on the planet. The Bay of Bengal Large Marine Ecosystem Project (BOBLME) has organized recent surveys of marine pollution in all the coastal States. These show that much information is available, but there are no time series or sufficient metadata for comparisons.

In the waters off India, along most of the coast, concentrations of mercury in sediments have declined: off Tamil Nadu, concentrations were observed at <0.1 µg/g; off Andhra Pradesh, there has been a substantial decline to a similar level; and the coast off Orissa exhibited a decline to concentrations of 0.1-0.2 µg/g. In contrast, off West Bengal mercury content of sediments showed a marginally increasing trend both in-shore and near-shore: recent values of up to 0.3 µg/g suggest continued release of industrial waste containing mercury (NIOT, 2014). Hot-spots for heavy-metal pollution are found in the Ganges estuary (the Hooghly River, Diamond Harbour, Sagar Island and Haldia). Further south, hot-spots have been reported at Bhitarkarnik, Visakhapatnam, Ennore, Cuddalore, and Tuticorin. At all these places, pollution from heavy metals results from direct industrial discharges and the inputs of rivers carrying industrial discharges. Pollution from POPs stems mainly from pesticide-manufacturing plants and ineffective storage of withdrawn pesticides, as well as the leaching of pesticides and past uses of PCBs. Recent surveys indicate significant levels of DDT, PCBs and dieldrin in both near-shore and off-shore fish in the Bay of Bengal (BOBLME, India, 2011).

For Bangladesh, the picture is very similar. In addition, heavy metal pollution is particularly noticeable near the Sitakunado ship-breaking area of Chittagong. Reports from 2004 suggest that banned organo-chlorine pesticides are being sold on

the black market and that some are being used in fish-processing plants (BOBLME, Bangladesh, 2011).

In the waters off Myanmar, significant levels of heavy metals have been reported in fish samples, but at levels below those at which human consumption is not advised. Organochlorine pesticides are not regarded as a problem because of lack of availability for use (BOBLME Myanmar, 2011).

In the Andaman Sea off Thailand, levels in sediments of lead and cadmium were reported in 2009 that were well above levels regarded elsewhere as likely to cause harm, and in 2007 levels of mercury in sample fish were reported that were above Thai and many other national standards for human consumption (BOBLME, Thailand, 2011).

On the western coast of peninsular Malaysia, levels of contamination of hazardous substances observed in 2009 and 2010 were in general within national standards, which are consistent with generally recognized standards. Exceptions were off the coast of Perak, where significant numbers of samples showed lead and cadmium levels in excess of these standards. This is attributed to major historic mining activities in that State (BOBLME, Malaysia, 2011).

5.4.6 Waters north and west of Australia

In general, the waters north and west of Australia are in very good condition. The large-scale mining in the catchments has not generally caused problems with hazardous substances because of the low rainfall and consequent absence of major watercourses. There are some localized problems around the Gulf of Carpentaria, such as Darwin Harbour and Melville Bay (Nhulunbuy, Northern Territory), where a localized, biologically dead area has been created by mining wastes (SE2011 Committee, 2011).

5.4.7 Indian Ocean open ocean

As with other open-ocean areas, information on levels of contamination from hazardous substances is limited. Studies in 1996 around the Chagos Archipelago (over 500 km from the nearest continental land) showed that only some PCBs and lindane were above the limits of detection, and then only just. The conclusions therefore were that atmospheric transport was the main source, and that the area was amongst the least affected coastal areas (Everaarts et al., 1999). Air sampling around the Chagos Archipelago has also concluded that the atmosphere over the Indian Ocean in 2006 was substantially less contaminated from atmospheric POPs than it was according to the available data from the 1970s and 1990s (Wurl et al., 2006). Samples of skipjack tuna from the mid-Indian Ocean were studied as a way of examining the distribution of airborne contaminants. They showed (like all tuna studied from around the world) detectable levels of brominated diphenyl ethers, but at lower levels than in the north Pacific (Ueno et al., 2004; Tanabe et al., 2008).

5.5 *Pacific Ocean*

5.5.1 *North-East Pacific*

- Waters west of Canada and the mainland of the United States

The United States applies the general principles of the National Coastal Condition Report to its Pacific coasts, although the sheer scale of the Alaskan coast makes some aspects inappropriate. For Alaska, the results show an overwhelmingly good condition: as with the Alaskan Arctic coast, there are some local natural sources of heavy metals, but the presence of other hazardous substances is mainly from long-range transport through the seas or the atmosphere (EPA, 2012).

In Canada, the situation is much the same for the northern and central coast of British Columbia, where population density and levels of industrial development are low. Further south, however, some hot-spots with severe adverse effects from high concentrations of chlorinated hydrocarbons and heavy metals have been found, for example, in the Port Moody arm of the strait separating Vancouver Island from the mainland (Belan, 2004).

For the area of the Alaska current as a whole, samples of biota obtained during 2003-08 have generally not detected concentrations of PCBs, pesticides or mercury at levels of concern (PICES, 2009).

The waters off the western coasts of the contiguous United States are also assessed as being “good”, with 86-89 per cent of the sampling stations being put in this class on the individual indices. The areas where the sampling stations fail to achieve “good” status are mainly around San Francisco, Los Angeles and San Diego in California (EPA, 2012). Nonetheless, the Mussel Watch shows significant decreasing trends of levels of heavy metals and other hazardous substances at sampling stations all along the Pacific coast of the contiguous United States, except for Puget Sound, where increases in the levels of lead contamination have been found (Mussel Watch, 2011).

- Waters west of Mexico, Guatemala, El Salvador, Honduras, Nicaragua and Costa Rica

From the point of view of contamination by hazardous substances, the waters west of the countries of Central America are affected mainly by the discharges from local, relatively small-scale industries and agricultural runoff. The overwhelming majority of industrial effluent is discharged to the sea without treatment, and usage of pesticides is one of the highest in Latin America (Heileman, 2008e).

5.5.2 *East Asian Coastal Seas - General*

At the regional level, no information is regularly collected on inputs of hazardous substances and their effects. Levels of heavy metal contamination in the East Asian coastal seas are, however, known to have been rising over the last two decades, largely due to untreated municipal waste-water and industrial effluents. The rise was rapid in some areas, particularly in coastal waters of China, over the twenty years to 2000. For most of the area, there is no general evidence that this has

ceased. In the Gulf of Thailand, lead and cadmium have been found at high levels near the mouths of all major rivers. In some areas, the levels of heavy metals in fish and shellfish have made them unsuitable for human consumption. Depth profiles of sediment samples suggest in many cases that these inputs of heavy metals are linked to recent rapid growth of electronics, ship-painting and chemical industries.

Persistent organic pollutants are measurably present in most coastal areas of the East Asian Seas at levels higher than many other parts of the world, but studies have shown decreasing levels of those which had previously been banned. Endosulfan has been found in most coastal sediments, especially off Malaysia, suggesting recent use. Both DDT and PCBs are found at levels above limits generally recognised as tolerable, but in some areas (for example, the Macau estuary in China), studies have shown that such levels peaked as much as twenty years ago (UNEP/COBSEA, 2010).

5.5.3 Coastal waters of China

At the national level, the Chinese authorities have been carrying out systematic monitoring of the coastal waters and coastal sediments as part of their national environmental monitoring programme. For water quality, their system uses an assessment classification based on a range of parameters covering not only hazardous substances but also problems caused by non-hazardous waste elements. As far as hazardous substances are concerned, levels are reported as satisfying national standards. The combined assessment is shown below in the section on nutrients. In addition, the Chinese authorities study sediment quality in relation to hazardous substances. Decreases in concentrations have been observed generally since 1997. However, in 2010 areas around 36 coastal pollutant discharge outfalls did not meet the sediment quality requirements, mainly because of the levels of copper and cadmium, and some of the area showed a worsening (China, 2012). In Hong Kong, China, waters, monitoring focused specifically on hazardous substances has been undertaken to evaluate the effects of the stringent measures to combat pollution from these substances. These monitoring programmes have demonstrated a steady decline between 1991 and 2012 of, in total, about 30 per cent in the levels of heavy metals in sediments at the west end of Hong Kong Island. Even there, however, levels in enclosed bays used as typhoon shelters can be much higher. Sediments around Hong Kong, China, show a slight decline in levels of PCBs (Hong Kong, China, 2013). Other evidence (from sea-bird feathers) shows that there are high levels of mercury in the South China Sea (Watanuki et al., 2013).

5.5.4 Yellow Sea and waters between Japan and the Korean Peninsula

The absence of data, and (even where they are available) their incompleteness and lack of consistency, make any assessment of the impact of hazardous substances on the Yellow Sea as a whole very difficult. There seems to be little doubt, however, that inputs of hazardous substances are at levels which give rise to concern, largely because of the discharges of untreated industrial waste-water (NOWPAP, 2007). Where detailed information is available about specific areas, however, there is good evidence of improvement: in the waters around Japan, for example, levels of PCB concentrations in both fish and shellfish have decreased by over 75 per cent between 1979 and 2005. Nevertheless, concentrations in both fish and sediments remain at levels sufficient to cause concern, particularly in enclosed sea areas

surrounded by big cities (Japan MOE, 2009). Local sources of pollution, mainly from mining, are also significant along the northern coast of the Russian Asia-Pacific Region (Kachur et al., 2000).

5.5.5 North-West Pacific (Kuroshio and Oyashio Currents)

The areas east of the Japanese main island and the islands north and south of it are significantly less affected by industrial, mining and agricultural activities than the seas along the coast of the Asian mainland, except close to the Japanese main islands. In enclosed sea areas surrounded by big cities on the Japanese main island, there are levels of contamination from POPs much (up to five times) higher than on the western coast. This is particularly the case in Ise Bay and Tokyo Bay (I. Belkin et al., 2008; Heileman and Belkin, 2008; Japan MOE, 2009).

5.5.6 North Pacific open ocean

Apart from some major island ports, such as Pearl Harbor, Hawaii (which shows evidence of PCB contamination (EPA, 2012)), contamination from heavy metals and other hazardous substances is not a major concern in the central north Pacific. However, mercury concentrations in the North-East Pacific increased between 2002 and 2006 and modelling suggests an average increase of 3 per cent per year between 1995 and 2006 (Sunderland et al., 2009). Samples of skipjack tuna from the western part of the central north Pacific, studied to assess airborne transport of contaminants, showed higher levels of brominated diphenyl ethers than samples from the central Indian Ocean and off Brazil. The suggestion is made that this might be the result of atmospheric transport from locations in south-east Asia where waste goods containing these fire retardants were being dismantled (Ueno et al., 2004).

5.5.7 South-East Pacific (Waters west of Panama, Colombia, Ecuador, Peru and Chile)

Little new information on the situation in this area as a whole is available since the survey conducted in 2000 by the Permanent Commission of the South Pacific (CPPS, 2000). In respect of discharges of hazardous substances, this survey showed a major problem with mining waste, particularly in the south of Peru and the north of Chile. The mining industry in these countries is mainly in the coastal areas. A substantial number of mines disposed of their waste directly into the sea, and others indirectly through rivers: none of these wastes were treated. The areas said to be highly polluted were at the mouth of the River Rímac (into which a number of mines discharged) and between Pisco and Ite in Peru, and around Chañaral in Chile. In the north of Chile, as well, there were beaches which had been used in the past for the disposal of mine waste, and from which heavy metals (especially copper) were leaching into the sea. In addition, a heavy load of agricultural pesticides was thought to be present: nearly 5,000 tons of active ingredient were thought to be used annually in the 1990s, resulting in what was judged to be serious pollution in the coastal areas of the province of Chiriqui in Panama, in the extreme south of Colombia, around Guayaquil in Ecuador, around Pisco in Peru, and in regions VI (Rancagua), VII (Talca), VIII Concepción), X (Puerto Montt) and XI (Cohaique) in Chile.

5.5.8 South Pacific open ocean

Even less is known about the contamination of the open ocean by hazardous substances in the South Pacific than in the other open-ocean areas. The island States of the area have neither major industrial sites, nor major mines. A wide range of pesticides has been used for local agriculture, although the most hazardous are no longer used. A result of this use, however, is that residues have been found in the soil, as well as stocks of persistent organo-chlorine pesticides and contaminated sites where the pesticides were stored (Samoa, for example, has three such sites). There were also a number of electrical devices containing PCBs (the Federated States of Micronesia had 13.5 tons). With Australian and GEF assistance, programmes are in place to dispose of stocks and remediate contaminated sites. The States have, however, recorded their concern about lack of capacity to prevent the accidental creation of dioxins and furans from imperfect incineration (Samoa, 2004; FSM, 2004).

5.5.9 Waters east of Australia and around New Zealand

The waters to the east of Australia are renowned for the Great Barrier Reef – the world's largest coral reef system. Although the catchments draining into this part of the sea are not heavily industrialized, they contain intensive agriculture, especially for sugar cane. The pesticides (and other runoff) from these catchments are judged likely to cause environmental harm, particularly to the central and southern parts of the Great Barrier Reef. Models of the mean annual loads of a range of common pesticides (ametryn, atrazine, diuron, hexazinone, tebuthiuron and simazine) show that inputs are in the range of 16-17 tons of active ingredient. The total pesticide load to the Great Barrier Reef lagoon is likely to be considerably larger, given that another 28 pesticides have been detected in the rivers (Lewis et al., 2009; RWQPP, 2013).

Further south, the coast of the south-eastern part of Australia is the most heavily populated area in the country: nearly one-third of the total population is in central New South Wales. Port Jackson (Sydney Harbour) is locally contaminated with heavy metals, especially lead and zinc, and a large proportion of the estuary has sedimentary metals at concentrations where some adverse biological effects can be expected. Most of the contamination is a legacy of past poor industrial practice, but some evidence exists for continuing entry of contaminants, probably from leaching (Birch, 2000). Further south, in the State of Victoria, the Government acknowledges that data on the condition of marine and coastal ecosystems are not gathered in a comprehensive manner, making assessment of the condition of coastal and marine systems difficult. Estuarine and bay systems, such as Port Phillip Bay (Melbourne), Western Port and the Gippsland Lakes, have impaired water quality, partly from industrial and agricultural sources (Victoria, 2013).

In New Zealand, a study was made of dioxins, furans, PCBs, organochlorine pesticides, estuarine sediments and shellfish. The catchments covered ranged from highly urbanized to areas relatively remote from anthropogenic influences. The results showed that concentrations of these substances in New Zealand estuaries are low, and in most cases markedly lower than concentrations reported for estuaries in other countries, although concentrations in some estuaries are approaching those

reported elsewhere for urbanized estuaries (NZMOE, 1999). Examination of sediment cores from Tamaki Creek, near Auckland (New Zealand's largest city) has shown a four-fold increase in levels of heavy metals since the European settlement of the area, with most of the increase in the last 50 years. Tamaki Estuary is classified as a polluted area (Abraham et al., 2008). The estuaries around Auckland and near other large urban areas seem likely to be subject to the same pressures.

5.6 *Southern Ocean*

Levels of contamination by heavy metals and other hazardous substances are low. Long-distance transport through marine currents and the atmosphere means that measurable levels of contamination are found, but not at levels that give rise to concern. Some of the research stations have accumulated waste contaminated with heavy metals and other hazardous substances. Australia has removed a quantity from the Thala Valley base (Australian Government, 2011). Recently, brominated flame retardants are reported to have escaped from McMurdo Sound base (NGN, 2014).

6. Endocrine Disruptors

As discussed above, hazardous substances are usually defined in relation to the qualities of being toxic, persistent and liable to bioaccumulate. Toxicity is usually defined in relation to being fatal when ingested, to causing cancers (carcinogens), to causing birth defects (teratogens) or to causing mutations (mutagens). Many of the substances regarded as hazardous substances within these accepted definitions were also shown to affect endocrine systems and thus to interfere with the reproductive success of individuals and populations, and were therefore described as "endocrine disruptors".

In the 1990s, a consensus emerged that certain substances outside the accepted definitions of hazardous substances could also disrupt endocrine systems, and thus affect the ability of individuals and populations to reproduce successfully. In the marine context, the issue was highlighted by the discovery that tributyl tin, which had been adopted widely as a component in anti-fouling treatments for ships' hulls, had a severe effect at very low concentrations on molluscs: initially, the effects were observed at concentrations so low that they could not be detected by the then available methods of chemical analysis. The effects were referred to as "imposex", and took the form of females developing male sexual characteristics and thus becoming infertile. In some harbours, whole populations of molluscs disappeared. Where such substances were not within the accepted definitions of hazardous substances, new initiatives were needed. The question of "endocrine disruptors" for those concerned with the marine environment therefore became more focused on substances which are not within the accepted definitions of hazardous substances, but which may nonetheless have serious effects on the health of the marine environment (OSPAR, 2003).

The case of tributyl tin is discussed further in Chapter 17 (Shipping). Systems have been developed, principally by the Organization for Economic Cooperation and Development (OECD), to test substances to see whether they have the potential to disrupt endocrine systems (OECD, 2012).

In the application of these testing procedures, some substances not otherwise identified as hazardous substances have been identified that are, or may be, of particular concern to the marine environment. These include:

- (a) *Nonyl phenyl ethoxylates*: These are used as emulsifiers, dispersive agents, surfactants and/or wetting agents. These degrade quickly to nonyl phenyls and short-chained nonyl phenyl ethoxylates, which are toxic to aquatic organisms and are thought to have endocrine-disrupting properties. The main users are the industrial, institutional and domestic cleaning sectors (30 per cent of use in Europe; other significant sectors in Europe are emulsion polymerisation (12 per cent), textiles (10 per cent), chemical synthesis (9 per cent) and leather (8 per cent)). Estimated use in Western Europe in 1997 was 76,600 tons. Action has been taken within the European Union and is proposed in the United States (OSPAR, 2009; EPA, 2010);
- (b) *Estrogenic contaminants*: There is some evidence that human-derived steroids, such as estradiol and ethinyl estradiol (the active ingredient of the contraceptive pill) can affect aquatic biota. In fresh water, intersex conditions induced in male fish (trout) in rivers in England were attributed to ethinyl estradiol from sewage (Desbrow et al., 1998; Routledge et al., 1998; Tyler and Jobling, 2008). In contrast, androgenic effects have been found in female fish in rivers carrying pulp and paper mill effluents (mosquito fish) and feedlot effluent (fathead minnows) (Orlando et al., 2004). Whether such substances persist enough to continue to cause such effects after a lapse of time, and how the substances might operate in more dynamic or more dilute environments (such as the sea) is not clear;
- (c) *Phthalates*: Phthalates are a class of chemicals most commonly used to make rigid plastics (especially PVC) soft and pliable. They can leach from PVC products, particularly when they enter waste streams. Phthalates can affect reproduction and development in a wide range of wildlife species. Reproductive and developmental disturbances include changes in the number of offspring and/or reduced hatching success and disruption of larval development. They generally do not persist in the environment over the long term, but there is evidence that environmental concentrations are above levels that give rise to concern in some aquatic environments. (Engler, 2012; Oehlmann et al., 2009).

7. Oil

The United States National Research Council has carried out two major studies, in 1985 and 2003, on the amounts of oil that enter the marine environment, both for

United States waters and for the world as a whole (NRC, 2003). The studies concluded that the global estimates of hydrocarbons from land-based sources were particularly uncertain. The 2003 study placed the best estimate of runoff from land globally at 140,000 tons/year, but recognized that this could be as much as 5 million tons, or as little as 6,800 tons. This compares with its estimate of:

- (a) The amounts of oil spilled (on average) in the process of extracting hydrocarbons from the seabed. Here the best estimate was 38,000 tons, within a range of 20,000 tons to 62,000 tons;
- (b) The amounts of oil seeping naturally into the sea from submarine seeps, such as those off south California. Here the best estimate was 600,000 tons/year, within a range of 200,000 tons to 2 million tons;
- (c) The total amount of hydrocarbons entering the sea from all sources. Here the best estimate was 1.3 million tons/year, within a range of 470,000 tons to 8.3 million tons.

Land runoff is therefore a significant component of the impact of hydrocarbons on the sea. As discussed in chapter 17 (Shipping), however, the significance for the marine environment depends crucially on the location: warm, sunny zones will result in much more rapid breakdown of the hydrocarbons by bacteria into harmless substances. Likewise, in areas with high levels of natural seepage of hydrocarbons, oleophilic bacteria will often be abundant and thus the breakdown of anthropogenic inputs will be quicker than in areas with little or no natural seepage. Moreover, within the land-based sources, much of the runoff is the result of relatively large numbers of relatively small accidents and mishaps, which are difficult to prevent. Mitigation, in the form of well designed drainage systems, accident-response systems and public education, has to be the main response.

Oil refineries, however, can represent significant point-sources of hydrocarbon discharges that can reach and affect the sea. No global information seems to be available on losses and discharges from oil refineries. In some areas the impact on the marine environment is serious. In the Persian Gulf, heavy (>200 µg/g) contamination of sediments in the central offshore basin is reported, and attributed to industrial effluents from onshore industries (Elshorbagy, 2005). Efforts in Europe and North America have shown, however, that it is possible to reduce this impact substantially. In Europe, CONCAWE (the oil companies' environmental organization) reports that, under pressure from regulators, the oil companies have diminished substantially the amounts of oil discharged in process water from refineries in relation to throughput:

Table 3. Levels of oil content of aqueous discharges from European oil refineries.

Year	Throughput (million tons per year)	Oil content of water discharges per ton of throughput (g per ton of throughput)	Year	Throughput (million tons per year)	Oil content of water discharges per ton of throughput (g per ton of throughput)
1981	440	24.0	1997	627	1.86
1984	422	12.1	2000	524	1.42
1987	449	10.3	2005	670	1.57
1990	511	6.54	2008	748	1.33
1993	557	3.62	2010	605	1.30

8. Nutrients and Waterborne Pathogens

8.1 General

The second main aspect of land-based inputs that cause marine pollution involves the input of organic matter and nutrients. Organic matter and nutrients are not in themselves harmful, but can cause pollution problems when the inputs are excessive. There are a number of sources from which they enter the ocean. One of these is sewage, in the narrow sense of the waterborne disposal of human faeces and urine. Given the origin of sewage in this narrow sense, inputs of human pathogens are unavoidably bound up with sewage inputs. It is convenient therefore to consider issues of waterborne pathogens alongside nutrients.

8.2 The effects of organic matter

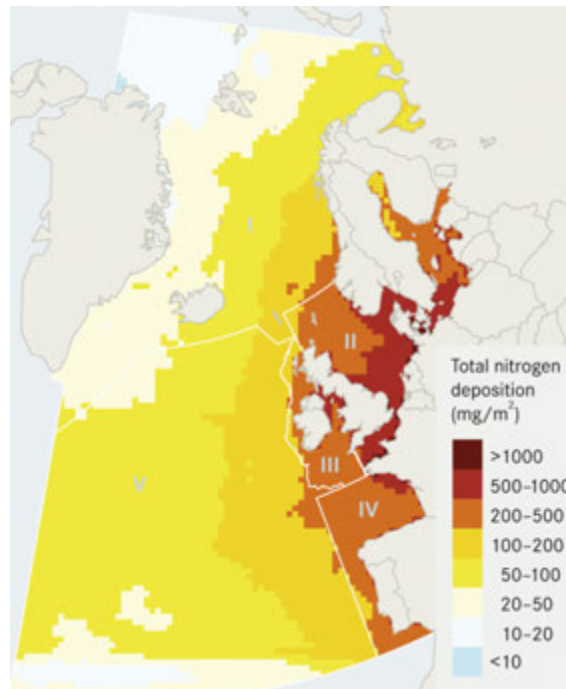

Sewage, in the narrow sense described above, contains high levels of organic matter, both particulate and dissolved. In a broader sense, the terms “sewage” and “municipal waste water” are used to describe the mix of waterborne disposal of human waste and discharges from artisanal and industrial undertakings when these are processed together. Organic matter also enters riverine discharges from natural sources, from direct or riverine inputs of industry and from aquaculture. Many artisanal or industrial discharges also contain high levels of organic matter, both particulate and dissolved. All this particulate and dissolved organic matter tends either to be oxidised or broken down by bacteria. Both processes require oxygen. The need for oxygen for chemical oxidation is the Chemical Oxygen Demand (COD). The oxygen needed by the bacteria is the Biological Oxygen Demand (BOD). When the COD and BOD in a body of water exceed the oxygen available, the body of water can become hypoxic or anoxic, with a reduced ability to support aquatic life (Metcalf & Eddy, 2004).

8.3 *The effects of nutrients*

Several nutrients are significant for the marine environment: mainly compounds of nitrogen, phosphorus, silicon and iron. In much of the ocean, primary production is limited by the availability of nitrogen. The inputs of nitrogen compounds are therefore of greatest significance. However, other aspects of nutrient input are also important: changes in the balance between available nitrogen and phosphorus can be the cause of blooms of various species of algae. Some species of algae produce toxins which can lead to amnesic shellfish poisoning, neurotoxic shellfish poisoning and paralytic shellfish poisoning (which can have death rates of 10 per cent-20 per cent) (GESAMP, 2001).

Anthropogenic inputs of nitrogen and phosphorus into estuarial and coastal ecosystems have more than doubled in the last century. These inputs are made through both the waterborne routes described above, but also significantly through airborne inputs, particularly in the forms of oxidized nitrogen, ammonia (especially from livestock), and water-soluble organic nitrogen. The importance of this airborne route for problems of the marine environment can be seen from the statistics for the North Sea and the Celtic Sea in the North-East Atlantic. In 2005 the total amounts of nitrogen estimated to be discharged in liquid discharges (riverine and direct) into these areas was 1,205 kilotons. These discharges came from 11 of the 15 States in the North-East Atlantic catchments. If we look at the airborne emissions of nitrogen from these 15 States, we find that these are estimated at 4,600 kilotons – 47 per cent from agriculture, 28 per cent from transport (including shipping), 21 per cent from combustion, and 3 per cent from other sources (OSPAR, 2010). These 4,600 kilotons of emissions are from a larger area (the total area of 15 States rather than the catchments in those States that discharge into the North-East Atlantic). Some will therefore be carried to sea areas other than the North Sea and the Celtic Sea, and some are already included in the 1,205 kilotons of riverine and direct inputs, since they will fall on land in the catchments of the North Sea and Celtic Sea. Nevertheless, it is clear that consideration of managing excessive inputs of nutrients must take into account the nutrients that reach the sea through the atmospheric transport of nutrients.

Atmospheric transport of nutrients is also important for the range over which the nutrients can be carried. As an example, the adjacent map shows the spread of nitrogen inputs to the North-East Atlantic from North-Western Europe in 2006: the inputs reach well into the open ocean (the area marked V on the map).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 6. Atmospheric Transport of Nitrogen to the North-East Atlantic from North-West Europe. Source: EMEP model in OSPAR, 2010.

At the global level, the scale of the problem can be grasped from studies aimed at showing the implications of the secular trends in airborne inputs of nitrogen to the world ocean. Drawing on work by Galloway and others (Galloway et al., 1995) and Ducklow (Ducklow, 1996), Duce and others have demonstrated the increases in the inputs of total atmospheric reactive nitrogen (N_r) over the last 140 years (Figure 7). This brings out the significance of urbanization and industrialization and of intensified agriculture.

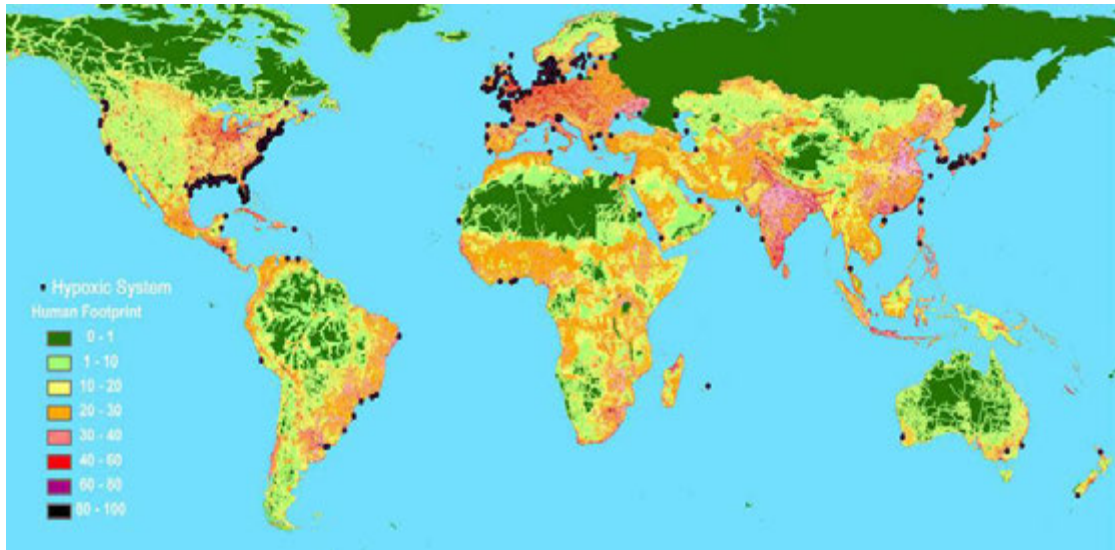

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 7. Airborne Reactive Nitrogen Inputs 1860 and 2000. Source: Duce et al., 2008. Total atmospheric reactive nitrogen (N_r) deposition to the ocean in mg per square metre per year in 1860 and 2000. Both organic and inorganic forms of nitrogen are included.

Inputs of nitrogen and phosphorus to the ocean provide nutrients to marine plants – especially to phytoplankton. Increased inputs stimulate growth (unless there is some countervailing factor, such as turbidity to reduce the availability of the light needed for photosynthesis). Excessive net phytoplankton production in coastal and shelf ecosystems can lead to an accumulation of phytoplankton biomass and to eutrophication problems. Among other phenomena, excessive net production of phytoplankton can result in *marées vertes* (“green tides”) and red tides, when large areas of sea are infested with algae. Eventually, primary production will tail off as nutrients are exhausted and again growth is limited. The masses of algae (phytoplankton) will decay under the action of bacteria. This process will use up the oxygen dissolved in the seawater, and the resulting hypoxic (where oxygen is below 2 mg per litre) or anoxic (absence of oxygen) conditions will result in the death of the animals on the seabed and of fish that cannot leave the area. In the worst cases, these conditions will lead to “dead zones” (Diaz et al., 2008), loss of sea grass beds (Orth et al., 2006), and increases in the occurrence of toxic phytoplankton blooms (Heisler et al., 2008). These dead zones reduce the amount of habitat available to aerobic animals upon which fisheries depend. The number of low-oxygen zones in coastal waters has increased exponentially to over 400 systems since the 1960s and has reached an area of about 245,000 km² worldwide (Figure 8; Rabalais et al., 2001; Diaz et al., 2008).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

The occurrence of stratification, where different layers in the sea do not mix, can be significant for problems from nutrients, since concentrations of nutrients may be much higher in one layer as a result of the water inputs having a different density. Since stratification is often seasonal, problems from nutrients can often also be seasonal. Significant seasonal meteorological changes (such as the monsoons, rainy seasons or changes in insolation (the amount of sunlight)) can also create seasonal problems from nutrients through changes in runoff and primary production.

At the same time, even high levels of nutrients in discharges to the seas do not necessarily create problems: in estuaries and coastal lagoons, depending on local circumstances, bacterial action can result in a net conversion of nitrates from land runoff into nitrogen gas released to the air, thus reducing the load to the sea. Also, the turbidity of coastal water, resulting from tidal disturbance of sediments and/or coastal erosion and other causes, can limit the depth to which sunlight can penetrate and thus inhibit photosynthesis and the growth of phytoplankton. The precise consequences of heavy loads of nutrients in discharges to the sea will therefore often depend on local circumstances, including the rate at which semi-enclosed areas are flushed by tides and currents.

In certain circumstances, anoxic zones occur naturally (Helly and Levin, 2004). In the Black Sea, the large inflows of fresh water from rivers such as the Danube, Don and Dnieper result in a high degree of stratification, with little mixing between the layers. The result is that a large part of the central deep water of the Black Sea (estimated at about 90 per cent of its volume) is naturally anoxic (Heileman et al., 2008c). Likewise, where narrow continental shelves and currents flowing from the open ocean against the continental slopes are found, nutrient-rich, oxygen-poor water can be brought up into coastal waters, and produce hypoxic or even anoxic conditions. Examples of this are found on the western coasts of America immediately north and

south of the equator, the western coast of sub-Saharan Africa, and the western coast of the Indian sub-continent (Chan et al., 2008).

8.4 Sources of nutrients

8.4.1 Municipal waste-water

Urban settlements have, of course, always produced waste-water, but a steep change in the quantities and their effect on the environment occurred from the middle of the 19th century, with the introduction of waterborne methods of disposing of human excrement and their connection to collective drains. Until then, the main system of disposal had been cess-pits and the collection of "night soil" in carts and its disposal on land for use as agricultural fertilizer. The first major changeover came in England in 1848, when legislation made the use of sewers for disposal of human excrement compulsory as a measure against cholera. Within ten years, some of the problems that the new approach could cause were shown by the Great Thames Stink of 1858, which, among other things, made the newly built Houses of Parliament almost unusable: the decomposition of the waterborne excrement produced intolerable levels of stinking gas. Sewage treatment for waste-water discharges to inland waters was adopted as the solution, and sewage treatment processes gradually improved in effectiveness and spread to more and more parts of the world.

The idea that treatment of waste-water discharges direct to the sea was also essential took much longer to be accepted: as late as 1990, some large towns in Western Europe still discharged major parts of their municipal waste-water untreated direct to the sea. The belief that the ocean had an almost unlimited absorptive capacity of the ocean was difficult to eradicate. However, the problems resulting from municipal waste-water discharges to relatively enclosed bays and harbours were acknowledged early - in the United Kingdom, the problems of the semi-enclosed Belfast Lough were one of the reasons for the investigations of the 1896 Royal Commission on Sewage Disposal, which established ground-breaking standards for sewage treatment, in terms of suspended solids and BOD per unit volume of discharge. However, it took the recognition of the significance of the problems from nutrients in relatively open sea areas such as Chesapeake Bay or the German Bight in the 1980s to create more general acceptance that action was needed, and to draw attention more generally to the issue of nutrient inputs to the sea.

The main routes of nutrient input are through rivers and direct discharges through pipelines of waste-water from sewage-collection systems and factories. When the Global Programme of Action for the Protection of the Marine Environment (GPA) was adopted in 1995, there was general agreement that the most important need for protecting the marine environment and improving human well-being was improved management of sewage, especially that from large conurbations. Where sewage treatment is applied to sewage discharges, three levels of treatment are typically recognized: primary (removal of solids and floating oil and grease), secondary (breaking-down of biological substances by microbes or protozoa) and

tertiary (disinfection and removal of nutrients). It is not always essential for discharges from sewage-collection systems to be treated before discharge. In some circumstances, very long discharge pipelines can take untreated sewage sufficiently far out to sea, and into sufficiently dynamically active waters, that the nutrients and microbes in the sewage are adequately dispersed and assimilated and problems of eutrophication avoided. For this to be the case, the pipelines must take the sewage well beyond immediate coastal waters and strong currents must be present to provide the dispersal. Even then, in most cases, at least primary treatment of the sewage is preferable. Progress has been made in many parts of the world but, overall, untreated sewage inputs remain a major threat to the marine environment.

Increasingly, in addition, inputs of water across the coastline through underground aquifers are being recognized as a significant pollution route, although statistical estimates of the amounts of water, nutrients and contaminants through this route are rarely available.

8.4.2 Food and related industries

The preparation of human food inevitably results in the generation of organic waste: milling grain produces chaff; brewing and distilling produce the spent malt or other grain used; wine-making leaves the pressed grapes; fish preparation leaves guts, heads and tails, and so on. Some of these wastes are liquid or semi-liquid and can be discharged to the sea. Others can conveniently be disposed of into the sea (especially the waste from fish-processing), directly or through a watercourse. As explained in chapter 12, aquaculture is also a source of nutrients to the marine environment. All these elements will create BOD or COD, and will release nutrients as they are decomposed or oxidized.

8.4.3 Land runoff

The world has been able to produce more and more food from land, through a combination of improvements in strains of crops, agricultural techniques and pesticides, increased use of fertilizers, as well as bringing new areas into cultivation. The scale of this increase in agricultural production can be seen from FAO statistics on cereal production: an increase of over 25 per cent in the tonnage of cereals produced worldwide between 2002 and 2012. This increase in overall tonnage is also reflected in increased yield per hectare: over the period 2002 to 2012, yields increased by over 7 per cent in southern Asia, by over 9 per cent in eastern and south-eastern Asia, by over 18 per cent in Africa and by over 20 per cent in western Asia.

The substantial increases in total crops and in yield, while essential to feed the world's growing population, carry with them some environmental problems for the marine environment. As discussed above, some of the pesticides used on land have had impacts on the marine environment as a result of runoff. Likewise, the increased use of fertilizers has resulted in increased runoff of nutrients to the seas. These nutrients, intended to promote photosynthesis in land plants, also encourage primary production in the seas, and result in eutrophication problems. The runoff not only takes the obvious form of surface water entering the sea through rivers and watercourses, it can also enter the sea through groundwater seepage through

aquifers. Estimates suggest that direct subterranean/submarine discharges of fresh water to the oceans around the world deliver up to 12 per cent of total surface water runoff, with the most accepted values between 5 per cent and 10 per cent (Basterretxea et al., 2010).

The use of nitrogen-based fertilizers has grown enormously in recent decades. This growth continues, as Table 4 shows: world consumption has increased by 42 per cent between 2002 and 2012, including more than doubling in Latin America, southern Asia, eastern Asia and Oceania.

Table 4. World Nitrogen Fertilizer Consumption

Increased use of agricultural fertilizers does not necessarily result in increased nutrient inputs to the seas: good agricultural practices can help avoid this. Adjusting amounts of fertilizer applied to likely take-up by crops, applying fertilizers at the time of year when take-up by crops will be greatest, ploughing so that the furrows do not promote runoff, and leaving buffer zones along watercourses can all help reduce the leaching of nutrients to the watercourses and the seas.

The type of crop cultivated can also be very significant. Legumes, such as soya beans, naturally fix nitrogen from the air into soil, from where it can then run off. The vast increases in soya bean cultivation in some tropical countries (such as Brazil) can increase nitrogen fluxes in the same way as the use of nitrogen fertilizers (Filoso et al., 2006).

Intensive raising of livestock is another major source of nutrients: both solid and liquid wastes are involved, as well as gaseous emissions of ammonia and methane, all of which can find their way to the seas through runoff from the land or deposition from the air.

8.4.4 Other sources of nutrients

The processing of many food products by food and drink industries for consumption also frequently results in waste-water containing nutrients in various forms. These waste-water streams are a further factor affecting nutrient inputs to the seas.

The combustion of petrol/gasoline and other liquid fuels also produces nitrogen compounds, which can be carried through the air to the seas. Vehicles powered by internal-combustion engines are obvious sources of such compounds (especially of ammonia). Near major shipping routes, the contribution from ships can also be significant. In north-western Europe, for example, over 25 per cent of nitrogen emissions to the atmosphere are from these sources (OSPAR, 2010).

8.5 Waterborne pathogens

Untreated municipal waste-water inevitably contains infectious microbes from humans. If these microbes reach the seas, they can infect humans both when they immerse themselves in sea water (sea-bathing) and through the consumption of fish and shellfish (especially the latter, since shellfish filter large quantities of seawater in the course of obtaining their food). Similar contamination also arises from animal excrement. In bathing waters, the probability of respiratory and intestinal diseases and infections rises for bathers rises in an almost direct relationship with the sewage pollution in the water. GESAMP and the World Health Organization estimated in 1999 that bathing in polluted seas causes some 250 million cases a year of gastroenteritis and upper respiratory disease. The same study estimated that eating contaminated shellfish is responsible for the loss every year of 3,500,000-7,000,000 disability-adjusted life-years (a standard measure of time lost due to premature death and time spent disabled by disease), putting it in the same bracket as stomach cancer, intestinal nematodes and upper respiratory tract infections (GESAMP, 2001).

9. Regional view of impacts of Nutrients and Waterborne Pathogens

The foregoing review of the sources of oxygen demand (both COD and BOD), nutrients and waterborne pathogens and the ways in which they can affect the ocean sets out the general mechanisms. It is necessary then to see to what extent the various parts of the ocean have in fact been affected. Because this kind of problem is confined to coastal waters (since distribution and dilution remove the detrimental effects), it is not necessary to examine the open ocean area.

9.1 Arctic Ocean

No problems are reported from elevated levels of nutrients in the Arctic Ocean because there are no major concentrations of population or agriculture.

9.2 *Atlantic Ocean and Adjacent Seas*

9.2.1 *North-East Atlantic, North Sea and Celtic Seas*

Serious problems from eutrophication became apparent in the North Sea in the 1980s, as dead zones appeared, particularly in the German Bight. As a result, the coastal States committed themselves to a 50 per cent reduction in inputs of nitrogen and phosphorus compounds by 1995. The 1998 OSPAR Eutrophication Strategy extended the goals of combating eutrophication to the whole of the North-East Atlantic. In 1991, the European Union adopted legislation requiring improved treatment of urban waste-water and reduction in inputs of nitrates from agriculture. Assessing the impacts of anthropogenic nutrient inputs (especially inputs from diffuse sources) is complicated by the delivery of nutrient-rich water from the deep Atlantic. Most North Sea countries achieved the target reduction in phosphorus inputs by 1995, and some countries have now reduced phosphorus inputs to 15 per cent or less of their 1985 level. Although the target for 50 per cent reductions in nitrogen inputs between 1985 and 1995 was not achieved (and still has not been achieved, except in Denmark), the resulting major programmes have achieved substantial reductions in inputs. Germany and the Netherlands have almost achieved the 50 per cent reduction. Even after these reductions, eutrophication problem areas, with enhanced levels of nutrients, are still found along the coasts of Belgium, Denmark, Germany and the Netherlands, while a number of estuaries and fjords in Ireland, Norway, Portugal, Spain and the United Kingdom also show such levels and are therefore regarded as eutrophication problem areas. In France, the estuaries of the Loire and Seine and much of the coast of Brittany (where beaches covered in sea-lettuce create serious health impacts on both locals and tourists) are still eutrophication problem areas. Mass mortality of benthic and pelagic animals has, however, been limited to a few estuaries and fjords in Denmark, the Netherlands, Norway and Sweden (OSPAR, 2010).

Since 1976, the European Union has had programmes to reduce the inputs of waterborne pathogens to the waters of its member States. This has required major investment in sewage treatment and the management of storm-water runoff. The results have been a steady improvement in water quality, both for bathing and for shell-fish production. By 2012 (which was a very wet summer in Europe) with consequential high levels of storm runoff, only 1.7 per cent of the monitored coastal bathing sites failed to meet the European Union's mandatory standards. Most of these were in the North Sea (EEA, 2013).

9.2.2 *Baltic Sea*

The Baltic Sea is sensitive to eutrophication because of the strong halocline, the limited water exchange with the North Sea and the consequent long residence time of water in it. High nutrient loads and a long residence time mean that nutrients discharged to the sea will remain in the basin for a long time. In addition, the stratification of the water masses increases the vulnerability of the Baltic Sea to eutrophication, because it hinders or prevents ventilation and oxygenation of the bottom waters and sediments. Furthermore, absence, or low levels, of oxygen

worsen the situation by affecting nutrient transformation processes by bacteria, such as nitrification and denitrification and the capacity of sediments to bind phosphorus, and lead to release of significant quantities of it.

As a result, most of the Baltic is regarded as suffering from problems of eutrophication. Only the Gulf of Bothnia (the northernmost part of the waters between Finland and Sweden) is generally free of these problems, although even here, there are small coastal sites with pronounced eutrophication problems. The worst affected areas are the Gulf of Finland, the Gulf of Riga, the Baltic Proper (the area between Sweden and Estonia and Latvia), the area east of the island of Bornholm, the Belts and the Kattegat. Smaller sites on the coasts of Sweden and the Gdansk Bight are also classified as suffering eutrophication (HELCOM, 2010a). In general, the anoxic and hypoxic areas of the Baltic Sea are regarded as one of the largest areas of dead zones in the world.

9.2.3 Mediterranean Sea

Eutrophication is assessed as being a localized problem in the Mediterranean basin. The main causes, as elsewhere, are inadequately treated sewage and runoff and emissions from animal husbandry and high usage levels of agricultural fertilizers. 37 per cent of coastal towns with a population of more than 2,000 have no sewage treatment at all, and a further 12 per cent have only primary treatment. These towns are concentrated on the southern shore of the western Mediterranean, in coastal Sicily, on the eastern coast of the Adriatic and in the Aegean and the north-eastern corner of the Levantine basin. Fertilizer usage reaches over 200 kg per hectare of arable land in Croatia, Egypt, Israel and Slovenia, and is over 100 kg per hectare in France, Greece, Italy and Spain. Since the eastern Mediterranean is naturally oligotrophic, locally enhanced levels of nutrient input can produce marked results. The main hypoxic area is along the delta of the River Nile (Egypt) and there are areas at high risk of hypoxia at the mouth of the River Po (Italy) and the River Rhône (France). Medium risks of hypoxia have been reported at the mouth of the River Ebro (Spain) and in the Gulf of Gabès (Tunisia), the Gulf of Sidra (Libya), some bays and estuaries around the Aegean Sea and the Gulf of Iskenderun (Turkey), although Turkish authorities indicated that risks of hypoxia have not been confirmed in the latter area (UNEP, 2012).

9.2.4 Black Sea

As noted above, the Black Sea has historically had an anoxic zone in deep waters below 200 m. However, a major hypoxic (and, at times, anoxic) zone developed in the shallower north-western shelf from the 1950s. The inputs of nutrients by 1990 were estimated at approximately 80 per cent from agriculture and 15 per cent from municipal waste-water (most large towns having at least secondary sewage treatment). Between 1960 and 1990 the nutrient input into the catchments of the Rivers Danube, Dnipro and Don increased approximately 10-fold. The resulting anoxic or hypoxic zones at their peak in 1983-1990 extended to between 18,000 and 40,000 square kilometres, with consequential effects on fisheries and benthic biodiversity.

Three causes reduced the massive agricultural inputs: the economic problems of Eastern Europe from 1990 onwards, the adoption of stringent standards for nitrate emissions by the European Union (which required changes in the practices of States in the upper Danube basin) and the preparation for the entry of some States in the lower Danube basin into the European Union (which required the adoption of those standards). The very substantial reductions in the nutrient inputs meant that the worst effects of the hypoxia had disappeared by 1995, although the effects of changes in benthic biodiversity are still being felt (Borysova et al., 2005; Diaz et al., 2008).

9.2.5 North-West Atlantic

Nitrogen releases to air and water are low in most of Canada, but southern areas where rapid development is taking place show signs of emerging problems. At present, there is little sign of estuarine eutrophication on the Atlantic coast of Canada, but hypoxic conditions have been found in the lower St Lawrence estuary areas since the mid-1980s. These are at depths below 275 m. About a third of the problem is attributed to land-based inputs. The other two-thirds seem to be the result of changed oceanic circulation, resulting in larger amounts of Atlantic water from south of the Gulf Stream entering the estuary. This water has lower oxygen levels and a higher temperature (resulting in more bacteriological activity and consequent consumption of oxygen) than the previously dominant Labrador Current water (Schindler et al., 2006; DFO-MPO, 2013).

The United States National Coastal Condition Report (NCCR) uses a measure of water quality relevant to the occurrence of eutrophication based on a combination of levels of dissolved inorganic nitrogen (DIN), dissolved inorganic phosphorus (DIP), chlorophyll a, dissolved oxygen and the degree of water clarity. Cut-off points (varying between regions) are used to classify these indicators into good, fair and poor categories, and an algorithm gives an overall value in the light of these classifications (EPA, 2012). The United States has also carried out a National Estuarine Eutrophication Assessment (NEEA), looking at 141 estuaries in the contiguous 48 states. An update was published in 2007. Although full conclusions could be reached on only 64 of the estuaries, 29 showed moderately high to high eutrophic conditions (NEEA, 2007).

For the North-East Region (Maine to Virginia, including Chesapeake Bay), there is a marked gradient from north to south: the overall evaluation is that the region has fair water quality, but this ranges from very good quality in the open estuaries of the north, to poor in many of the southern estuaries, which have poor levels of water exchange and drain densely populated catchments. Particular problem areas are Great Bay (New Hampshire), Narragansett Bay (Rhode Island), Long Island Sound (between Connecticut and Long Island, New York), New York/New Jersey (NY/NJ) harbour, the Delaware Estuary, and the western tributaries of Chesapeake Bay. High levels of enteric bacteria resulted in advice for short periods in the mid-2000s against bathing at about 17 per cent of the beaches monitored. Further out to sea, the water quality in the Mid-Atlantic Bight was generally rated as “good” (EPA, 2012). The NEEA showed a similar division between the estuaries in the northern and southern parts of this region, with the former being generally good and the latter generally

showing the worst conditions nationally. It also noted a worsening between 1999 and 2004 in the status of 8 of the 22 estuaries assessed in the southern part (NEEA, 2007).

Chesapeake Bay presents a complex of problems, in part because of its large catchment basin with extensive industrial agriculture and a large and rapidly growing population, and in part because of the long residence time of water in the estuarine system (measured in months) (Kemp et al., 2005). Efforts to address the problems began in 1983 with the Environmental Protection Agency's Chesapeake Bay Program. By the mid-1990s, this seemed to be bearing fruit, but by 2005 it was clear that it was not reaching its goals (GAO, 2005). New efforts began in 2009, focused on a range of measures to address the multiple causes of the problems, including measures to achieve by 2025 a specified total maximum daily load from all sources of nitrogen and phosphorus (Chesapeake Bay Program, 2014).

For the South-East Region (North Carolina to Florida), the overall rating was that the water quality was "fair", with only 22 per cent of the sampling points rated "good" and 13 per cent "poor". The main problem areas were the large estuaries of Albemarle and Pamlico Sounds (North Carolina) and the major ports of Charleston (South Carolina) and Savannah (Georgia). Away from the immediate coast, the South Atlantic Bight was regarded as having overwhelmingly "good" water quality (EPA, 2012). This picture is generally consistent with the NEEA, but that assessment was unable to classify the Albemarle and Pamlico Sounds, while judging the Charleston and Savannah port areas as presenting lesser problems (NEEA, 2007).

9.2.6 Wider Caribbean

The water quality of the waters of the Gulf Coast of the United States along the immediate shoreline is judged by the National Coastal Condition Report to be "fair", with 30 per cent of the sampling stations "good" and 10 per cent "poor" (and 7 per cent not evaluated because of lack of data) (EPA, 2012). This picture was consistent with that presented by the NEEA (NEEA, 2007).

However, a little further out into the shelf waters, there is a major eutrophication problem area. Since 2000 this dead zone has fluctuated annually in size from about 8,500 sq km to about 21,750 sq km (NOAA, 2013). This is regarded as the second-largest dead zone in the world. The reasons for the fluctuation are not fully understood, but are largely connected with the levels of flow in the Mississippi River. This drains about 3.1 million sq km (about 40 per cent of the contiguous United States), with a very high level of arable and livestock agriculture and a correspondingly high level of nitrogen and phosphorus runoff. The first problems were noted by shrimp fishermen in the 1950s. Studies of the sediments show that algal growth (and hence eutrophication problems) in the area of the dead zone increased significantly in the second half of the 20th century. The dead zone has had a significant effect on the shrimp fishery (Turner et al., 2008; Rabalais et al., 2001; Diaz et al., 2008).

In other parts of the wider Caribbean, significant progress has been made in addressing the problems of sewage and other nutrient discharges. In 2010, the Caribbean Environment Programme conducted a comprehensive survey of the

problems. In spite of some uncertainties, this showed major progress in Colombia and Venezuela in reducing inputs from municipal waste-water since an earlier survey in 1994: total nitrogen inputs had reduced by more than 80 per cent, and also substantial reductions in organic matter (BOD). Elsewhere, smaller reductions had been achieved in mainland States, but large increases were found in the island States. Much more general progress had been made in reducing organic matter (BOD) and nutrients from industrial sites in coastal areas: reductions of 50 per cent-90 per cent in the former in all parts, and 90 per cent or more in the latter everywhere except in the United States and Mexico (UNEP-UCR/CEP, 2010).

Nevertheless, there are major issues with sewage, both in terms of health and eutrophication. The Caribbean relies heavily on the tourist industry for its economic well-being. Clean bathing waters and coral reefs are two important supports for that tourist industry. Eutrophication leads to excessive algal growth which can smother and kill corals – especially if the herbivore fish (such as groupers) have been reduced by over-fishing. Untreated sewage harms the health of both local populations and visiting tourists. Both effects have serious implications for the tourist industry.

9.2.7 South-East Atlantic

Detailed studies and analysis conducted in the Guinea Current region, and more generally in West and Central Africa, show that sewage constitutes the main source of pollution in that area from land-based activities. A similar situation applied in the regions of the Benguela Current (where harmful algal blooms also appear to be on the increase) and the Canaries Current (where the waters off the cities of Dakar in Senegal and Casablanca and Rabat in Morocco appear to be specially affected). All the countries assessed reflect high urban, domestic loads, sometimes from industrial origin, which create problems from BOD, suspended sediments, nutrients, bacteria and pathogens. For example, the mean annual amount of oxygen required to meet BOD for the entire West and Central Africa region, including the countries adjoining the Guinea Current, has been estimated to be 288,961 tons for BOD from municipal sewage and 47,269 tons for BOD from industrial discharges: a total of 336,230 tons (For comparison, the mean annual amount of oxygen required to meet BOD for the River Rhine at the border between Germany and the Netherlands is about 60,000 tons.). Again, the rapid growth of urban populations is far beyond the capacity of relevant authorities and municipalities to provide adequate basic services of sewage and waste-water-treatment facilities (GCLMEP, 2003; Heileman, 2008b).

9.2.8 South-West Atlantic

The waters off the northern coasts of Brazil have naturally relatively low levels of nutrients. During most of the year, therefore, there are no problems from eutrophication. However, during the rainy season, runoff from land brings sudden increases in the levels of nutrients, and consequently algal blooms then occur (de Lacerda et al., 2002). Estuaries, bays and lagoons close to the larger conurbations tend to show eutrophication from sewage and other nutrient inputs, often enhanced by the effects of limited water circulation (Costa, 2007).

Further south, in the heavily populated areas of south-eastern Brazil, high levels of nutrients and consequent eutrophication problems are common. Guanabara Bay

(on which the city of Rio de Janeiro (population 6.3 million) is located) is the most heavily affected area, with very high nutrient levels and high levels of microbial pollution (de Lacerda et al., 2002). In the south of Brazil, in the State of Santa Catarina, in urban estuaries, the dissolved inorganic nitrogen (DIN) was generally three times greater than in non-urban ones (Pagliosa et al., 2006).

In Brazil, the majority of households and industries generally do not have access to sewerage. The national average of those with connections to a sewer in 2008 was 44 per cent, ranging from 1.7 per cent in the State of Pará in the north, to 82 per cent in the State of São Paulo in the south. Supply of piped water was much more common than sewerage connections, and sewerage connections were more common than sewage treatment: only 28 per cent of the volume of water supplied passed into the sewer system and only 68 per cent of the sewage was treated, only a little over half of that treated receiving secondary or higher treatment. This situation in 2008, however, represented a big improvement (for example, an increase of 40 per cent of households connected) on that at the time of the previous survey in 2000. Brazil currently has a major programme of investment (equivalent to 4.2 billion United States dollars) for the improvement of sanitation. So it is reasonable to hope that the situation will improve (IBGA, 2008; PAC2, 2014). Further south again, Uruguay and Argentina, which contain the large conurbations of Montevideo and Buenos Aires, have serious microbial pollution in some localized areas of their coastal waters, where pathogens have been detected which in some cases have exceeded international recommended levels for recreational water. Toxic red tides are becoming more frequent and of longer duration (Heileman, 2008e).

9.3 Indian Ocean

9.3.1 Western Indian Ocean

Throughout this area, there is a tendency for high nutrient levels to encourage ecosystem change, leading to dominance by algal communities. On the coasts of the Agulhas Current, the growing coastal populations and increasing tourism, for which sewage treatment facilities are inadequate, result in the increasing discharge of raw sewage directly into rivers or the sea, leading to eutrophication in localized areas. Untreated effluents from fish processing plants and abattoirs are also frequently discharged into the sea, causing varying degrees of localized pollution.

On the coasts of the States bordering the Somali current, most of the coastal municipalities do not have the capacity to handle the vast quantities of sewage and solid wastes generated daily. Raw sewage containing organic materials, nutrients, suspended solids, parasitic worms and benign and pathogenic bacteria and viruses is discharged into coastal areas. High microbial levels are observed in areas near sewage outfalls (Heileman and Scott, 2008).

In the Comoros, there is no sewerage, drainage or waste-water treatment. In Kenya, microbial water quality studies have been completed in a number of locations and microbial pollution levels near urban centres, such as Mombasa, were several orders of magnitude higher than in coastal waters in rural areas. In Mozambique, faecal coliform counts in the channel adjacent to the Infulene River in Maputo were found

to be worryingly high. In Madagascar, similar high counts of bacteria from human excrement have been measured in coastal waters. Microbial pollution is an ongoing problem in several Mascarene coastal areas. Periodic draining of waste-water ponds on fish farms adds to nutrient discharges. At present, in Mauritius, 73 per cent of households use cesspits or septic tanks whilst 2 per cent use pit latrines; so most of the effluents are discharged directly to the sea or are carried to the sea by runoff and rivers with higher potential for microbial pollution, particularly after heavy rains. Agricultural practices in Mauritius (both intensive agriculture and small-scale market gardening, and livestock rearing) also pose a serious threat to coastal ecosystems and give rise to algal blooms and red tides (ASCLME/SWIOFP, 2012).

9.3.2 Red Sea, including the Gulf of Aden, the Gulf of Aqaba and the Gulf of Suez

Although its effects are usually limited to a small area around urban areas and large tourist developments, sewage is a major source of coastal contamination throughout the Red Sea and the Gulfs of Aden, Aqaba and Suez. Because of rapid population growth and inadequate treatment and disposal facilities, poorly treated or untreated sewage is dumped in coastal areas. Inputs of sewage also results in eutrophication of the coastal waters around some population centres, major ports and tourist facilities (Gerges, 2002).

9.3.3 Persian Gulf

The shortage of freshwater resources and the availability of financial resources resulted in an extensive investment in sewage treatment in the Gulf States on the southern shore of the Persian Gulf, in order to permit re-use of the treated water for irrigation and other purposes. The treatment applied is generally secondary or tertiary. This re-use also reduces the demand for water from desalinization. Hence there has not been the same pressure from discharge of nutrients as in other parts of the world from urban growth and consequent increases in urban waste-water. As long ago as 1999, 252 million cubic metres of water were being produced annually in this way (Alsharhan et al., 2001). The latest FAO figures show that this has risen to 551 million cubic metres/year. Elsewhere in the area, coastal water quality at the Iraq-Kuwait border has declined as a result of increased agricultural pollution due to the draining and subsequent loss of the filtering role of the Mesopotamian marshlands (Heileman et al., 2008b). On the northern shore, moreover, some cities, such as Bushehr, are discharging treated sewage effluent, which is giving rise to enhanced levels of nutrients, although it is not clear that this results in eutrophication problems (Rabbaniha et al., 2013).

9.3.4 Arabian Sea, including waters west of India, the Maldives and Sri Lanka

This area is affected by natural nutrient enrichment, at the time of the south-western monsoon, as deep-level nutrient-rich water is brought up onto the narrow continental shelf (Naqvi et al., 2009).

In the north of the area, sewage, fertilizers and other effluents have resulted in eutrophication in coastal areas such as Karachi. Fish kills in some localities, such as off the Karachi coast and Gawadar Bay, have been attributed to harmful algal blooms caused by the growing pollution (Heileman et al., 2008b).

Further south, the Indian Central Pollution Control Board (CPCB) estimates that the 644 cities and towns of over 50,000 population across the country (coastal and inland) discharge 5,500 megalitres a day of sewage, of which only 522 megalitres a day – less than a tenth – receives any treatment before discharge. Of this, the 120 cities and towns of populations of over 50,000 in the coastal area generate about 6,835 megalitres a day of waste-water, out of which only 1,492 megalitres (22 per cent) receive any treatment. The rest is discharged without any kind of treatment to the coastal waters. This represents an increase of about 150 per cent over the levels of discharge twenty years ago, although the rate of increase has recently slowed (CPCB, 2014). There have also been large increases in the amounts of artificial fertilizers used. However, it is argued that much of this usage is in relative dry areas from which there is little runoff (NIOT, 2014). Considering the west coast of India separately, the state of Maharashtra, in the middle, accounts for the majority of the 3,220 megalitres discharged daily into the Arabian Sea (CPCB, 2014). In spite of this heavy nutrient load, which produces some hypoxic zones, few eutrophication problems (such as harmful algal blooms) are reported, probably because of the very dynamic tidal action which produces rapid dispersal. The algal mass, measured as chlorophyll-a, is lower in this area than in the Bay of Bengal (BOBLME, India 2011).

Given the statistics on sewage, it is not surprising that high levels of pathogenic bacteria are reported all along the coast (except in the Karwar (Karnataka) region), with increasing levels on the coasts of Goa, the rest of Karnataka and Kerala. These increasing trends in levels of nutrients and waterborne pathogens point to the significant influence of sewage inputs (NIOT, 2014).

9.3.5 Waters east of India, the Maldives and Sri Lanka (Bay of Bengal, Andaman Sea, Malacca Strait)

In the waters to the east of the Indian subcontinent, hypoxic areas regularly occur along the coast, although severe eutrophication problems appear to be rare. These hypoxic areas are partly a natural situation brought about by enhancement of nutrient levels by the monsoon winds bringing nutrient-rich water to the surface (Vinayachandran, 2003), and partly by high levels of nutrient input from the land. The major inputs are from West Bengal in India (which provides well over 50 per cent of the inputs from the Indian coast) and from Bangladesh. The Indian input of sewage is around 2,330 megalitres/day into the Bay of Bengal, 80 per cent of which has had no treatment (CPCB, 2014). The hypoxic areas are also associated with frequent harmful algal blooms, for which seven hotspots have been identified (Gopalpur (Orissa), Visakhapatnam and Coringa (Andhra Pradesh) and Ennore, Kalpakkam, Porto Nova, and the Gulf of Mannar (Tamil Nadu)) (BOBLEME, India 2011; Satpathy et al., 2013; NIOT, 2014). High levels of pathogenic bacteria are found all along the Indian coast of the Bay of Bengal (NIOT, 2014).

In Bangladesh, sewage collection and treatment exists only for one-third of Dacca (the capital), although investment is taking place to extend this and develop a sewerage system for the port city of Chittagong. Human wastes from most of the 150 million population are therefore liable, eventually, to find their way into the Bay of Bengal. Increasing amounts of artificial fertilizers are being used – imports rose by 2.3 times between 2003 and 2006 – but no data are available for inputs to the sea.

Harmful algal blooms are frequent, and have been linked to mass mortalities in shrimp farms. Information is lacking on illnesses linked to food from the sea, but is thought to be increasing in parallel to increasing marine pollution (BOBLME, Bangladesh, 2011).

In Myanmar, there seems to be no evidence of hypoxic zones linked to major population centres. Generally, seawater samples showed acceptable levels of nutrients and dissolved oxygen, although samples from the mouth of the Yangon (Rangoon) river showed increased levels of suspended solids and COD (BOBLME, Myanmar, 2011).

On the Andaman Sea coast of Thailand, little provision is made for sewage treatment of the human wastes from the massive tourist industry. In particular, at Patong (the main town of the tourist island of Phuket), sewage discharges are leading to elevated nutrient levels and algal blooms in December-February of most years. However, the Thai authorities have established a comprehensive marine water-quality monitoring system, which shows that around 90 per cent of the sampling stations on this coast are “fair” or better. The only station with badly deteriorated water quality is at the mouth of the Ranong River, on the border with Myanmar. A major algal bloom and fish kill took place on this coast in 2007, but it seems likely that this was due to unusual upwelling of nutrient-rich water from the deep ocean (BOBLME, Thailand, 2011).

Malaysia also has a long-standing marine water-quality monitoring system. On the basis of this Malaysia more recently developed a marine water-quality index. This brings together parameters for suspended solids, oxygen demand and microbes, together with those for heavy metals. For the coasts facing the Andaman Sea and the Straits of Malacca, this index shows that in 2012, of the 62 coastal monitoring stations in this area, 3 per cent were rated “excellent”, 10 per cent “good”, 79 per cent “moderate” and 8 per cent “poor”. Three of the five “poor” monitoring stations were near the port of Malacca and the other two were beaches apparently badly affected by oil pollution. Similar results were reported for estuarine and island monitoring stations (BOBLME, Malaysia, 2011).

9.3.6 Waters west of Australia

In general, the waters around Australia have naturally low levels of nutrients, since they are not affected by any marine current that can bring water with a high nutrient content to the coastal waters, and since much of the coast has limited land runoff because of the low rainfall. Blooms of toxic and nuisance algae, however, continue to be a problem in a number of the estuaries and in inshore waters along the western coast, with adverse impacts that include major events of fish mortality. When they occur, algal blooms in this region can cover large areas. In Western Australia, major nutrient and algal bloom problems have a long history in the Peel–Harvey Estuary, caused principally by nutrient pollution from upstream agricultural lands. Major works were undertaken to improve flushing of the estuary, but they seem to have brought only temporary relief (SE2011 Committee, 2011).

9.4 Pacific Ocean

9.4.1 Waters west of Canada and the mainland of the United States

The low population density and the small areas that are devoted to arable and livestock farming of Alaska as compared with the rest of the United States mean that problems of enhanced nutrient and microbiological inputs do not exist. The handful of sampling sites classified as “fair” rather than “good” from the point of view of water quality by the National Coast Condition Report are thought probably to be the result of so-far-unidentified natural factors rather than of human impact (EPA, 2012).

The west coast of Canada also does not show any problems of eutrophication or microbiological disease. However, there appear to be risks that such problems may develop near the border with the United States, where the main population centres and agriculture are found. This is the possible result of expanding human populations and intensifying agriculture in the lower Fraser Valley and Puget Sound (Schindler et al., 2006).

9.4.2 Waters west of Mexico, Guatemala, El Salvador, Honduras, Nicaragua and Costa Rica

In the coastal waters of these countries, waste-water discharges and agriculture runoff are the main sources of anthropogenic nutrient enrichment. Very little urban waste-water is treated: for example, in El Salvador, less than 3 per cent is treated (Romero Deras, 2013). Fertilizer consumption increased from 76 kilogrammes per hectare to about 131 kilogrammes per hectare between 1990 and 2001, and has continued to rise. Deforestation and associated increases in erosion and runoff also contribute to enhanced nutrient runoff. Eutrophication problems have been noted in the Gulf of Nicoya (Costa Rica), Jiquilisco Bay (El Salvador) and Corinto and El Realejo (Nicaragua). Harmful algal blooms associated with eutrophication have also been observed (Heileman, 2008d).

9.4.3 East Asian Coastal Seas – General

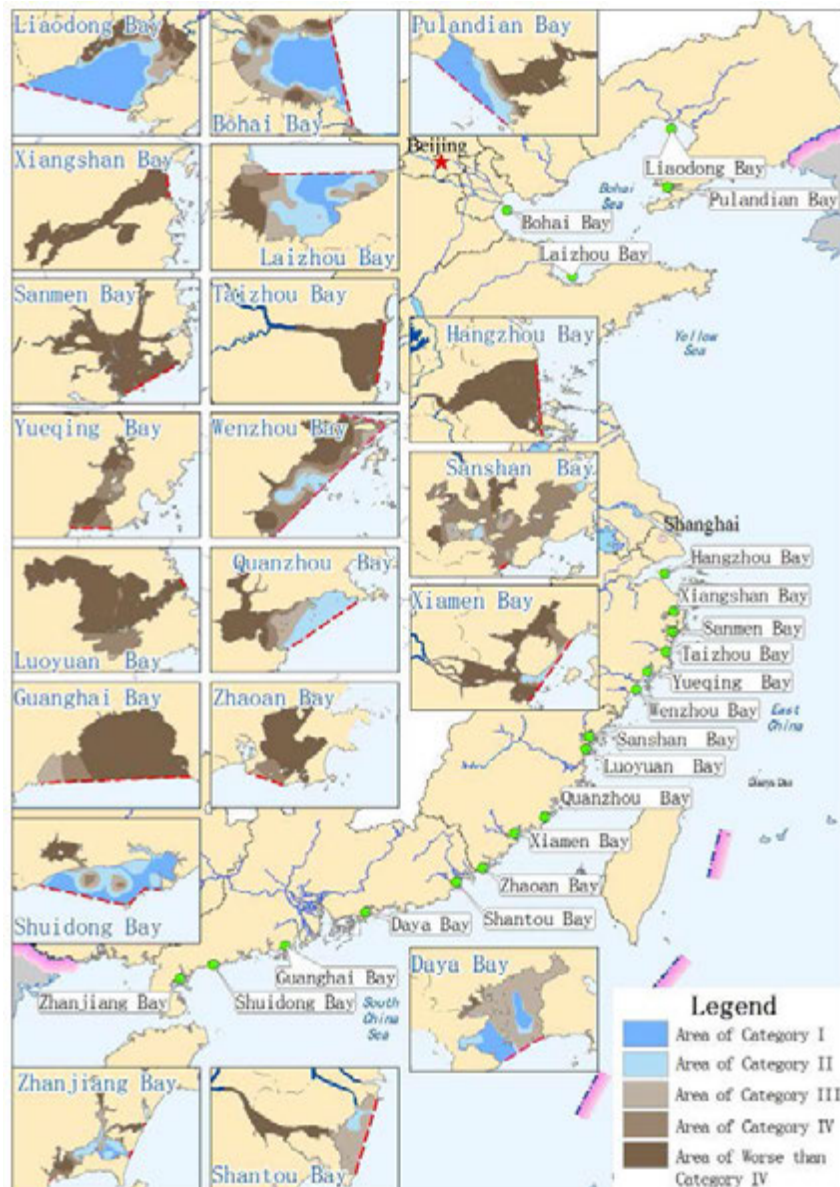

Both municipal waste-water and agricultural runoff present problems for the East Asian Seas. No consistent assessment is possible across the area as a whole, but it is clear that both these major sources are causing problems, particularly in the areas near the major conurbations. In the Philippines, Manila Harbour is a clear example of this. In Thailand, the national marine water-quality index shows that the main problem areas are in the inner Gulf of Thailand, around the mouths of the Chao Phraya, Thachin, Mae Klong, and Bangpakong Rivers. In Malaysia, the overwhelming majority of sampling stations on the east coast of the peninsula and in Sarawak, Sabah and Labuan were put into the “moderate” quality classification. The best areas are in the north of Sabah. Harmful algal blooms have become much more frequent in recent years in all parts of the region (UNEP/COBSEA 2009).

9.4.4 Coastal waters of China

The Chinese authorities have developed a water-quality assessment system which looks at the parameters related to (a) oxygen and nutrients (dissolved oxygen, COD, pH, inorganic nitrogen and phosphates), (b) heavy metals and (c) oil. Microbiological parameters are also monitored. Norms have been established for each of four

categories (Category I: Clean water, Category II: Relatively clean water, Category III: Slightly polluted water, Category IV: Medium polluted water). Water that is worse than Category IV is classed as “Heavily polluted water”. Classifying waters, works on the “one out, all out” principle: if the samples from an area fail to meet the level specified for a category for any one of the parameters, then the area is demoted to a lower category. In practice, the determinant parameter for all areas is the parameter for inorganic nitrogen, except for Liaodong Bay (the north-eastern gulf of the Bohai Sea), where the determinant parameter is inorganic phosphate. Figure 9 shows the results in 2014 for studies in major bays along the coast of China: many are heavily polluted (the absence of indications seaward of the lines enclosing the bays, of course, does not mean that the water there is clean; merely that the data for such areas is not included in this map). The total area of waters that could not be classified as Category I (clean water) increased steeply, at about 20,000 square kilometres/year, from 1990 to 2000. Since then, the amount of water that is classified as other than clean has remained more stable, although the areas within the different categories below Category I have fluctuated. In particular, the total area classified as heavily polluted water (worse than Category IV) has remained more or less stable over the decade from 2000 to 2009. The fluctuations have, however, been different in the different areas. In the Bohai Sea, although the area of clean water has increased, the other areas have deteriorated in status. It should be remembered that about 10 per cent of the planet’s population live in the catchments of the Bohai Sea. In the Yellow Sea, the area in category II and worse increased by about 40 per cent between 2003 and 2004, but by 2009 had recovered its pre-2003 level. In the East China Sea, the area in Category I (clean water) increased until 2005, but after that point remained constant. In the South China Sea, the area of water in Categories II and worse increased by about 75 per cent from 2000 to 2004, but then fell back again in 2005; it then worsened again by 2009 to a level worse than in 2004. These figures show that the extent of marine pollution measured in this way is probably significantly related to changing levels of runoff from land, since it is the levels of nutrients that are determinative (Wang et al., 2011).

Harmful algal blooms in Chinese coastal waters increased massively in number and extent since the 1990s, affecting areas up to 30,000 square kilometres (Wang et al., 2011). Since 2006, the areas affected by “red tides” have decreased, now being less than 20,000 square kilometres. The areas affected by “green tides” have, however, increased since 2008 (China, 2012).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

9.4.5 Bohai Sea, Yellow Sea, and the NOWPAP region

Assessment of relative inputs of nutrients to the Yellow Sea from China and the Korean Peninsula is not possible because comparable data are lacking. The same applies to discharges into the parts of the NOWPAP region⁸. From the pattern of

⁸ The NOWPAP (Northwest Pacific Action Plan) was established by China, Japan, the Republic of Korea and the Russian Federation in 1994 as an integral part of the Regional Seas Programme of the United Nations Environment Programme (UNEP). As stated in the Northwest Pacific Action Plan, it covers the "marine environment and coastal zones of the following States: [Democratic People's Republic of Korea]; Japan; People's Republic of China; Republic of Korea; and Russian Federation from about 121°E to 143°E longitude and from approximately 52°N to 33°N latitude, without prejudice to the sovereign right of any State".

harmful algal blooms, however, it is clear that real problems exist here. Harmful algal blooms have been observed along all the coasts, particularly concentrated in the Bohai Sea, on the south of the Korean Peninsula and on the north-west of the island of Kyushu (Japan). Harmful algal blooms off the Chinese coast are usually judged to be much larger than those off the Korean Peninsula and Japan. This may be due to the means of observation: China uses aircraft more than the Republic of Korea and Japan, which rely on ships. In Russian Federation waters, the blooms are confined to Peter the Great Bay, and appear to be the result of the size of the local urban population: no serious harm is attributed to them (NOWPAP, 2007). A UNDP-GEF Strategic Action Programme has committed China and the Republic of Korea to reduce nutrient discharges to the Yellow Sea by 10 per cent every 5 years up until 2020 (UNDP, 2011).

9.4.6 North-West Pacific (Kuroshio and Oyashio Currents)

Japan has a long history of sewage collection and treatment. The sewage from about 85 per cent of the population is treated: about 60 per cent by sewerage networks and about 25 per cent by small local plants. Nutrient removal during sewage treatment is, however, much less common (JSWA, 2014). On the eastern coasts of Japan, there are problems of high levels of nutrients, but these appear to be confined to the more enclosed waters near major conurbations, such as Tokyo Bay and Osaka Bay (Japan MOE, 2009).

9.4.7 South-East Pacific Ocean

As with hazardous substances, the information available on a consistent basis is relatively old. What it showed is that major conurbations lack effective sewage treatment works: the Tumaco estuary in Colombia, the Gulf of Guayaquil (especially the inner area, where oxygen levels were so low that fish were absent) in Ecuador, areas near Ferrol, Callao and Ilo-Ite in Peru, and the bays of San Vicente, Valparaiso and Concepción in Chile showed high levels of nutrients, and consequent eutrophication problems (CPPS, 2000). In spite of substantial programmes of investment in sewage collection and treatment (Peru has increased the proportion of the population served from 9 per cent to 37 per cent between 1985 to 2010), problems remain. Likewise, high levels of fertilizer use add to the problems.

Darwin was one of the first to record red tides (algal blooms) in this area, but they remained rare until the 1980s. Since then, they have become frequent (several a year) along the whole length of the coast from Colombia to Chile (ISP, 2010).

9.4.8 South-West Pacific

The east coast of Australia suffers from enhanced levels of nutrient runoff. These are particularly serious for the Great Barrier Reef. Compared to pre-European conditions (before 1850), modelled mean annual river loads to the Great Barrier Reef lagoon have increased 3.2 to 5.5-fold for total suspended solids, 2.0 to 5.7-fold for total nitrogen and 2.5 to 8.9-fold for total phosphorus. However, the effects vary widely depending on the level of agriculture in the catchment. Almost no change in loading for most pollutants has been observed in the rivers capable of affecting the northern Great Barrier Reef, but there have been much greater changes in rivers capable of affecting the central and southern Great Barrier Reef. Given the

sensitivity of the corals of the Great Barrier Reef, the risk of adverse effects is high. Recent work suggests that a substantial part of the decline in hard coral is due to the high nutrient levels in the southern areas (Bell et al., 2014).

Further south, more than half the estuaries in New South Wales are subject to double the natural levels of sediment and nutrient inputs, and around one-third of these estuaries have been cleared of more than 50 per cent of their natural marine vegetation. These and other pressures are directly linked to the poor water quality found in a high proportion of New South Wales estuaries: only 11 per cent of the estuaries have been found to comply more than 90 per cent of the time with the guidelines for chlorophyll-a. Many of the estuaries are under pressure from excessive inputs of sediments and nutrients, and altered freshwater inputs and hydrological regimes (SE2011 Committee, 2011).

In New Zealand, significant eutrophication problems generally only occur in shallow estuaries and bays with restricted circulation. Guidelines for nutrient discharge have been adopted to deal with these problems (ESNZ, 2014). However, delivery of suspended sediment to the sea around New Zealand is 1.7 percent of the world total delivery, when the New Zealand land area is only 0.2% of the global land area (Hicks et al., 2011).

10. Inputs of Radioactive Substances

The waters, biota and sediments of the ocean all contain radioactivity. Some of this is entirely natural, representing the dispersion of naturally radioactive isotopes throughout the earth and the effects of cosmic radiation. Some, however, is the product of relatively recent human activities: the use of atomic bombs during World War II, the testing of further nuclear weapons, discharges and emissions from nuclear power plants and nuclear reprocessing plants, dumping of radioactive waste, accidents involving nuclear material and other less significant activities. Some human activities that concentrate naturally occurring radioactive material (NORM) have a longer history.

In considering radioactivity in the marine environment, it is essential to distinguish between:

- (a) The occurrence of ionizing radiation, emitted through the decay of radionuclides, with the level of activity measured in becquerels (one becquerel being the activity of a quantity of radioactive material in which one nuclide decays every second); and
- (b) The impact of such radiation on living organisms, where the energy deposited in the tissues of the organism (the absorbed dose) is measured in grays, and the sum of the effects of that dose on the different parts of the body (the effective dose) is measured, for humans, in sieverts. The biological effects of the absorbed dose vary according to the nature of the radiation (α -radiation can have a much more significant effect than β - or γ -radiation) and the part of the body affected. When the radioactive substance is incorporated into the

body (for example, by being eaten), its effects integrated over a period of 50 years (70 years for children) are estimated through the committed effective dose, expressed in sieverts.

Naturally occurring radioactivity in the oceans

The natural background radioactivity in the ocean varies considerably. A study conducted under the auspices of the International Atomic Energy Agency (IAEA) in 1995 examined the variations between the FAO major fishing areas. This looked at the distribution of polonium-210 (^{210}Po), based on the view that, on a global scale, this isotope was radiologically the most important representative of naturally occurring radioactive material. The study concluded that insufficient evidence was then available to estimate the levels of polonium radioactivity in seawater in the different areas of the world. However, data for levels of polonium radioactivity in fish (shown in Figure 10), crustacea and molluscs for those areas for which data were available showed variations by factors of 58, 250 and 71, respectively, between the highest and lowest levels (MARDOS, 1995).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

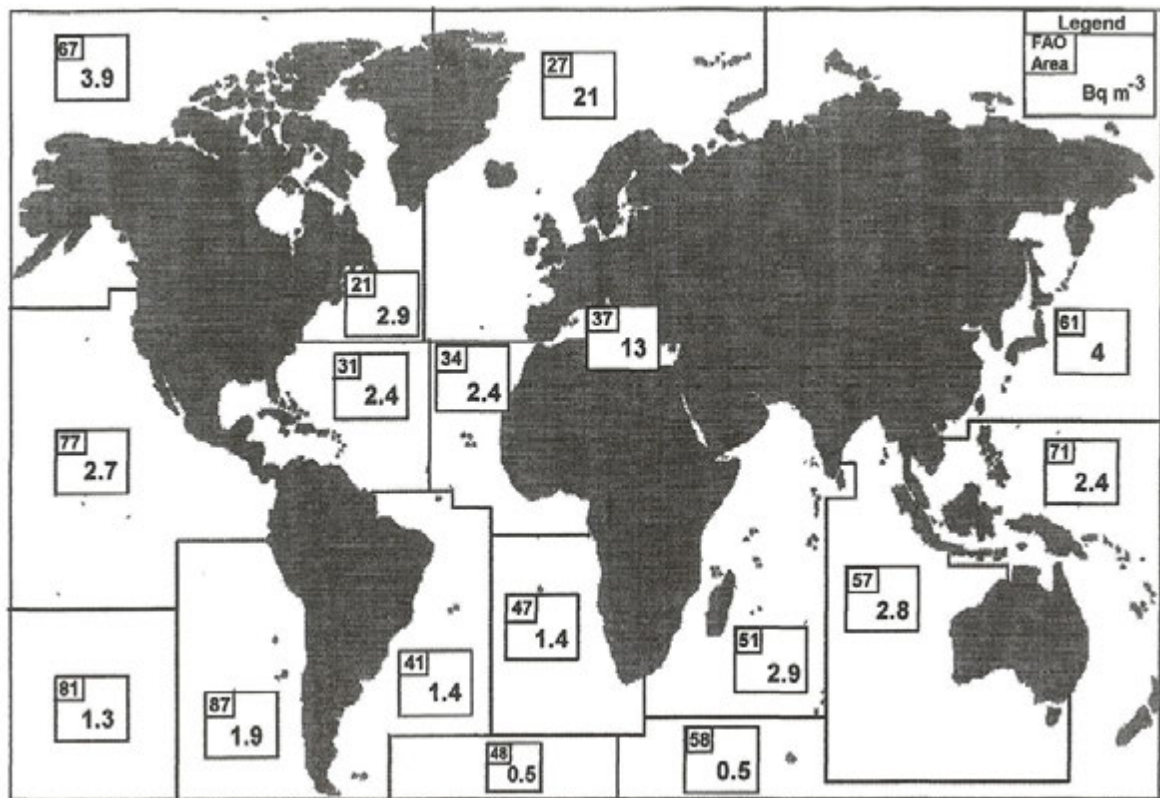

Figure 10. Concentrations of ^{210}Po in fish for FAO major fishing areas. Becquerels per kilogramme of wet weight. Source: IAEA, MARDOS, 1995.

10.1 Anthropogenic radioactivity in the oceans

Anthropogenic releases of radionuclides into the ocean have had a measurable effect on the levels of radioactivity in the oceans and its distribution. The distribution

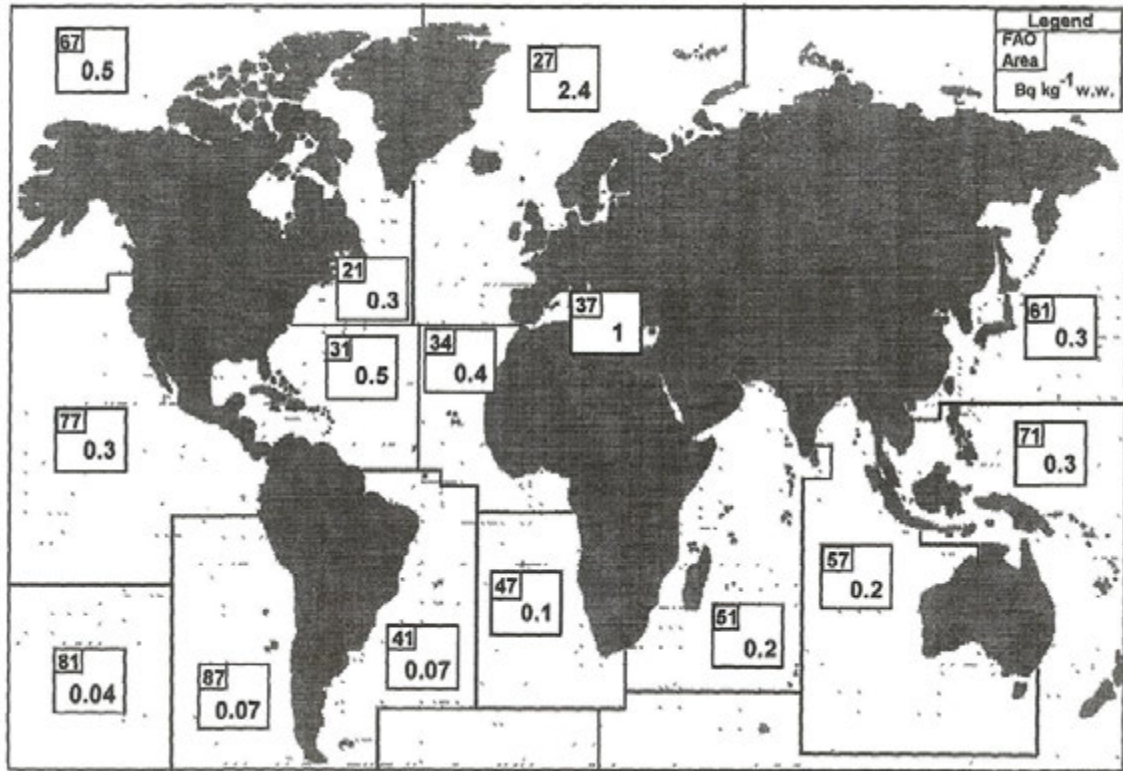

in space and time can be quite complex, but is always related to four general processes: the type and location of the input, radioactive decay, biogeochemistry and oceanic processes, such as transport by ocean currents and sedimentation. The complex interaction of these processes over time means that all parts of the ocean are affected by anthropogenic releases of radionuclides, but that the distribution is quite varied. The 1995 IAEA study, using caesium-137 (^{137}Cs) as typical of anthropogenic radionuclides, estimated that radioactivity levels of ^{137}Cs in seawater and fish vary by factors of around 40-60 between the Southern Ocean (the lowest) and the North-East Atlantic (the highest) (MARDOS, 1995). Although the ocean contains most of the anthropogenic radionuclides released into the environment, the radiological impact of this contamination is low. Radiation doses from naturally occurring radionuclides in the marine environment (for example, ^{210}Po), are on average two orders of magnitude higher (WOMARS, 2005).

Becquerels per cubic metre

10.1.1 Testing of nuclear weapons

Much of the anthropogenic radioactivity in the ocean derives from global fall-out from the atmospheric testing of nuclear weapons between 1945 and 1963. Most of this global fall-out resulted from the input of radioactive material from the explosions into the stratosphere. There was also additional local fall-out from material which did not reach the stratosphere. The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) estimates that this global fall-out totalled around 2,500 million terabecquerels (TBq) (UNSCEAR, 2008). Using ⁹⁰Sr and ¹³⁷Cs as indicators, an IAEA study estimated that about 64 per cent of this fell on the oceans, of which 1 per cent fell on the Arctic Ocean, 26 per cent on the North Atlantic Ocean, 7 per cent on the South Atlantic Ocean, 14 per cent on the Indian Ocean, 35 per cent on the North Pacific Ocean and 17 per cent on the South Pacific Ocean. The IAEA study further estimated that the inventory of radioactivity from this source in the oceans had decreased (through natural decay) by 2000 to about 13,850,000 TBq. Much of this reduction was, of course, the result of the decay of short-lived isotopes (WOMARS, 2005). There have been no atmospheric tests of nuclear weapons since 1980, and so this major source of anthropogenic radioactivity appears to be purely historic.

10.1.2 Nuclear reprocessing

Overall, the second largest source of anthropogenic inputs of radioactive material into the ocean has been nuclear re-processing plants. In this sector, the major sources are the plants at Cap de la Hague (France: current capacity 1,700 tons/year of waste reprocessed) and Sellafield (United Kingdom: current capacity 2,100 tons/year). When the plants at these sites started work in the 1970s, relatively high levels of radioactive materials were discharged to the sea, reaching a peak in 1975 of 5,230 TBq of ^{137}Cs and 466 TBq of ^{90}Sr from Sellafield. Over the period 1970 – 1983, discharges from Cap de la Hague were much lower, representing about 2 per cent and 16 per cent respectively, of the levels of ^{137}Cs and ^{90}Sr discharges from Sellafield. In both cases, steps were taken to reduce discharge levels drastically, and new technology was developed and installed. The result was that aggregate annual discharges (other than tritium) from the two sites were reduced, by 2000, to around 98.2 TBq (0.2 TBq of α -emitting substances and 98 TBq of β -emitting substances other than tritium). Since then efforts at reductions have continued: by 2011, discharges were down to 18.2 TBq (0.1 TBq of α -emitting substances and 18.1 TBq of β -emitting substances other than tritium). This represents a reduction of 99.7 per cent from the peak of annual discharges (WOMARS, 2005; OSPAR, 2013; NEA, 2013). Although some States remain concerned at these discharges, the major impact is now only historic. It has been announced that one of the Sellafield plants (the Thermal Oxide Reprocessing Plant (THORP)) will close in 2018, when the currently programmed reprocessing has been completed, although this programme is currently reported to be behind schedule (NDA, 2014).

During the implementation of these reductions, some European States raised concerns about discharges of technetium-99 (^{99}Tc) from a new plant at Sellafield. Technetium has chemical properties close to those of manganese, which is naturally concentrated by many crustacea, especially lobsters. The ^{99}Tc discharges from the new plant at Sellafield were initially high: just over 180 TBq in 1994. This was substantially due to treating a backlog accumulated while the new plant was built, but ^{99}Tc discharges were still at around 40 TBq/year in 2003. In response to continued pressure from these European States, the United Kingdom has now implemented a chemical process to remove much of the ^{99}Tc from the discharge stream, and levels are now below 5TBq/year (OSPAR, 2010).

Other civilian reprocessing plants on much smaller scales were operational in Belgium, Germany and Italy, but have been closed since 1991 or earlier. China has a small nuclear reprocessing plant (capacity 50 tons/year) in operation in the inland province of Gansu. A larger plant (capacity 800 tons/year) is reported to be planned to start operation in the same province in 2017, and plans for a further plant exist. India has small reprocessing plants at coastal sites at Trombay (near Mumbai: capacity 60 tons/year), Tarapur (in Maharashtra: capacity 100 tons/year) and Kalpakkam (in Tamil Nadu: capacity 100 tons/year). A further plant (capacity 100 tons/year) was opened in 2011 at Tarapur, and further capacity is being built at Kalpakkam. Japan has a pilot reprocessing plant at Tokai on the coast north of Tokyo (capacity 40 tons/year) and is in the process of opening a large plant (capacity 800 tons/year) at Rokkasho (on the coast at the northern end of Honshu). No data on

discharges from any of these plants seem to be available. The Russian Federation has operated the Mayak reprocessing plant (capacity 400 tons/year) near Ozyersk in the Ural Mountains since 1971. The nearby Lake Karachay has been used for the discharge of large quantities of radioactive waste. The IAEA 2005 study noted that this lake represents a potential source for future contamination of the Ob River system, and thus of the Arctic Ocean. New reprocessing facilities are also under construction at Zhelenogorsk, near the border with the Ukraine. Apart from the risk from Lake Karachay, there is no evidence to suggest that these other civilian reprocessing plants have led, or might lead, to significant contamination of the ocean (NEA, 2013; WNA, 2013; WOMARS, 2005).

10.1.3 Nuclear accidents

There have been two nuclear accidents that reached level 7 (the highest level) on the IAEA's International Nuclear and Radiological Event Scale: Chernobyl and Fukushima. These have resulted in substantial amounts of radioactive material reaching the ocean.

10.2 Chernobyl

On 26 April 1986, the Number Four reactor at the nuclear power plant at Chernobyl, Ukraine, went out of control during a test at low power, leading to an explosion and fire that demolished the reactor building and released large amounts of radioactive material into the atmosphere. Around 100,000 TBq of ^{137}Cs were released to the atmosphere. Although most of this activity was deposited on land, a significant part went to the sea, particularly the Baltic Sea. The total input of ^{137}Cs from Chernobyl to the Baltic Sea has been estimated at 4,700 TBq, including post-Chernobyl river discharges of ^{137}Cs to the Baltic Sea estimated at 300 TBq. Inputs from Chernobyl to the Black Sea have been estimated at 2,000-3000 TBq ^{137}Cs . The North Sea and the Mediterranean Sea also received inputs of radioactive material, and continue to do so through outflows from the Baltic Sea and Black Sea, respectively.

Because of the Chernobyl input, the Baltic Sea has the highest concentrations of ^{137}Cs of any sea region. Average concentrations of ^{137}Cs in fish from the Baltic Sea in 1990 were similar to those in the Irish Sea (which were affected by the Sellafield discharges), about 4 times higher than in the Black Sea, and about 30 times higher than in the Mediterranean Sea. However, radiation doses to humans in the Baltic Sea area from marine pathways (including those from ^{137}Cs in fish) during 1999-2006 have not exceeded an annual value of 0.02 mSv, and the dose for a person eating 90 kilogrammes a year of fish was estimated at 0.014 mSv over the period 2007 – 2010 – both well below the limit of 1 mSv per year for the general public set in the IAEA Basic Safety Standards. HELCOM assessments in 2009 and 2013 concluded that concentrations of radioactive substances in the Baltic Sea are not expected to cause harmful effects to wildlife in the foreseeable future (WOMARS, 2005; HELCOM, 2009; HELCOM, 2013). Likewise, a 2006 IAEA report concluded that radioactivity concentrations in marine fish resulting from the inputs from the Chernobyl disaster to the marine environment are not of concern (IAEA, 2006).

10.3 Fukushima

On 11 March 2011, a 9.0-magnitude earthquake occurred near Honshu, Japan, creating a devastating tsunami that left a trail of death and destruction in its wake. The earthquake and the subsequent tsunami, which flooded over 500 square kilometres of land, resulted in the loss of more than 20,000 lives and destroyed property, infrastructure and natural resources. They also led to the worst civil nuclear disaster since Chernobyl. Three of the six nuclear reactors at Fukushima Daiichi nuclear power station suffered severe core damage. This resulted in the release, over a prolonged period, of very large amounts of radioactive material into the environment. UNSCEAR concluded that the information available to it implied atmospheric releases of iodine-131 (^{131}I) and caesium-137 (^{137}Cs) in the ranges of 100,000-500,000 TBq and 6,000-20,000 TBq, respectively. (^{131}I and ^{137}Cs are two of the most significant radionuclides from the point of view of exposures of people and the environment). Winds transported a large portion of the atmospheric releases onto the Pacific Ocean. In addition, liquids containing radioactivity were discharged directly into the surrounding sea. The direct discharges amounted to around 10 per cent (for ^{131}I) and 50 per cent (for ^{137}Cs) of the corresponding atmospheric discharges. Low-level releases into the ocean were still ongoing in May 2013. The estimated releases are about 10 per cent (^{131}I) and 20 per cent (^{137}Cs) of the corresponding estimated atmospheric releases from the Chernobyl accident (UNSCEAR, 2013), but because of the sea-side site and the effects of the winds, the Fukushima event was the largest-ever accidental release of radioactive material to the ocean, being slightly more than the amount reaching the sea from the intrinsically much larger Chernobyl event (Japan, 2011; Pacchioli, 2013).

UNSCEAR further concluded that exposures of marine biota to radioactivity following the accident were, in general, too low for acute effects to be observed, though there may have been some exceptions because of local variability. Effects on biota in the marine environment would have been confined to areas close to where the highly radioactive water was released into the ocean (UNSCEAR, 2013).

Within a few weeks of the disaster, traces of ^{134}Cs were found over 1,900 km across the Pacific from Fukushima. By August 2011, bluefin tuna caught off California were found to contain ^{134}Cs which could only have come from Fukushima. ^{134}Cs has a half-life of only two years, and so material from pre-Fukushima sources (such as weapons testing) would have decayed long before. Further sampling suggested that the strong Kurushio current acted as a barrier preventing significant amounts of radioactive material moving south in the Pacific, and confining it to around the latitude of Fukushima (Pacchioli, 2013; Fisher et al., 2013).

In December 2013, the IAEA confirmed that a comprehensive Sea Area Monitoring Plan had been established, noting that radionuclide concentrations remain within the WHO guidelines for drinking water and that the public is safe. The IAEA assessment also addressed monitoring of food products, adding that the joint FAO/IAEA Division concluded that measures taken to monitor and rapidly respond to any issues regarding radionuclide contamination in the food system are appropriate and that the public food supply (including food from the sea) is safe (IAEA, 2013a; IAEA, 2014).

10.4 Other nuclear accidents

The 2005 IAEA study reviewed the full range of accidents involving radioactive material resulting in inputs to the ocean, but did not consider that the amounts were significant, beyond noting that the six sunken nuclear submarines which remain in the ocean with their reactors may be considered as potential sources of radioactive contamination of the ocean, and that nuclear-powered satellites burning up in the atmosphere on re-entry can affect radioactivity in the ocean (a 1964 incident over the southern hemisphere resulted in a measurable increase in the ratio between ^{238}Pu and $^{239,240}\text{Pu}$ between the northern and southern hemispheres (WOMARS, 2005).

10.4.1 Nuclear power plants

There were 434 commercial nuclear power reactors in 30 countries in operation at the end of 2013. The plants containing them have a total capacity of over 370,000 megawatts (MW). A little over 300,000 MW of this capacity is in OECD countries. About 72 more reactors are under construction. These plants produce over 11 per cent of the world's electricity: from nearly 75 per cent of the national supply in France to 1.5 per cent in the Islamic Republic of Iran (see Table 5). Other States which do not have nuclear power plants, such as Denmark and Italy, import substantial amounts of their electricity from neighbouring States which rely substantially on nuclear power (IAEA, 2013b). Electricity generated from nuclear power is therefore a significant source of energy.

Table 5. Proportion of electricity generated from nuclear power 2013.

STATE	PER CENT OF ELECTRICITY FROM NUCLEAR POWER	STATE	PER CENT OF ELECTRICITY FROM NUCLEAR POWER	STATE	PER CENT OF ELECTRICITY FROM NUCLEAR POWER
France	73.3	Bulgaria	30.7	South Africa	5.7
Belgium	52.1	Armenia	29.2	Mexico	4.6
Slovakia	51.7	Korea, Republic of	27.6	Argentina	4.4
Hungary	50.7	United States of America	19.4	Pakistan	4.4
Ukraine	43.6	United Kingdom	18.3	India	3.5
Sweden	42.7	Russia	17.5	Brazil	2.8
Switzerland	36.4	Romania	19.8	Netherlands	2.8
Czech Republic	35.9	Spain	19.7	China	2.1
Slovenia	33.6	Canada	16.0	Japan	1.7
Finland	33.3	Germany	15.4	Iran, Islamic Republic of	1.5

Source: IAEA PRIS Database, IAEA, 2013b.

Emissions and discharges are inevitable from the operation of these plants. For the purposes of the World Ocean Assessment, the crucial question is the extent of the impact of these emissions and discharges on the marine environment. The 2005 IAEA survey of sources of anthropogenic inputs of radioactive materials to the ocean commented that routine discharges from nuclear power plants contribute orders of magnitude less to the radioactive contamination of the world ocean than nuclear-weapons testing, nuclear reprocessing plants and nuclear accidents (WOMARS, 2005). The supporting material for the 2008 UNSCEAR report to the United Nations General Assembly gives a figure of approximately 1.3 TBq as the worldwide aggregate level of radioactivity from radionuclides other than tritium released from nuclear power plants in liquid effluents in 2002 (UNSCEAR, 2008). Data from some plants is not included but, as can be seen from comparison with the figures quoted above for other sources, this is consistent with the WOMARS conclusion. The 2008 UNSCEAR report further comments that radiation doses from nuclear power reactors decrease over time because of lower discharge levels. This is consistent with the observations recorded by the OSPAR Commission, which noted a statistically significant reduction of 38 per cent in total β -activity (other than tritium) from nuclear industries discharging into the North-East Atlantic (OSPAR, 2010). At the same time, aggregate discharges from nuclear power plants are likely to increase somewhat as the nuclear power stations under construction and planned come on stream.

Discharges of tritium are, however, rather different. The production of tritium by nuclear power plants is normally related to the level of electricity generated. No accepted abatement technology exists, and the amount of radioactivity in discharges can be many times that from other radionuclides. However, tritium is a natural product produced by cosmic rays. This source accounts for a significant amount of the radionuclide found in the sea. It also has a very low dose coefficient and therefore exhibits a very low radiotoxicity to humans and inherently low radiotoxicity to biota (OSPAR, 2007).

10.4.2 Human activities concentrating naturally occurring radioactive material (NORM)

A wide range of materials used in an even wider range of human activities contain natural radioactivity. The effects of the human activities can be to concentrate this naturally occurring radioactive material (NORM) from these materials, usually in the form of waste. Recent studies by the OSPAR Commission (summarized in OSPAR, 2010) conclude that the major source of NORM reaching the North-East Atlantic is the offshore oil and gas industry, where produced water (water coming from the reservoir with the oil and gas) and the scale that it deposits in pipelines (which has to be cleared periodically) contains low levels of radionuclides (mainly ^{210}Pb , ^{210}Po , and $^{226/228}\text{Ra}$). Although the proportion of total- α activity is higher than for discharges from the nuclear industries, the overall concentrations are not so far thought to be significant, although work to assess the levels is continuing. Apart from phosphate rock processing (see below), other anthropogenic sources of NORM in the marine environment are not thought to be significant.

One form of NORM reaching the marine environment that has been thought to be significant in some States is the ^{210}Po found in phosphogypsum, a by-product of the treatment of rock containing phosphate to produce phosphate fertilizers. In many cases, this phosphogypsum has been discharged directly into the sea as slurry. At Workington, England, in the area affected by the Whitehaven phosphate-processing plant releases, it was found that molluscs were concentrating this ^{210}Po to an extent that those who consumed substantial quantities of the molluscs might be ingesting ^{210}Po at potentially dangerous levels. The closure of the plant in 1992 resolved the problem. Similar problems were also found at a plant at Rotterdam in the Netherlands, which was also closed. For these and other reasons, this method of disposing of phosphogypsum has been phased out in most countries. It continues in Lebanon, Morocco (where it is under review) and South Africa (IAEA, 2013c).

10.5 Impact of radioactivity in the marine environment

Two issues need to be differentiated: the impact of radioactivity from the marine environment on humans, and the impact of such radioactivity on marine biota.

As far as concerns the radiation impact on humans through food from the marine environment, the IAEA MARDOS study in 1995 reported on the exposure of humans to ^{137}Cs and ^{210}Po , as the anthropogenic and natural radionuclides, respectively, of most radiological significance. This study concluded that, worldwide, the mean individual committed effective doses in 1990 were:

Table 6. Estimated mean individual committed effective doses in 1990 from ^{137}Cs and ^{210}Po

Radionuclide	Food source	Mean individual effective dose commitment worldwide (microsieverts)	Uncertainty factor as a result of limited data
^{137}Cs (anthropogenic)	Fish	0.03 μSv	0.5
^{137}Cs (anthropogenic)	Shellfish	0.002 μSv	0.5
^{210}Po (natural)	Fish	1.9 - 2.3 μSv	5
^{210}Po (natural)	Shellfish	2.8 – 7.2 μSv	5

Source, MARDOS, 1995

In another way of considering the data, the study identified the critical group of humans (the group most at risk) as those eating seafood from the North-East Atlantic, the FAO major fishing area with the highest levels of radioactivity. Taking as the definition of the critical group those consuming 100 kg of fish and 10 kg of shellfish per year (a daily consumption of about 300 g (about 10½ oz) of seafood), the total individual committed effective doses were estimated for 1990 at 3.1 μSv from ^{137}Cs and 160 μSv from ^{210}Po . There is no reason to consider that current levels would be significantly higher. All these figures must be considered in relation to the

IAEA's recommended annual limit for exposure of the general public to radiation of 1mSv (1,000 μ Sv).

For a long time, the International Commission on Radiation Protection (ICRP – the international body of experts that agrees standards of radiation protection) considered that the precautions necessary to protect humans will be adequate to protect other species: “The Commission believes that...if man is adequately protected, then other living things are also likely to be sufficiently protected” (ICRP, 1977). In the 1990s, this approach was questioned, particularly for habitats where humans do not go – which covers much of the marine environment. It was not suggested that there were any obvious cases where the approach was failing to protect non-human species, but rather that it was desirable to adopt an approach which would explicitly demonstrate the proper protection of the whole environment. The ICRP debated this extensively from 2000 and in 2005 set up a new standing committee to consider the radiological protection of the environment. This debate resulted in the inclusion of an approach for developing a framework to demonstrate radiological protection of the environment, as part of the general 2007 revision of the ICRP recommendations (ICRP, 2007). The ICRP considered that this approach needed to be based on a sound scientific system similar to that developed for human protection, and that this could best be achieved by the creation of a set of Reference Animals and Plants. Descriptions of 12 “reference animals and plants” have been developed, of which three – a flatfish, a crab and a seaweed – are relevant to the marine environment. These are generic biological descriptions of the types of animal and plant, accompanied by consideration of their vulnerability to radiation and the relationship between environmental levels of radionuclides and the corresponding levels in such animals and plants. Most recently, in 2014, the ICRP has published guidance on the application of their recommendations to different exposure situations with respect to the animals and plants living in different types of natural environments. Central to this approach is the “Derived Consideration Reference Level” (DCRL): a band of dose rates within which there is some chance of a deleterious effect from ionizing radiation occurring to individuals of that type of Reference Animal or Plant. The recommended DCRLs are shown in Figure 13 (ICRP, 2009; ICRP, 2014). This work is being taken forward through the IAEA International Plan of Activities on the Radiation Protection of the Environment.

11. Significant environmental, economic and social aspects of land-based Inputs and related information and capacity-building gaps

The world needs to feed, clothe, house and keep happy its 7¼ billion people. The agricultural and industrial developments of the past two centuries have substantially enabled this to be done and, to a significant extent, have assisted in improving human well-being. But these achievements have been obtained at a price: these agricultural and industrial developments have seriously degraded important parts of the planet, including much of the marine environment. Land-based inputs to the ocean have contributed substantially to this degradation of the marine environment.

The GPA highlighted the need for action to deal with sewage. Although much has been done to implement national plans adopted under the GPA, particularly in South America, this chapter shows that lack of sewage systems and waste-water treatment plants is still a major threat to the ocean. This is particularly the case in respect of very large urban settlements. The lack of proper management of waste-water and human wastes leads to excessive inputs of both nutrients and hazardous substances, which damage the marine environment. It also causes problems for human health, both directly and through bacteriological contamination of food from the sea.

From the point of view of industrial development, many of the earlier industrial processes brought with them serious environmental damage, especially when concentrations of industry led to intense levels of waste inputs to the sea, beyond its carrying capacity. New technologies and processes have largely been developed which have the ability to avoid these problems, but there can be gaps in the capacity to apply these newer processes, often because of the costs involved.

This is particularly significant because of the major transfer in the growth of industrial production demonstrated in this chapter. In the past, industrial production has been dominated by the countries around the North Atlantic basin and its adjacent seas, together with Japan. Over the past 15 years, the rapid growth

of industries along the rest of the western Pacific Rim and around the Indian Ocean has changed this. Rapidly growing proportions of the world's industrial production – and the associated waste discharges – are focused on the South Atlantic, the Indian Ocean and the western Pacific.

The survey in this chapter shows that some major information gaps need to be filled before this process of industrial growth can be managed in a way that can avoid reproducing, in the new areas of growth, the many problems that have been discovered in the areas that have been industrialized longer. For long stretches of the coastal zones, information is lacking on what is happening with heavy metals and other hazardous substances. Information is also lacking on the extent to which developing industries are able to apply the newer, cleaner technologies. Moreover, information is very scarce on how problems in the coastal zones are affecting the open ocean.

The agricultural revolution of the last part of the 20th century, which has largely enabled the world to feed its rapidly growing population, has also brought with it problems for the oceans, in the form of enhanced runoff of both agricultural nutrients and pesticides, as well as the airborne and waterborne inputs of nutrients from wastes from agricultural stock. In the case of fertilizers, there is a rapid growth in their use in parts of the world where only limited use has occurred in the past. This has the potential to lead to increased nutrient runoff to the ocean, if the increased use of fertilizers is not managed well. There are therefore problems in educating farmers, promoting good husbandry that causes less nutrient runoff and monitoring what is happening to agricultural runoff alongside sewage discharges. In the case of pesticides, the issues are analogous to those of industrial development. Newer pesticides are less polluting than older ones, but gaps remain in the capacity to ensure that these less-polluting pesticides are used, in terms of educating farmers, enabling them to afford the newer pesticides, supervising the distribution systems, and monitoring what is happening in the oceans.

The growth of dead zones, resulting from excessive nutrient runoff and the consequent eutrophication problems, is serious in terms of all three of environment, economics and society. The dead zones drive fish away and kill the benthic animals. Where the dead zone is seasonal, such regeneration as happens is usually at a lower trophic level, and the ecosystems are therefore degraded. This affects the maritime economy seriously, both for fishers and (where tourism has some dependence on the attractiveness of the ecosystem (for example, where there are coral reefs)) for the tourist industry. Social consequences are then easy to see, both through the direct economic effects on the fishing and tourist industries and in depriving the local human populations of the benefits of an attractive environment.

In respect of heavy metals and hazardous substances, frameworks have emerged at the international level for addressing some of these problems. In particular, the Stockholm Convention on Persistent Organic Pollutants and the Minamata Convention on Mercury provide agreed international frameworks for the States that are party to them to address the issues that they cover. Implementing them, however, will require many capacities and, as the organizations involved with these

Conventions have noted, there are important gaps in those capacities around the world.

In the case of radioactive discharges into the ocean, the survey shows that, in the past, there have been human activities that have given rise to concern, but that reactions to these concerns have largely removed the underlying problems, although there is a continuing need to monitor what is happening to radioactivity in the ocean. What remains is the concern voiced in the GPA that public reaction to concerns about marine radioactivity could result in rejection of fish as a food source, with consequent harm to countries that have a large fisheries sector and damage to the world's ability to use the important food resources provided by the marine environment.

Underlying all these issues is the major information gap in the information needed to see what is happening around the world to the ocean as a result of land-based inputs. This chapter has noted a range of differing systems for assessing the state of the ocean in respect of both hazardous substances and eutrophication. These systems usually differ for good reasons: conditions vary widely around the world. There is a lack, however, of methods to compare explicitly the information that each assessment system produces. This does not imply a need for a single global system of monitoring: as has been said, good reasons for the differences often exist. But an important gap in information results from the lack of any means of comparing the answers given by the different assessment systems. Comparison between monitoring systems also presupposes good quality-assurance of monitoring data.

An even more important gap in information is the absence of any form of regular, systematic assessment of the impact of land-based inputs in many parts of the world. In some parts of the world, such as the Caribbean, many one-off, independent examinations of several aspects of the marine environment have been undertaken, but they are not in forms which enable them to be assembled into a wider, continuous assessment. Given the potential significance of transboundary effects from land-based inputs, this is a very serious information gap. In at least some parts of the world where this is the case, universities and marine research institutes have the capacity to carry out the monitoring and analysis that is needed: what is lacking is more the capacity to organize these existing capacities to fill the wider information gap.

In summary, therefore, important changes are under way in the location around the world of industrial activity and agriculture, which have the potential to cause serious problems if past errors are reproduced. Worrying gaps exist in the capacities needed: to provide sewerage systems and waste-water treatment plants, to implement international conventions regulating which substances can be put into the sea from the land, and to monitor what is happening in the marine environment as a result. Finally, overall, major gaps remain in knowledge about land-based inputs and what knowledge about them is available in different parts of the world.

This information is based on the "Guide to the Business of Chemistry 2013" published by the American Chemistry Council Inc (ACC), and derived from data from: the Associação Brasileira da Indústria Química, the Mexican Asociación Nacional de la Industria Química, the USA Bureau of the Census, Statistics Canada, the United Nations, the Conseil Européen des Fédérations des Industries Chimiques (CEFIC), the German Verein der Chemischen Industrie (VCI) and estimates by the American Council of Chemistry.

The adjustment to constant 2013 prices has been made by the use of the Producers' Price Index (PP Index) of the USA Bureau of Labour Statistics for chemicals and allied products (<http://data.bls.gov/cgi-bin/surveymost> accessed 10 February 2014). Since chemicals are traded internationally, it was not judged necessary to adjust for differential growth in GDP.

Chapter 21. Offshore Hydrocarbon Industries

Contributors: Peter Harris (Lead member and Convenor of Writing Team), Babajide Alo, Arsonina Bera, Marita Bradshaw, Bernard Coakley, Bjorn Einar Grosvik, Nuno Lourenço, Julian Renya Moreno, Mark Shrimpton, Alan Simcock (Co-Lead member), Asha Singh

Commentators: Ana Paula Falcão, Nathan Young, Jim Kelley

1. Scale and significance of the offshore hydrocarbon industries and their social and economic benefits.

1.1 *Location of offshore exploration and production activities*

Offshore oil and gas exploration and development is focused in specific geographic areas where important oil fields have been discovered. Notable offshore fields are found in: the Gulf of Mexico (Fig. 1); the North Sea (Fig. 2); California (in the Santa Barbara basin); the Campos and Santos Basins off the coast of Brazil; Nova Scotia and Newfoundland in Atlantic Canada; West Africa, mainly west of Nigeria and Angola; the Gulf of Thailand; off Sakhalin Island on the Russian Pacific coast; in the ROPME/RECOFI area¹ and on the Australia's North-West Shelf.

1.2 *Production*

According to the United States of America National Research Council (2003) in a snapshot of the global offshore oil and gas industry, there were (in 2003) more than 6,500 offshore oil and gas installations worldwide in 53 countries, 4,000 of which were in the United States Gulf of Mexico, 950 in Asia, 700 in the Middle East and 400 in Europe. These numbers are constantly changing as the industry expands and contracts in different places in response to numerous factors involved in the global energy market. An indicator of this volatility is that by 2014 there were only 2,410 rigs in the United States Gulf of Mexico, for example.

Global crude oil production is currently 84 million barrels per day (BPD; CIA Factbook, 2012 figures) of which about 33 per cent is from the offshore (Fig. 3). Data compiled by Infield (2014) indicate that onshore crude production plateaued at around 65 million BPD as early as the 1990s and growth in offshore production has accounted for most of the increased global productivity since then. Production from deep water² (>100 m water depth and as deep as 2,900 m at Shell Oil's "Stones" field

¹ Regional Organization for the Protection of the Marine Environment (ROPME) Members: Bahrain, Iran (Islamic Republic of), Iraq, Kuwait, Oman, Qatar, Saudi Arabia, and the United Arab Emirates. Regional Commission for Fisheries (RECOFI) Members: Bahrain, Iran (Islamic Republic of), Iraq, Kuwait, Oman, Qatar, Saudi Arabia, United Arab Emirates.

² Although Infield (2014) uses 500 ft (152 m) as the divide between shallow and deep water, there is no agreed definition of "deep water". The geomorphic continental shelf break is typically around 100

in the Gulf of Mexico) platforms accounted for about 1 per cent of production in 2000 but this figure had increased to 7 per cent by 2010 and is anticipated to reach 11 per cent of total global production by 2015 (Infield, 2014; Fig. 3).

Over 1,000 offshore oilfields are forecast to be developed between 2011 and 2015, about 80 per cent of which will be in shallow water depths (<100 m). Capital spending on shallow water platforms and pipelines is forecast to grow from an estimated 50 billion United States dollars in 2011 to nearly 60 billion United States dollars by 2015, whereas spending on deep water infrastructure is forecast to rise from 45 billion dollars in 2011 to nearly 80 billion dollars by 2015 (Infield, 2014).

Offshore natural gas production is geographically dispersed: key areas include the North Sea, Gulf of Mexico, Southeast Asia, Australia, New Zealand, Qatar, West Africa and South America. The geographic areas of major investment are (in order of decreasing numbers of projects): the North Sea; Southeast Asian seas; the Gulf of Mexico; Eastern Indian Ocean; and Gulf of Guinea.

In 2001, the United States received 23 per cent of its domestic natural gas from the Gulf of Mexico but by 2013 federal waters of the Gulf of Mexico provided only 5 per cent of United States production (EIA, 2014). The reason is the fracking (hydraulic fracturing) revolution combined with horizontal drilling into tight (i.e. low permeability) geological formations, which has led to a significant increase in the United States' production of onshore shale gas and shale oil such that domestic production will meet US requirements in the short to medium term (until the mid 2020s). Fracking is also employed in some offshore locations (e.g. off southern California).

The southernmost offshore petroleum facilities in production in the world are in gas fields located 70 km offshore Tierra del Fuego, Argentina. These fields are currently producing 15 million cubic metres of gas per day. The offshore platforms are designed to resist the roughest sea conditions and wind speeds of up to 180 km/hr. The northernmost facilities in production are the Prirazlomnoye oil fields, located off the coast of Russia in the Pechora Sea (adjacent to the Barents Sea). The field is estimated to hold 72 million tons of recoverable oil and production is expected to reach six million tons annually. In 2014, some 300,000 tons will be shipped out from waters that are ice-covered for 7-8 months a year (Barents Observer, 2014).

1.3 Exploration

Oil and gas explorers rely on seismic reflection surveys to produce images of the stratigraphy and structure of subsurface rocks. They use this information to determine the location and size of oil and gas reservoirs. Globally, there were about 142 specialized seismic vessels in operation in 2013 (Offshore Magazine, 2013) and each year the Bureau of Ocean Energy Management³ gives permits for about 20 3-D

to 200 m in depth (it is around 120 m deep in the Gulf of Mexico between Texas and Florida; Harris et al., 2014), so any rig in water deeper than this is located on the continental slope (deep water).

³ On October 1, 2011, the Bureau of Ocean Energy Management, Regulation and Enforcement (BOEMRE), formerly the Minerals Management Service (MMS), was replaced by the Bureau of Ocean

seismic surveys in the United States Gulf of Mexico. Every seismic vessel tows a seismic source comprising a number of compressed air-guns, and an array of hydrophones in a “streamer” to capture the sound waves reflected from sedimentary layers below. Multi-streamer marine seismic surveys can image the subsurface in 3 dimensions (3-D seismic), acquired by a vessel equipped with between 8 and 16 streamers towed 50 to 100m apart, each 3 to 8 km long. Seismic reflection surveys are not restricted to the exploration phase but may be periodically repeated during the production phase of an offshore field. Once in production, some oil fields are re-surveyed to assess how well the reservoir is drained over time (4-D seismic).

Exploratory drilling is carried out mainly by jack-up rigs, semi-submersibles, or drillships. A jack-up rig consists of a buoyant hull fitted with extendable legs that, resting on the sea floor, are capable of raising its hull over the surface of the sea. There are about 540 jack-up rigs currently in operation globally, normally limited to shallow water (<100 m) drilling.

In order to explore in deep water, either drillships or semi-submersible vessels (also referred to as Mobile Offshore Drilling Units, or MODUs) are used. These vessels must maintain their position over the well to within a percent or so of water depth, requiring either dynamic position capability (using powerful propeller “thrusters”) or anchoring to the seabed. The world fleet of offshore drilling ships currently comprises about 80 vessels of various sizes and capabilities. Semi-submersible vessels are built with ballasted pontoons with tall legs that support a platform. Once on location the pontoons are partly flooded so that they sink below the ocean surface and wave action, while holding the platform at a safe height above the waves. When oil fields were first developed in deep water offshore locations, drilling semi-submersibles were converted for use as combined drilling and production platforms. As the oil industry has progressed into deeper water, purpose-built production semi-submersible platforms were designed. There are currently about 40 semi-submersible, deep-water exploration vessels in operation globally (Offshore Magazine, 2013).

1.4 Social aspects of the offshore oil and gas industry

Over 200,000 people work on offshore rigs and platforms globally, although the exact number is difficult to estimate⁴. In 2011 there were 23,758 core offshore workers spending over 100 nights a year offshore on the United Kingdom’s North

Energy Management (BOEM) and the Bureau of Safety and Environmental Enforcement (BSEE) as part of a major reorganization (<http://www.boemre.gov>).

⁴ The estimate of over 200,000 offshore workers was derived by adding the number for the North Sea (about 24,000) to the number in the Gulf of Mexico (about 121,000) and multiplying by 1.5 to account for the remainder of the global workforce. It does not include shore-based staff. Another way to estimate the numbers working offshore is to use the average crew numbers (from www.oilpro.com) as follows: (A) 540 jack-up exploration rigs (crew = 55 per rig) total of ~30,000; plus (B) 142 seismic vessels (crew = 80 per vessel) total of ~11,000; plus (C) 80 drill ships (crew = 80 per ship) total of ~6,500. For each crew at sea there is another crew ashore (on leave) so multiply by 2, making over 100,000 personnel in total (oilpro.com), not including shore-based workers or the crews of fixed production platforms.

Sea oil rigs. According to the United States Bureau of Labor Statistics, there were 120,676 people employed in the Gulf of Mexico oil and gas industry in 2009 earning 15.6 billion United States dollars (average income of 129,000 dollars pa). Salaries of offshore oil and gas industry workers have a broad range (Hays, 2013). In Nigeria, expatriate workers are the highest paid in Africa with an average annual salary of 140,800 dollars whereas local workers in Nigeria's oil and gas sector have an average salary of 55,100 dollars (43 times higher than the average annual income in Nigeria, which is 1,280 dollars (World Bank, 2010)). Local oil and gas sector workers have average salaries ranging from 31,100 dollars in Sudan to 163,600 dollars in Australia (Hays, 2013). The average salaries paid to foreign workers are generally higher than local remuneration rates, ranging from 59,800 dollars in Sudan to 171,000 dollars in Australia (Hays, 2013).

Most offshore oil workers spend extended periods, often one or more weeks, at their workplace – usually a production platform or a MODU. They then leave to live at home onshore for a non-work period that is also commonly one or more weeks. The offshore accommodations, recreational facilities and food are provided by their employer, which also provides transportation between the workplace and some onshore “pick-up point”, commonly a heliport. This work system is variously called “fly-in”, “fly-in/fly-out”, “FIFO” or “long-distance commute” employment (Shrimpton and Storey, 2001).

Like other employment systems, this work pattern offers advantages and disadvantages for offshore workers, their families and the communities and regions in which they live. However, it is important to note that there are important limitations to the understanding of offshore employment effects; for example, the research to date has focused on developed countries (mostly Australia, Canada, Norway, United Kingdom and of Great Britain and Northern Ireland and the United States), large operations and companies, fixed work schedules and married male workers.

This work system has implications for various interrelated work and family life issues, the most important of which are Health and Safety and Family Life:

Health and Safety: This includes issues relating to working in a hazardous environment, the remoteness of the operations, the hazardous and stressful nature of the commute, the use of extended shifts and rotations and in some instances the possible risk of abduction by pirates or militants.

Family Life: Offshore commute work presents challenges to family relationships, but these must be assessed in the context of an understanding of the range of advantages and disadvantages that the system can present. As identified by workers and their family members, these are:

- income from offshore work;
- secondary and family employment;
- separation of work and family life;
- access to services and facilities;
- independence and decision-making;

- inappropriate worker behaviour;
- family separation; and
- isolation from and within the community.

However, these advantages and disadvantages are not always experienced in the same ways and to the same degree, with the main factors underlying such variations being differences in the availability of alternative employment, the work environment and workers' experience of it, the regularity and security of employment, family members' experience and expectations of family life, and workers' and spouses' perceptions of the effects on the family.

Various responses and interventions may be appropriate in addressing family life challenges, including those that improve the compatibility of the work organization and family life, improve the compatibility of the work culture and home life, improve self-selection during hiring, help new hires and their families get used to a new work pattern, and provide counselling or other support to employees and family members.

Overall, while research has shown that commute operations have somewhat higher proportions of separated and divorced workers than do conventional ones, it is not clear that this is a direct consequence of the work system, because these workplaces seem to attract separated and divorced employees.

Piracy and abductions: (Kashubsky, 2011) compiled a database of 60 known attacks against maritime and petroleum infrastructure between 1975 and 2010. Out of these incidents, 41 have occurred since 2004, the majority of which have taken place in Nigeria (Kashubsky, 2011). The majority of incidents involved violence (whether actual use of violence or threat of violence), but 15 of 60 incidents (25 per cent) were non-violent.

Since 2006 there have been about 200 abductions in the Niger Delta of foreign workers from offshore platforms, survey vessels and pipe-laying barges. Such abductions are carried out by militant groups, especially the Movement for the Emancipation of the Niger Delta (MEND), whose stated goals are to localize control of Nigeria's oil and to secure reparations from the federal government for pollution caused by the oil industry.

1.5 Communities wholly or mostly dependent upon the offshore hydrocarbon industries

Offshore petroleum activity has had significant, and sometimes dramatic, effects on infrastructure development, education and training, and research and development (Stantec, 2012), primarily focused on such major centres of activity as Aberdeen (United Kingdom of Great Britain and Northern Ireland), Stavanger (Norway), Houston (United States), New Orleans (United States) and St John's (Canada). Industry activity has also increased the entrepreneurship and competitiveness of local individuals and companies at the local level, and generated population growth, commonly reversing previous demographic trends.

Aberdeen is a good example of the way in which these effects can affect a port city. It receives many benefits from the petroleum industry but there are also “displacement and deterrence effects” on traditional industries (Harris et al., 1988). Displacement sees existing activity being crowded out by new activity, while deterrence sees new activity preventing other activity by making a region unattractive for it. The offshore petroleum industry generated upward pressure on wages and increased the price of housing and office space, although industrial property shortages were avoided due to an increase in warehouse and factory space. The high housing prices deterred outside workers from entering the region for employment.

As a result of these forces, several industries had local growth rates below their national averages, while ones that were already declining saw that decline accelerate. The industries that declined faster than average in the 1970s included: fishing, food and drink, clothing and footwear, building materials, and timber and furniture. Harris et al. (1988) conclude that “for every 100 jobs created by the oil industry in Aberdeen, at least eight jobs have been lost in traditional industries. By 1981, displaced and deterred employment amounted to more than 3,000 jobs. Of this, only about 25 percent has been absorbed by the oil sector.”

This decline of other industries resulted in a higher dependence on the oil industry. Newlands (2000) estimates that, in 1985, 40 percent of Aberdeen’s workforce relied upon oil. He also notes that, in the 1960s, “most businesses in Aberdeen were locally owned and controlled with only a few examples of external ownership [but] a survey conducted in 1984 suggested that the figure had fallen to as low as 11 percent”.

By contrast with the potential negative impacts on traditional sectors of the economy, there may also be benefits for them. Harris et al. (1988), note that “better communications... benefit individuals as well as firms. Indeed, they are just one example of the improvement in the range and quality of services available to people in Aberdeen which has taken place in recent years. There has been a marked increase in the number, variety, and quality of shops and restaurants. There are more entertainment spots such as wine bars, discos and nightclubs. These developments cannot be attributed wholly to the establishment of the oil industry in Aberdeen, but oil developments have undoubtedly influenced the extent and pace of change”. However, such benefits are concentrated in and around major centres of offshore petroleum activity.

Such changes have had significant positive consequences for tourism in Aberdeen, Stavanger, St. John’s and other activity centres. Various studies have shown the industry making a major contribution to tourism through improved air links, meetings, conferences, trade shows, corporate hospitality and the personal expenditures of petroleum industry personnel. Newlands (2000) notes that new hotels opened, and others expanded, in Aberdeen in the 1970s. This increased the number of hotel rooms by 27 percent between 1970 and 1975 and by 58 percent between 1975 and 1980. The number of restaurants rose from 17 to 36. A similar expansion and “cosmopolitanization” of the hospitality, accommodations and hence tourism sectors has been seen in St. John’s (Shrimpton 2002).

Generally speaking, management strategies have limited the negative biophysical environmental and other effects of offshore petroleum activity on Norway, the Shetland Islands, Nova Scotia, Newfoundland and Labrador, which continue to experience rapid growth in tourism, including eco-tourism and adventure tourism.

Harris et al. (1988) also note that: “the maintenance or improvement of services applies also to the public sector. There are better hospital facilities and a larger and more comprehensive educational system than would have been the case had oil developments not reversed the trend of economic decline and emigration from Aberdeen”.

Given the nature of the offshore employment system (Section 1.4) it has a number of effects on the communities and regions where the workers live (Shrimpton and Storey, 2001), including those on:

- *Residential Patterns:* The commute system can give workers and their families considerable flexibility as to where they live. Depending largely on the schedule, transportation systems and employee preferences, they may live close to, or distant from, the workplace.
- *Expenditures:* Offshore work wage rates are often high, they are commonly combined with long hours of work and considerable amounts of overtime, and workers generally have few expenses or spending opportunities at the workplace. As a result, these workers generally also have high disposable incomes. Their expenditure patterns, including payment of taxes, are largely dependent on where they live, and can make a significant contribution to the economy of those communities and regions.
- *Non-Commute Employment:* Some offshore employees have secondary paid work while in their home communities. This can involve the use of oil industry work skills and/or involvement in traditional local farming or fishing activity. In the latter case, offshore oil labour and incomes can help sustain the local primary sector.
- *Community Life and Social and Recreational Services:* Offshore work removes some citizens from communities on a part-time basis, affecting their ability to participate in formal and informal social events and networks, including local service groups, sports teams and elected government.

1.6 Description of economic benefits to States

Daily global offshore oil production is currently about 28 million barrels (Fig. 3), which is worth between 1.4 billion dollars and 2.8 billion dollars per day (assuming 50 dollars and 100 dollars per barrel). Oil and gas production from the United Kingdom continental shelf (for example) has contributed 271 billion United Kingdom pounds (2008 money) in tax revenues over the last forty years. In 2008, tax rates on United Kingdom continental shelf production ranged from 50 – 75 per cent, depending on the field. The industry paid 12.9 billion pounds in corporate taxes in 2008-9, the largest since the mid-1980s, because of high oil and gas prices. This represented 28 per cent of total corporation tax paid in the UK. In addition to

production taxes, the supply chain contributes another 5-6 billion pounds per year in corporation and payroll taxes (UK National Archives, 2013).

In Australia, from 1999 to 2013, the offshore petroleum industry has contributed over 21.9 billion Australian dollars in petroleum resource rent tax in addition to corporate taxes (data.gov.au, 2014).

The offshore oil and gas industry accounts for about 1.5 per cent of United States GDP, 3.5 per cent of the United Kingdom's GDP, 12 per cent of Malaysia's GDP, 24 per cent of Norway's GDP and 35 per cent of Nigeria's GDP (OPEC, 2013; EIA, 2014). In Norway, crude oil, natural gas and pipeline transport services accounted for about 100 billion dollars in 2010, nearly half of the value of Norway's total exports and 10 times higher than the export value of fish (Norwegian Petroleum Directorate, 2012). In Nigeria crude oil export was valued at around 94 billion dollars pa and accounts for about 70 per cent of total exports revenue (OPEC, 2013 figures). Thus the overall value of the offshore oil and gas industry accounts for a significant part of GDP but varies dramatically among countries in terms of its overall importance.

Offshore petroleum activity can have a range of other impacts, some of them negative, on the local economy. Some early literature described negative effects on the local economy. For example, Galenson (1986) argues that Norway's performance in curbing inflation was less than it might have been without oil revenues, and that they allowed the government to pursue policies that harmed manufacturing: "Oil money was used to preserve the existing pattern of industry. The restructuring necessary to meet changing market demands was slowed, if not stopped. New initiatives were not encouraged". Mallakh et al. (1984) and Noreng (1980) argue that one of problems was that Norwegian government policy prevented labour from moving to more productive firms and sectors. It was not only prevented from moving to and from manufacturing, but from less to more productive uses within manufacturing.

However, petroleum taxes and royalties can help address the challenges posed by the fact that the sector is cyclical and involves a non-renewable resource, meaning that the state's revenue from it can be highly volatile. In 1990, Norway established a government pension fund to transfer capital from the state's petroleum revenue. The fund was designed to be invested for the long term, but in a way that made it possible to draw on when required. Its purpose is to support the government's long-term management of the petroleum revenues. The fund gives the government room for manoeuvring in fiscal policy should oil prices drop or the mainland economy contract. This facilitates economic stability and predictability. The fund also serves as a tool to manage the financial challenges of an ageing population and an expected drop in petroleum revenues.

There is growing interest, globally, nationally and locally, in creating sustainable economic development. Notwithstanding the fact that the offshore petroleum industry activity involves large technologically-complex projects and the exploitation of a non-renewable resource, the evidence from Canada, Norway, the United Kingdom, and other States indicates that it has been the engine for significant and sustainable (over many decades) economic development in a number of jurisdictions on both sides of the Atlantic. This is partly because it can make a major contribution

to output, income, employment and government finances. Such activity has often also had a transformative effect, by helping to enhance the productive capacity of the economy through stimulating growth in the quantity and quality of factor inputs to the production process, thereby contributing to sustainable long-term economic development.

1.7 Emerging technologies and potential for future developments

An example of an emerging technology relevant to offshore oil and gas facilities is the design of structures that could be deployed on the seafloor (rather than floating). Equipment that can be fixed directly to the sea floor, where it is relatively protected from ice and violent weather, could be used for subsea produced water removal and re-injection or disposal, single-phase and multi-phase boosting of well fluids, sand and solid separation, gas/liquid separation and boosting, and gas treatment and compression (Sorenson, 2013). Re-injection of produced gas, water and waste increases pressure within the reservoir that has been depleted by production. Also, re-injection helps to decrease unwanted waste, such as flaring (because the gas that would have been flared is re-injected), by using the separated components to boost recovery.

Disadvantages of robotic (unmanned) seafloor mounted facilities include difficulties in monitoring their operation and implementing any necessary repairs. The 2010 Deepwater Horizon (DWH) underwater spill in the Gulf of Mexico took months to bring under control, partly because of the challenges imposed by the water depth of the structure. The added complications that would arise in an Arctic setting, where repairs may have to be undertaken in winter months beneath floating sea ice, are factors that any such operations would need to address.

Another new technology is Floating Liquefied Natural Gas (FLNG) production where the processing of gas from offshore fields takes place at sea. The world's first FLNG vessel, Shell's Prelude, is currently under construction in the Republic of Korea for deployment on Australia's North-West Shelf. The LNG plant will be located on a large vessel that will be moored above the gas field – several hundred kilometres from the coast. The successful deployment of FLNG may allow for the production of gas from smaller or more remote offshore fields (Geoscience Australia and BREE, 2012).

A potential future development in the offshore energy sector is the possibility of mining methane gas hydrates from seabed deposits. Methane clathrate, also called methane hydrate, is composed of methane trapped within the crystal structure of water, forming a solid similar to ice, found in seabed sediments in water depths of greater than 300 to 500 m (Ruppel, 2011). When brought to the earth's surface, one cubic metre of gas hydrate releases 164 cubic metres of natural gas. Methane that forms hydrate can be both biogenic, created by biological activity in sediments, and thermogenic, created by geological processes deeper within the earth. A conservative estimate (Boswell & Collett 2011) for the global gas hydrate inventory is ~1,800 gigatons of carbon. While global estimates vary considerably, the energy content of methane occurring in hydrate form is immense, possibly exceeding the combined energy content of all other known fossil fuels. However, methane production from hydrate has not been documented beyond small-scale field

experiments and its contribution to global gas supply has probably been delayed by several decades by the increasing development of onshore gas resources from shale, coal seams and other unconventional deposits (Geoscience Australia and BREE, 2012).

2. Environmental impacts from exploration, including seismic surveys, offshore facility development and decommissioning

2.1 Environmental impacts

Environmental impacts arise throughout petroleum exploration-drilling-production development operations as well as in the decommissioning of facilities once the oil field is no longer economic, although the nature and degree of impact varies (Swan et al., 1994). Seismic surveys, oil and gas production, transportation and decommissioning all have associated environmental impacts; these are described briefly below.

The risks of impact from oil spills are greatest during transport, from pipeline rupture and vessel loss or spillage, when large volumes of oil can be released suddenly. It is important to realize that accidental (anthropogenic) spills occur against a background of continuous leakage from the seafloor. Crude oil is a naturally-occurring substance. An amount of oil approximately equal to that spilled accidentally by humans enters the oceans each year through natural seepage (Kvenvolden and Cooper, 2003; National Research Council, 2003). Natural seepage is a gradual, ongoing process and ecosystems have evolved that use it as a food source. Spills are ecologically damaging because they result in unnatural concentrations of oil at a particular site that are incompatible with local marine life.

Also it should be noted that accidental oil spills account for only a small percentage of the total volume of oil that enters the oceans due to humans. Most oil enters the ocean mixed with sewage and urban stormwater runoff (GESAMP, 2007) but such diffuse sources do not have the same dramatic impact on ecosystems as a spill because the oil is delivered continuously in low concentrations over a broad area. The long-term effects of low-level oil pollution from diffuse sources are unknown (GESAMP, 2007).

2.2 Drilling and production activities

Drilling activities are carried out from ships or fixed platforms during exploration and to extract oil once it has been found. Direct damage to the seafloor is caused by the anchors used to hold the rig in place as well as by the impact of the well emplacement itself. Drilling requires the use of lubricant (drilling mud) and the disposal of drill cuttings onto the seabed at the drill site. Drilling mud and some of the drill-cuttings contain crude oil residues, polycyclic aromatic hydrocarbons (PAHs) and heavy metals that can be toxic. The environmental impacts of drilling may include smothering the seabed by blanketing it with dense drilling mud and cuttings and toxicity effects (Swan et al., 1994). The initial impact is generally confined to the

immediate surrounds, typically within 150 m of the drill site. However, Olsgard and Gray (1995) reported that barium, total hydrocarbons, zinc, copper, cadmium and lead contamination sourced from production platforms on the Norwegian shelf had spread considerably after a period of 6 to 9 years, so that evidence of contamination was found 2 to 6 km away from the platforms. This led to a ban in the North Sea on discharging oil-based muds or cuttings contaminated with them from 1993. The ban gradually decreased the affected zone around drilling installations from several km to approximately 500 m (Bakke et al., 2013).

During the production of oil and gas, water from the hydrocarbon reservoir is also brought to the surface. This is known as “produced water” (PW), is a by-product of oil production and it is either disposed of into the ocean or may be re-injected into the well to promote oil recovery (Swan et al., 1994). Produced water can also include sea-water injected into the well to promote recovery. Compared with ambient seawater, PW may contain elevated concentrations of heavy metals (e.g. arsenic, mercury, barium, copper, lead and zinc), radium isotopes, as well as hydrocarbons. The proportion of oil/water varies between locations but generally the proportion of water increases over time as the oil deposit is depleted (i.e. older wells discharge more PW than new wells). The proportion of water produced per barrel of oil typically ranges from around 3:1 to 7:1 although the relative amount of PW increases over time, such that in extreme cases the fluid pumped from a well might be 98 per cent water and only 2 per cent oil (Holdway and Heggie, 2000). At the production platform, most of the PW is separated from the oil, treated (typically to around 30 mg/L hydrocarbon) and disposed of into the ocean. Because the increase in the absolute amount of PW discharged leads to an increase in the absolute amount of oil discharged, unless the proportion of oil in the PW discharged is decreased, regulatory measures have been adopted in some areas, such as the North Sea, which have resulted in reductions between 2001 and 2006 of around 33 per cent in the amount of oil discharged in PW (OSPAR Decision 2001/1; OSPAR 2010).

PW forms a buoyant plume because it is typically 40° to 80°C warmer (and therefore less dense) than ambient seawater and thus it will be dispersed by wind and currents away from the production platform. Mixing and dilution with seawater results in toxic effects of PW being generally confined to within 1 km of production platforms, although PW plumes may be detected in surface waters for distances exceeding 10 km from the point source (Jones and Hayward, 2003). Cases of coral discolouration (coral bleaching) have been attributed to dilute (~12 per cent) PW concentrations (ITOPF, 2007). Hence, the situation of production platforms in relation to prevailing winds and currents and to the proximity of sensitive habitats is a consideration for offshore petroleum development.

There are additional environmental consequences of the emplacement of rigs and floating platforms into the marine environment, which include effects on migratory birds and artificial habitat. Electric lights used on the rigs have been shown to interfere with the natural migration pathways of some species of birds, causing them to accidentally collide with platform structures. Although the actual numbers of birds killed due to having collided with platforms is unknown, modelling has shown that the numbers could be significant (OSPAR, 2012b). Any seafloor disturbing activities

such as anchor placement and retrieval, drilling, construction and decommissioning activities, and jetting into the seafloor for pipeline trenches has the potential to disturb or cause permanent and irreversible damage to natural and cultural resources. Underwater cultural heritage such as shipwrecks and submerged prehistoric sites are especially vulnerable to seafloor disturbing activities as these resources are finite and each site is unique. Natural resources such as coral reefs, fish habitat, and deepwater chemosynthetic communities can also be impacted by these activities. In order to reduce the risk of damage in United States waters, the United States Bureau of Ocean Energy Management (BOEM) requires the operator to conduct high-resolution geophysical surveys to identify potential resources before the operator can receive their permit and commence seafloor disturbing activities.

Once in place, the legs (jacket) of an offshore platform become habitat for some species of fish and sessile marine biota and can create a local area of elevated biomass and biodiversity. This is because access to the immediate area around the platform is restricted for reasons of safety such that the platform creates a zone that acts as a de facto marine reserve. In addition, the steel structure provides a hard substrate for colonization that would otherwise not be present, thus artificially increasing the local biodiversity (Page et al., 1999; Shaw et al., 2001; Whomersley and Picken, 2003).

Over the lifespan of a platform, shell debris derived from molluscs that colonize the platform legs accumulates at the base of the platform. The shell accumulation is draped over drill cuttings (described above) forming a characteristic, mound-shaped deposit. The shell drape provides a new habitat that has different properties from the surrounding seabed and thus offers habitat to different species. Disturbance of the shell drape will expose the (potentially toxic) drill cuttings that are a factor for consideration for rig decommissioning.

Because of the biological colonization of MODUs, the relocation of the vessel between drilling locations has been identified as a vector for the introduction of non-native species (Paula and Creed, 2005; Sammarco et al., 2010).

2.3 Seismic surveys and their impact on marine mammals and other ocean life

Marine acoustic survey equipment is used by the oil and gas industry as well as by the military, marine industries and academic researchers to map the seafloor, study the sediments beneath the seafloor and image the water column. Depending on the purpose, sonars differ in frequency, source level and beam pattern. Sonar signals diminish as they propagate, affecting different parts of the water column with different biological consequences. Towed, low frequency systems (such as seismic air guns) are omni-directional, radiating sound in all directions. Hull-mounted systems are higher frequency (kHz or greater) and utilize beam forming to obtain higher resolution images at lower source levels.

Airguns employed to acquire seismic reflection data are far more powerful (225 to 255 decibels re 1 micro-Pascal peak; Richardson et al., 1995) than equipment used for marine research or normal ship navigation. Airguns used in seismic reflection surveys emit sound at a frequency of typically ~100 Hz which overlaps with the range

of marine mammals' hearing and is therefore most likely to affect marine mammals and other marine life (McCauley et al., 2000; O'Brien et al., 2002; NRC, 2003; Boebel et al., 2005; Nowacek et al., 2007; 2013; CBD, 2014).

Cetaceans have been observed avoiding powerful, low frequency sound sources. A study by McCauley et al (2000) has shown that migrating humpback whales will leave a minimum 3 km gap between themselves and an operating seismic vessel, with resting humpback whale pods (groups) containing cows exhibiting increased sensitivity and leaving an increased gap of 7–12 km. Conversely, the study found that male humpback whales were attracted to a single operating airgun as they were believed to have confused the low-frequency sound with that of whale breaching behaviour. In addition to whales, sea turtles, fish and squid all showed alarm and avoidance behaviour in the presence of an approaching seismic source. While there has not been any documented direct linkage between seismic surveys and the beaching of marine mammals, Gordon et al., (2004) noted that concerns over the stranding of beaked whales in two separate incidents was sufficient for United States courts to agree to a restraining order on seismic operations by the RV *Maurice Ewing*. Nowacek et al. (2007) noted that displacement (relocation to an un-impacted area) is a common response of mammals, which may cause harm if the impacted site is an important feeding ground (see also Cerchio et al., 2014). Lucke et al (2009) found that harbour porpoises consistently showed aversive behavioural reactions at received sound pressure levels above a certain threshold level produced using a seismic airgun.

The historical record of cetaceans stranding themselves prior to the industrial age includes the English Crown holding rights on stranded cetaceans from at least 1324, when they were known as “fishes royal” since the Crown had first claim on them (Fraser, 1977). Thus cetacean stranding occurs under natural environmental conditions. Additional evidence in support of this conclusion is the occurrence of marine mammal strandings within the geological record (Pyenson et al., 2014).

It is not known whether there has been any increase in whale strandings that can be attributed directly to seismic surveys. Nowacek et al. (2007; 2013) conclude that major data deficiencies are: the lack of studies linking animal responses to received acoustic level data; gaps in species representation; and poor understanding of habituation, sensitization and tolerance. In the case of marine animals other than cetaceans, there is some evidence for short-term displacement of seals and fish by seismic surveys, but there is little literature available (Thompson et al., 2013; see also Chapter 37).

2.4 Pipeline construction, main causes of leaks and decommissioning

In order to bring oil and gas ashore to refineries and transport systems, pipelines are laid across the seabed, in places forming complex networks (Fig. 2).⁵ Before a pipeline can be laid, the proposed route is surveyed using acoustic seabed mapping technology and underwater cameras to identify any obstacles such as natural bedrock formations, boulders, seabed valleys or migrating sand dunes as well as

⁵ The following summary of pipeline construction is based primarily on Palmer and King (2004).

shipwrecks, other cables and pipelines and dumped ammunition. The pipe is then laid along the surveyed route using either a specialised pipe-laying vessel or else a pull/tow system where the pipeline is built onshore and then towed by ship to its desired location. The first process usually involves one pipe-laying vessel supported by barges that supply the ship with pipe sections plus other support ships that monitor the seabed. Pipe sections are welded together on board, the joints tested (by ultrasound) and the pipe coated with an anticorrosion application.

The diameter of the pipe varies between 0.15 to 1.4 m, but is ~0.3 m in most cases. A distinction is made between a flowline and a pipeline. Flowlines are intrafield pipelines used to connect subsea wellheads, manifolds and the platform within a particular development field. Pipelines (export pipelines, also called trunk lines) are used to bring the resource to shore.

Problems that affect the stability and integrity of submarine pipelines are: (1) expansion/contraction of the steel pipe causing lateral or upheaval buckling; (2) erosion of the seabed around the pipeline by storms, waves and currents leaving unsupported spans of pipeline vulnerable to fracture; and (3) corrosion. Solutions to the expansion/contraction problem are: adding expansion joints; burial; anchoring; applying a concrete or rock cover; or laying the pipe in an “S”- shaped configuration (S-lay). Problems of seabed erosion can be overcome by burial (Xu et al., 2009; Yang et al., 2012). Burial of the pipeline is also required in areas where vessels might anchor, where bottom fishing activities occur or where the pipeline crosses the shoreline. However, burial is more expensive than simply laying the pipeline along the seabed, so it is not used unless necessary (or a legal requirement).

Pipelines are maintained and inspected using a “pig,” a tool that can be inserted in one end of the pipeline and pushed by the fluid to the other end. The most basic pigs are used to clean the inside of the pipes; highly-complex “smart pigs” can inspect the condition and thickness of the pipeline and detect points of corrosion or fracturing. Smart pigs are used more in the North Sea than in the Gulf of Mexico because the majority of existing Gulf of Mexico lines were not originally designed or built to accommodate smart tool pigs (MSL, 2000).

Pipelines are monitored for leakage by analog and computer-assisted systems (Stafford and Williams, 1996). The mass balance approach simply measures the amount of oil going in the pipeline and the amount coming out. Real-time transient modelling compares actual measured data with a computer model. If the results are outside normal operating limits, an alarm alerts the operator to take appropriate action. Other methods of monitoring pipelines include chemical and radioactive tracers, acoustic emission, neural networks, fibre-optic sensors and pressure point analysis (Stafford and Williams, 1996).

Woodson (1990) compiled a database of 1,047 submarine pipeline failures reported in the Gulf of Mexico between 1967 and 1990. The results indicate that a pipeline failure occurred in the Gulf of Mexico on average once every 5 days over the period of data collection. The source of failure was reported in 916 incidents in which the main causes were attributed as follows: 50 per cent (456 out of 916 incidents) due to internal or external pipeline corrosion; 12 per cent (106 incidents) due to storms and hurricanes; 14 per cent (124 incidents) due to damage from ship’s anchors and

fishing gear; 10 per cent (94 incidents) due to material failure of valves, gaskets or other joints; and 15 per cent (136 incidents) due to other or unknown causes. Pipelines over 10 years in age had a greater number of failures due to corrosion than younger pipelines; there was a trend of an increasing rate of failure due to corrosion in the last 5 years of the database (1986-1990), presumably attributable to the aging of the pipeline network. Pipelines damaged by storms (in which pipes are excavated by waves and currents exposing an unsupported span that is liable to fracture) were not buried in 40 out of 52 cases (Woodson, 1990).

In its review of offshore pipeline safety, the United States Marine Board Committee on the Safety of Marine Pipelines (Marine Board, 1994) cited the work of Woodson (1990) and noted that during the 1990s, transmission and production pipeline leakage and accidents accounted for about 98 per cent of accidental releases by offshore production activities. However, although corrosion is the most commonly cited cause of pipeline failure, corrosion-related ruptures do not result in significant release of oil into the environment. Rather, damage caused by a few major incidents involving ship's anchors caused pipe leakage that is attributed to 95 per cent of the 250,000 barrels that leaked from pipelines in the Gulf of Mexico from 1967 to 1990 (Marine Board, 1994).

The National Research Council (NRC) (1997) noted that, in the United States Gulf of Mexico "no agency coordinates the collection of information and the available data on offshore pipeline failures are correspondingly "incomplete". Data on pipeline failures from state waters are collected by states (when collected) and may not be readily accessible. This is in spite of the fact that pipelines in state waters are commonly the oldest and most exposed to collision with ships (Marine Board, 1994). Since 2006, data on offshore pipelines (outside of state waters) has been the responsibility of the Bureau of Safety and Environmental Enforcement (BSEE).

In Europe, a pipeline data base compiled by PARLOC (2001) includes records from 1971 to 2000 during which time there were 542 pipeline incidents including 96 pipeline leaks into the environment plus 92 leaks of pipeline fittings. The cause of failure of pipeline fittings is not recorded (PARLOC, 2001); for pipelines the database shows that corrosion is the major cause of failure (51 per cent) followed by maritime actions such as anchoring (23 per cent), material failure and other or unknown causes (26 per cent).

Less than 2 per cent of the North Sea pipeline inventory has been decommissioned as of 2013 (Oil and Gas UK, 2013). Of North Sea pipelines that have been decommissioned, 80 per cent are less than 16 inches (40.64 cm) in diameter. Half of the larger diameter pipelines (16 inches (40.64 cm) or greater) decommissioned to date were removed (i.e. 10 per cent of decommissioned pipelines were removed). Cleaning and purging is carried out following cessation of production, pipeline system depressurisation and removal of bulk hydrocarbons. Cleaning involves chemical cleaning to detach hydrocarbon residue from the pipe wall and bi-directional magnetic, disc and brush cleaning to remove ferrous and other loose debris using a specialist pig (Oil and Gas UK, 2013; see also Chapter 20).

The Gulf of Mexico offshore oil and gas has been operating since 1936 (Owen, 1975) and more of the pipeline infrastructure has been retired than in other parts of the world. Rach (2013) reported, based on data from the United States Bureau of Safety and Environmental Enforcement, that the inventory of Gulf of Mexico pipelines (as of mid-2013) includes 24,126 miles (38,827 km) that are in active use, 2,409 miles (3,877 km) proposed for installation, 12,628 miles (20,323 km) that have been abandoned, 2,264 miles (3,643 km) proposed to be abandoned and 2,425 miles (3,902 km) of pipeline that are out of service. Thus 42 per cent of existing (66,695 km) pipelines in the Gulf of Mexico are either abandoned, proposed to be abandoned or are no longer in service.

Apart from leakage of oil, other environmental and economic consequences of abandoned pipelines are their impacts on fishing (inhibiting bottom-trawling), other pipe and cable-laying activities and creating artificial habitats.

2.5 Rig decommissioning, dismantling and disposal, “Rigs to Reefs” programme

In its assessment of environmental governance in 27 developing countries, the World Bank (2010) found that governments lack a policy and process for decommissioning and abandonment and do not routinely assess, determine, or assign the future liability costs of decommissioning and abandonment. Only about 50 per cent of countries have an established process for managing the decommissioning and abandonment of oil and gas projects. Disposal of man-made structures (including platforms) at sea and abandonment or toppling on site of man-made structures falls under the scope of the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, 1972 (1972 London Dumping Convention) (LDC) and the 1996 London Protocol (LP). These treaties are global agreements and provide relevant dumping management policies, provisions, and assessment guidelines (London Convention and Protocol/UNEP, 2009). The 1989 International Maritime Organization (IMO) guidelines provide for the removal of offshore installations in order to leave 55 metres of clear water over any remains left in place (IMO, 1989).

In the United States, the BSEE has jurisdiction over decommissioning of wells and structures, pipelines, and the so-called “Rigs-to-Reefs” program. The Rigs-to-Reefs programme is the practice of converting decommissioned offshore oil and gas rigs into artificial reefs, which has occurred mostly in the Gulf of Mexico. However, less than 10 per cent of rigs decommissioned in the Gulf of Mexico have so far been converted to reefs; 90 per cent are removed (The Economist, 2014; BSEE data). Apart from a few platforms converted to reefs in Brunei Darussalam and Malaysia, opposition to the practice has meant that none have been allowed off California or in the North Sea to date (Day, 2008; Macreadie et al., 2011, 2012; Jørgensen, 2012). In the North Sea, 122 decommissioned installations were brought ashore between 1999 and 2010, and four large concrete installations and the footings of one large steel installation have been left in place (OSPAR 2010). One estimated cost of removing the existing North Sea production platforms, in the United Kingdom sector alone, was over 14 billion dollars (Prince, 2004). About 60 rigs are nearing the end of their working life in Australia (Macreadie et al., 2011).

The BSEE has granted permits for about 420 platforms to be converted to artificial reefs in the Gulf of Mexico. There are three methods for converting a non-producing platform into an artificial reef: (1) partially remove the platform; (2) topple the platform in place; or (3) tow-and-place the platform to one of about 28 sites designated as an artificial reef area. Partial removal typically relies on non-explosive means to cut the platform below the sea surface, leaving the legs in their vertical position. Toppling in place uses non-explosive or explosive severance to cut the platform from its legs and lay the platform legs on their side (the platform itself is removed). The tow-and-place method entails removing the platform and detaching the structure from the seafloor before towing it to a designated artificial reef area for disposal.

In the United States Gulf of Mexico there were about 2,996 production platforms as of March 2013, of which 813 (27 per cent) are no longer producing. In 2010, the United States Government issued notices to companies requiring them to set permanent plugs in nearly 3,500 nonproducing wells and dismantle about 650 unused oil and gas production platforms (Rach, 2013). Decommissioning means ending operations and returning the lease or pipeline right-of-way to a condition that meets the requirements of regulations of BSEE and other agencies that have jurisdiction over decommissioning activities. The regulations apply to any installation, other than a pipeline, that is permanently or temporarily attached to the seabed. Very few deep sea (>200 m depth) oil and gas fields have as yet been depleted, hence decommissioning of infrastructure has not yet become an issue (Macreadie et al., 2011).

Regulations for the decommissioning of a platform vary between countries. The United States requires plugging the well(s) supported by the platform and severing the well casings 15 feet (5 m) below the seabed; cleaning and removing all production and pipeline risers supported by the platform; removing the platform from its foundation by severing all bottom-founded components at least 15 feet (5 m) below the seabed; disposing of the platform onshore or placing the platform at an artificial reef site; and cleaning the platform site to ensure that no debris or potential obstructions remain. Over the lifespan of a platform a mound of debris accumulates beneath the platform that may contain toxic chemicals; removal of such mounds is also a requirement for decommissioning.

In the North Sea, OSPAR Decision 98/3 requires the topsides of all decommissioned installations to be removed to shore and all sub-structures or jackets weighing less than 10,000 tons to be completely removed. The regulations stipulate that, where there may be practical difficulty in removing installations (i.e. the footings of large steel platforms weighing over 10,000 tons, the concrete gravity based platform sub-structures, or concrete anchor bases and other structures with significant damage or deterioration, which would prevent removal), a decision may be taken to leave parts of the structure on the seabed, on a case-by-case basis.

3. Offshore installation disasters and their impacts, including longer-term effects.

3.1 Impacts of offshore installation disasters

Impacts of offshore oil and gas installation disasters include loss of human life, loss of revenue and environmental impacts. Offshore disasters have resulted in loss of life on several occasions in the history of the offshore oil and gas industry. In March 1980, the “flotel” (floating hotel) platform Alexander L. Kielland capsized in a storm in the North Sea with the loss of 123 lives. In February 1982, the Ocean Ranger semi-submersible mobile offshore drilling unit sank on the Grand Banks of Newfoundland; none of the 84 crew members survived. In July 1988, 167 people died when Occidental Petroleum's Piper Alpha offshore production platform exploded in the United Kingdom sector of the North Sea after a gas leak. In 2001 Petrobras-36 in Brazil exploded and sank five days later killing 11 people. In April 2010, the Deepwater Horizon platform exploded, killing 11 people. The Kolskaya floating oil rig capsized and sank in the Sea of Okhotsk in December 2011, killing 53 crew members. In December, 2013, a rig owned by Saudi Arabia's state-run petroleum company, Aramco, sank in the ROPME/RECOFI area, killing three crew members. Such disasters have resulted in the imposition of new regulations on industry (Turner, 2013); for example, the Piper Alpha disaster resulted in the United Kingdom Government passing the 1992 Offshore Installations (Safety Case) Regulations. However, there have been subsequent disasters around the world and the industry, as a whole, has continued to make the changes needed to improve its safety record (Harris, 2013).

From 2001 to 2010, the United States Minerals Management Service reported 69 offshore deaths, 1,349 injuries, and 858 fires and explosions on offshore rigs in the Gulf of Mexico. During 2003–2010, the United States oil and gas extraction industry (onshore and offshore, combined) had a collective fatality rate seven times higher than that for all United States workers (27.1 versus 3.8 deaths per 100,000 workers; Centers for Disease Control and Prevention, 2013). Catastrophic events attract intense media attention but do not account for the majority of work-related fatalities during offshore operations. A report by Baker et al. (2011) found that helicopter crashes were the most frequent fatal event in this industry.

Economic impacts stemming from offshore oil and gas installation disasters include the direct loss of income for the period that the facility remains offline, the costs to repair the facility, the costs to other industries (e.g. fishing and tourism) affected by the disaster and other compensation. As a result of the Deepwater Horizon oil spill, BP established a Trust Fund of 20 billion dollars for natural resource damages, state and local response costs and individual compensation. Other industry-wide consequences may follow such disasters. For example, exploration drilling in the Gulf of Mexico was slow to recover from the moratorium that followed the Deepwater Horizon oil spill in 2010. By 2012 36 rigs were back working off Louisiana and 4 off Texas, compared with 21 and 2, respectively, in late 2010. On 3 June, 2008, a high-pressure 12 inch export sales gas pipeline (SGL), critically weakened by a region of external corrosion, ruptured and exploded on the beach of Varanus Island

off the coast of Western Australia. There was approximately 60 million Australian dollars in damage to the plant. Plant closure led to up to 3 billion dollars of losses to the West Australian economy, which lost 30 per cent of its gas supply for two months.

A blowout of the Montara wellhead platform on 21 August 2009, on Australia's remote North-West Shelf, leaked an estimated 30,000 barrels of crude plus an unknown quantity of gas until 3 November 2009 (total of 74 days), when the leak was finally stopped. The rig later caught fire but all 69 workers on the rig were safely evacuated with no injuries or fatalities. The company spent about 5.3 million Australian dollars on clean-up, about 300 million dollars in lost revenue and repair bills and was fined 510,000 dollars in August 2012 by the Australian Government (ABC News, 2012); the well finally went into production in June, 2013. However, fishermen and seaweed farmers in Indonesia are seeking compensation with support from the Australian Lawyers Alliance (ALA), claiming that environmental damage caused by the spill has cost them more than 1.5 billion dollars per year in lost earnings (ALA, 2014).

In 1980, within the ROPME/RECOFI area, the Hasbah Platform Well 6 blew out for 8 days, spilling 100,000 barrels of oil and costing the lives of 19 men. However, the worst disaster in the region occurred during the 1991 war between Iraq and Kuwait, when there were 22 incidents that spilled amounts of oil variously estimated at between 2 and 11 million barrels into the ROPME/RECOFI area (Khordagui and Al-Ajmi, 1993; Elshorbagy, 2005). The coast of Saudi Arabia was the most heavily impacted by the spill. Initial assessments of the environmental damage caused by the spilled oil were optimistic of rapid recovery (e.g. Fowler et al., 1993), but more recent studies have documented lingering effects of oil trapped in intertidal sediments and salt marshes over broad spatial scales (Michel et al., 2005; Barth, 2007). As of 2011, the Government of Saudi Arabia had invested 180 million United States dollars and the United Nations had spent U45 million dollars in rehabilitating impacted areas.

Natural disasters also take a toll on offshore oil and gas facilities. In August 2005, Hurricane Katrina affected 19 per cent of United States oil production by destroying 113 offshore oil and gas platforms, damaging 457 oil and gas pipelines, and spilling an unquantified amount of oil (<http://www.bsee.gov/Hurricanes/2005/katrina/>).

Environmental consequences of offshore oil and gas installation disasters are perhaps the most widely publicized aspect of such events. In the 2010 Deepwater Horizon (DWH) Gulf of Mexico oil spill, it is estimated that around 4.9 million barrels (about 670,000 tons, assuming a specific gravity of 0.88) was discharged into the sea before the well was capped, approximately 16 times more oil than was spilled by the Exxon Valdez in 1989 (about 37,000 tons of crude oil; Crone and Tolstoy, 2010; Oil Spill Commission, 2011). The impact of this huge volume of oil on deep water habitats in the Gulf of Mexico is unknown at the time of this writing (April, 2014). Prior to the DWH incident, the total volume of oil spilled in the Gulf of Mexico between 1964 and 2009 is estimated to be 517,847 barrels (Mufson, 2010).

Numerous smaller-sized spills have also occurred in recent years. Examples include a North Sea spill of 200 tons in August 2011 that occurred at Shell's platform Gannet

Alpha; in 2012 Chevron suspended activities after two oil leaks (of around 5,000 barrels) occurred in a space of four months off the Brazilian coast; in March 2012 the platform Elgin-Franklin, operated by the Total group in the North Sea, was evacuated after an uncontrollable gas leak of an estimated 300 million cubic feet over a 45 day period (Beall and Ferreti, 2012).

The number of accidents reflects the massive scale of the offshore drilling and production enterprise. For every accident there are environmental consequences. Before the Deepwater Horizon accident, such major incidents were anticipated to occur with such extreme rarity that they were not considered relevant. One explanation could be that risk assessments are performed for single wells and not for whole areas (or on an industry-wide basis). However, a study of accidental oil spills based on global historical data has shown that the DWH accident was not an outlier, but an accident that can happen every 17 years with an uncertainty interval from 8 to 91 years (5–95 per cent). When the DWH accident was excluded from the data set, the resulting frequency was 23 years with an uncertainty interval from 10 to 177 years (Eckle et al., 2012).

Accidents that occur in coastal waters have the most severe environmental impact. Most oil floats on the sea surface where it can be readily delivered to the shoreline, where the concentrated consequences are evident. The coast is also a habitat for a diversity of species of birds, mammals, invertebrates and marine plants. For this reason spills that impact the coast, such as the Exxon Valdez spill that occurred in Alaska in 1989, have the greatest impact on the ecosystem (Shaw, 1992). The speed of ecosystem recovery is generally slower for colder and deeper habitats than it is for warmer and shallower habitats (Harris, 2014). However, every ecosystem is different and recovery times are difficult to estimate. For example, oil spilled in the Niger Delta over the last 50 years has penetrated up to 5 m into the soil profile and caused groundwater contamination in 8 out of 15 sites investigated that could take up to 30 years to clean up (UNEP, 2011).

3.2 Impact of oil spills on the marine ecosystem

The impacts of oil spills range from the immediate effects of oiling to longer term consequences of habitats being modified by the presence of oil and tar balls. Traces of hydrocarbons can remain in coastal sediments for many years after an oil spill (Hester and Mendelssohn, 2000). For example, for some of the rocky shores where oil stranded after the Exxon Valdez spill in 1989, oil is still found subsurface, only slightly weathered (Irvine et al., 2014). Similarly, oil from the 1991 Gulf War is still apparent in intertidal sediments and in salt marshes along the coast of Saudi Arabia (Michel et al., 2005; Barth, 2007).

There is no clear relationship between the amount of oil spilled in the marine environment and the likely impact on wildlife. A smaller spill at a particular season of the year and in a sensitive environment may prove much more harmful than a larger spill at another time of the year in another or even the same environment. Even small spills can have very large effects. Species that use the sea surface are most vulnerable (birds and mammals) and the eggs and larvae of many other species can be damaged by oil (Alford et al., 2014).

Some species may exhibit reduced abundance due to spills (Sánchez et al., 2006) although direct causal evidence is not always available (Carls et al., 2002). Some opportunistic species are able to take advantage of the changed habitat conditions and the attendant reduced abundance of impacted species, giving rise to a short-term increase in local biodiversity (Edgar et al., 2003; Yamamoto et al., 2003); this is an example of why biodiversity statistics alone are not a reliable indicator of environmental health. Recovery time for sites varies as a function of the type of oil spilled, the biological assemblage impacted, substrate type, climate, wave/current regime and coastal geomorphology and ranges from years to decades depending on these and other factors (Ritchie, 1993; Jewett et al., 1999; French-McCay, 2004).

There are a number of pathways for oil to reach the oceans, namely:

- Land-based sources (urban runoff, coastal refineries);
- Oil transporting and shipping (operational discharges, tanker accidents);
- Offshore oil and gas facilities (operational discharges, accidents, blow-outs);
- Atmospheric fallout;
- Natural seeps.

Figures published by National Research Council (2003) range from an average of 470,000 tons to a possible 8.4 million tons per year for the sum of all of these sources. It is generally agreed that the largest single source is the land-based (urban runoff, coastal refineries) input, although there is little agreement on the absolute values for any source terms.

When oil enters the sea, it reacts according to physical, chemical and biological processes that change the properties of the oil and consequently, its behaviour. Factors include:

- The quantity and duration of the discharge/spill;
- The time of the year at which it occurs;
- The temperature of the air and the receiving water body;
- The weather and sea (e.g. waves and currents) conditions;
- The species composition in the area affected;
- The properties of the shoreline (rocky, sandy, mud flats, mangroves, etc.).
- The presence and abundance of oil-degrading micro-organisms;
- The concentration of dissolved oxygen in the water.

Different types of oil have different physical properties, which affect the way the oil will react in the environment (Table 2).

Table 2. Oil classification for four groups having different physical properties according to the International Tanker Owners Pollution Federation Limited (ITOPF; <http://www.itopf.com/marine-spills/fate/models/>).

Group	Density	Examples
Group I	< 0.8	Gasoline, Kerosene
Group II	0.8 - 0.85	Gas Oil, Abu Dhabi Crude
Group III	0.85 - 0.95	Arabian Light Crude, North Sea Crude Oils
Group IV	> 0.95	Heavy Fuel, Venezuelan Crude Oils

Oil, when spilled at sea, will normally break up and be dissipated or scattered into the marine environment over time. This dissipation is a result of a number of chemical and physical processes that change the compounds that make up oil when it is spilled. The key natural processes are evaporation, dispersion, dissolution, oxidation, emulsification, biodegradation and sedimentation. The addition of chemical dispersants (also surfactants) can accelerate this process of natural dispersion.

Lighter components of the oil will evaporate to the atmosphere. The amount of evaporation and the speed at which it occurs depend upon the volatility of the oil. Evaporation of oil with a large percentage of light and volatile compounds occurs more quickly than one with a larger amount of heavier compounds.

Waves, currents and turbulence at the sea surface can cause all or part of a slick to break-up into fragments and droplets of varying sizes. These become mixed into the upper levels of the water column.

Water soluble compounds in oil may dissolve into the surrounding water. This depends on the composition and state of the oil, and occurs most quickly when the oil is finely dispersed in the water column. Components that are most soluble in sea water are the light aromatic hydrocarbons compounds, such as benzene and toluene. However, these compounds are also those first to be lost through evaporation, a process which is 10-100 times faster than dissolution.

Oils react chemically with oxygen either breaking down into soluble products or forming persistent compounds called tars. This process is promoted by sunlight although it is very slow even in strong sunlight such that thin films of oil break down at no more than 0.1 per cent per day. The formation of tars is caused by the oxidation of thick layers of high viscosity oils or emulsions. This process forms an outer protective coating of heavy compounds that results in the increased persistence of the oil as a whole. Tar balls, which are often found on shorelines and have a solid outer crust surrounding a softer, less weathered interior, are a typical example of this process.

Emulsification occurs when two liquids combine, one suspended in the other. Emulsification of crude oils refers to the process whereby sea water droplets become suspended in the oil. Oils with an asphaltene content greater than 0.5 per cent tend to form stable emulsions which may persist for many months after the

initial spill has occurred. Emulsions may separate into oil and water again if heated by sunlight under calm conditions or when stranded on shorelines.

Sea water contains a range of micro-organisms or microbes that can partially or completely degrade oil to water soluble compounds and eventually to carbon dioxide and water. Many types of microbe exist and each tends to degrade a particular group of compounds in crude oil (Hazen et al., 2010).

Sinking usually occurs due to the adhesion of particles of sediment or organic matter to the oil, in which case the oil accumulates in the seabed sediments. In the ROPME/RECOFI area for example, Elshorbagy (2005) reported that oil-contaminated seabed sediments occur, particularly in coastal areas. The highest levels of hydrocarbons were $1600 \mu\text{g l}^{-1}$ found near Bahrain compared with background levels of 10 to $15 \mu\text{g l}^{-1}$. Oil washed ashore at Pensacola Beach, Florida, from the DWH spill resulted in weathered oil petroleum hydrocarbon concentrations in beach sands ranging from 3.1 to $4,500 \text{ mg kg}^{-1}$ (Kostka et al., 2011).

4. Significant environmental aspects in relation to offshore hydrocarbon installations.

Drilling operations may require the use of many chemicals. In the OSPAR region, chemicals are categorised in four colour classes depending on degradability, octanol-water coefficient and toxicity. The green category means it “shall pose little or no risk to the environment”. Chemicals in the black category should be prohibited and chemicals in the red category should be substituted. Chemicals in the yellow category have characteristics between the red and the green class and are considered to be environmentally acceptable.

Other operational discharges are drill cuttings and small spills of oil and chemicals connected to exploration, production or transport.

For the offshore industry in the North East Atlantic, OSPAR has agreed on several decisions and recommendations to reduce discharges of oil and chemicals. These include Recommendation 2001/1: Management of PW and 15 per cent reduction target for oil discharged with PW, in addition to agreements on decisions and recommendations for use of chemicals offshore, decommissioning and environmental management (OSPAR, 2010).

OSPAR reports discharges, spills and emissions from oil and gas installations. Between 2001 and 2007 an average of between 400 and 450 million $\text{m}^3 \text{ yr}^{-1}$ PW were discharged (OSPAR 2009). For 2010 a sum of 361 million m^3 PW was discharged in this area. The main contributing countries were Denmark (25 million m^3), Norway (131 million m^3) and United Kingdom (196 million m^3 ; OSPAR, 2010). The numbers account for the whole OSPAR region, but the main region of activities is the North Sea. Oil content in PW was reported as dissolved and dispersed oil, and annual average oil content was reported to be 12 and 13 mg/l, respectively. Annual average oil content in dissolved and dispersed oil was 4,227 tons and 4,746 tons, respectively, giving a total of 8,972 tons in 2010. Annual quantity of injected PW was

81 million m³ (OSPAR, 2012a). Yearly discharge of approximately 400 million m³ PW has been relatively constant since 2001 (OSPAR, 2010).

Most of the concern regarding negative effects on ecosystems due to operational discharges from offshore oil and gas activities has been directed to the oil fraction of PW discharges, and less towards the added chemicals. This is due to the content of polycyclic aromatic hydrocarbons (PAHs) and alkylated phenols from the oil fraction. PAHs have received focus because they can be metabolically activated in fish and bound to DNA as DNA adducts. PAHs are also shown to damage early developmental stages of fish creating several effects at low doses, including effects on heart development (Incardona et al., 2004; Brette et al., 2014). Alkylated phenols have received focus because some of these compounds have hormone-mimicking effects (Heemken et al, 2001).

Norway monitors the levels of contaminants in sediments, deployed fish and mussels and in wild caught fish, in addition to effect studies in fish and mussels. Monitoring of sediments shows very small areas with increased total hydrocarbon content or disturbed fauna. Mussels and fish deployed in cages for 6 weeks around different platforms did not show effects in distances further than 1 km (Brooks et al., 2011). No increased levels of contaminants were found in fillets of wild caught fish, although in some cases wild caught fish had increased levels of PAH metabolites in bile. The most surprising findings have been levels of DNA adducts in haddock liver from the North Sea, at levels giving rise to environmental concern in 2002 (Balk et al., 2011) and in 2011 (Grøsvik et al., 2012) because the levels were above the environmental assessment criteria (EAC) for DNA adduct in haddock liver (ICES, 2011).

5. Gaps in capacity to engage in offshore hydrocarbon industries and to assess the environmental, social and economic aspects.

The hydrocarbon industry is an extremely technical endeavour and it has evolved over a period covering more than 70 years. The offshore industry must deal with the fact that the hydrocarbon resource lies hidden, often several kilometres beneath the seafloor. Therefore, the industry employs highly skilled specialists and advanced technologies to image and sample the seafloor to find the hidden hydrocarbons. In general, oil and gas resource development requires the deployment of considerable technology to access, control, and transport the hydrocarbons.

In many parts of the world, massive oil revenues have not overcome high levels of poverty. Indeed, in some cases, they have led to significant social problems. Many oil and gas companies do not publish information what royalties, taxes and fees they pay country by country, and there is thus often a lack of transparency about these transactions. (FESS, 2006; Ross, 2008).

Only 80 out of the known 974 sedimentary basins on earth contain exploitable hydrocarbons (Li, 2011). Therefore, huge risks and uncertainty are inherently associated with hydrocarbon exploration activities. Many “dry” exploration wells are drilled for every winner (for example, see BSEE web site). The industry invests

expertise, money and time to reduce risk and uncertainty so that the maximum amount of hydrocarbons is found with minimum effort and investment.

Exploration and production companies are international and operate with sophisticated technologies to make discoveries, across international boundaries wherever hydrocarbons may be found. Individual fields may cross international boundaries, further complicating their development and adding risk to investors; the Timor Gap, an area of disputed seafloor located on the border between Australia and Timor-Leste is a good example (Nevins, 2004).

In the initial stages of their development, many oil-endowed countries lacked the highly specialized knowledge or the substantial funds required to successfully find and produce offshore hydrocarbons. So, offshore hydrocarbon exploration became a primarily private-sector activity worldwide, dominated by international oil companies with the relevant skills, experience and finances needed to take on significant risk.

Over the past few decades there has been a significant shift in ownership of the offshore oil and gas global enterprise. In the 1970s, 85 per cent of all offshore oil reserves were owned by seven international oil companies (IOCs). By 2012, 18 of the top 25 oil and gas producers were National Oil Companies (NOCs), controlling 75 per cent of oil production and holding 90 per cent of the world's oil reserves (Wagner and Johnson, 2012). NOCs have competed with IOCs developing new technologies and productive resource capacity to potentially overtake the largest IOCs in size and scope. NOCs like Brazil's Petrobras, Malaysia's Petronas and Norway's Statoil have specialized in deepwater drilling technologies, once monopolized by the IOCs (Wagner and Johnson, 2012). This is an example of technology transfer that has benefitted developing countries by allowing them to participate in (if not dominate) the offshore oil and gas industry.

Assessing the environmental impact of offshore oil and gas development in developing countries has not progressed at the same pace as the capacity to develop and exploit the resource. In its assessment of environmental governance in 27 oil-producing developing countries, the World Bank (2010) found there was a “lack of a sufficiently organized administrative structure that enables efficient regulatory compliance and enforcement. Additionally, the human and financial resources needed for effective environmental governance are generally lacking.” A case study from Trinidad and Tobago published by Chandool (2011) illustrates the key issues: paucity of accessible data, lack of public participation, lack of post-approval enforcement and lack of quality control in environmental impact assessment (EIA) practice.

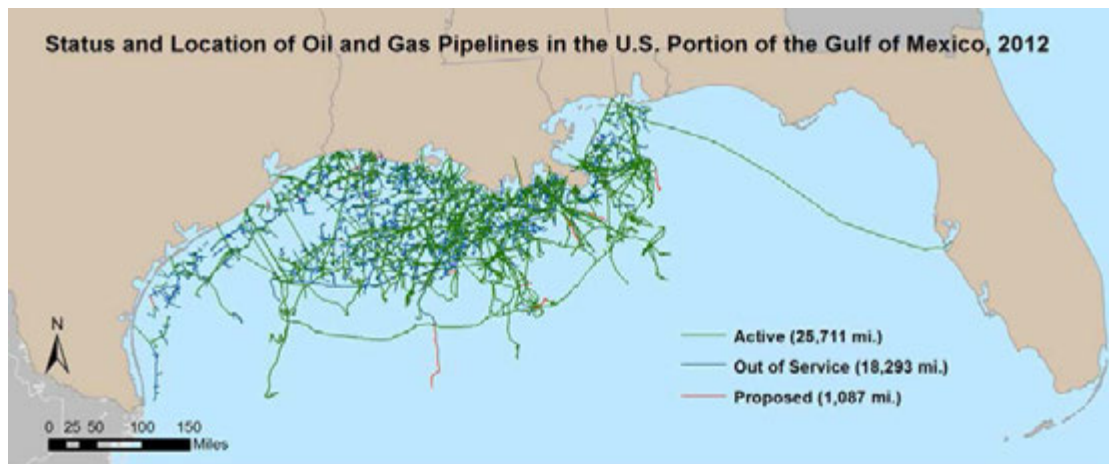

In Malaysia, companies are required to complete an EIA that is prepared by a registered consultant (Mustafa, 2011). The industry was found to have breached its license to operate in 28 cases that went to court in 2009, with fines totalling Ringgit Malaysia (RM) 250,000 (about 76,000 dollars or an average fine of 2,700 dollars). Given the overall value of the industry (Petronas alone had a net worth in 2012 of over 157 billion dollars and had nearly 40,000 employees), there is a *prima facie* lack of proportion between the potential damage from the offences and the deterrent level of such fines.

More broadly, there are gaps in monitoring the offshore oil and gas industry by the responsible government departments. It has already been mentioned above (Section 2.4) that the collection of information on offshore pipeline failures is not coordinated in the Gulf of Mexico between state and federal jurisdictions (NRC, 1997). The data that are collected by government departments charged with monitoring the offshore oil and gas industry are often incomplete or not strategic. For example, PARLOC (2001) notes that whilst corrosion has been identified as one of the major causes of leaking pipes in the North Sea, corrosion protection data are not currently recorded in the pipeline database, so it is not possible to derive failure rates for specific types of corrosion prevention. The lack of coordination between different agencies having a share of responsibility in managing the offshore oil and gas sector was identified as a key issue by the Australian Government's Montara Commission of Inquiry Report (2010), whose conclusion was: "A single, independent regulatory body should be created, looking after safety as a primary objective, well integrity and environmental approvals. Industry policy and resource development and promotion activities should reside in government departments and not with the regulatory agency. The regulatory agency should be empowered (if that is necessary) to pass relevant petroleum information to government departments to assist them to perform the policy roles."⁶ Thus, there is a gap in the capability of the responsible government departments to collect and share relevant information among different departments and authorities.

Another gap is with respect to the capacity for local communities to engage with the offshore oil and gas industry in decision-making. As has been already noted above for Trinidad and Tobago, lack of public participation in environmental impact assessments is a clear capacity gap (Chandool, 2011). The Australian company, Santos, engaged with local communities in Indonesia's Jawa Timur Province, who were concerned with the impact of offshore oil activities on their coastal habitats (Anggraeni, 2013). Although the community expressed concerns over Santos' air quality risk management and employment opportunities for local people, a dialogue was established allowing for a more satisfactory outcome for the local community (Anggraeni, 2013).

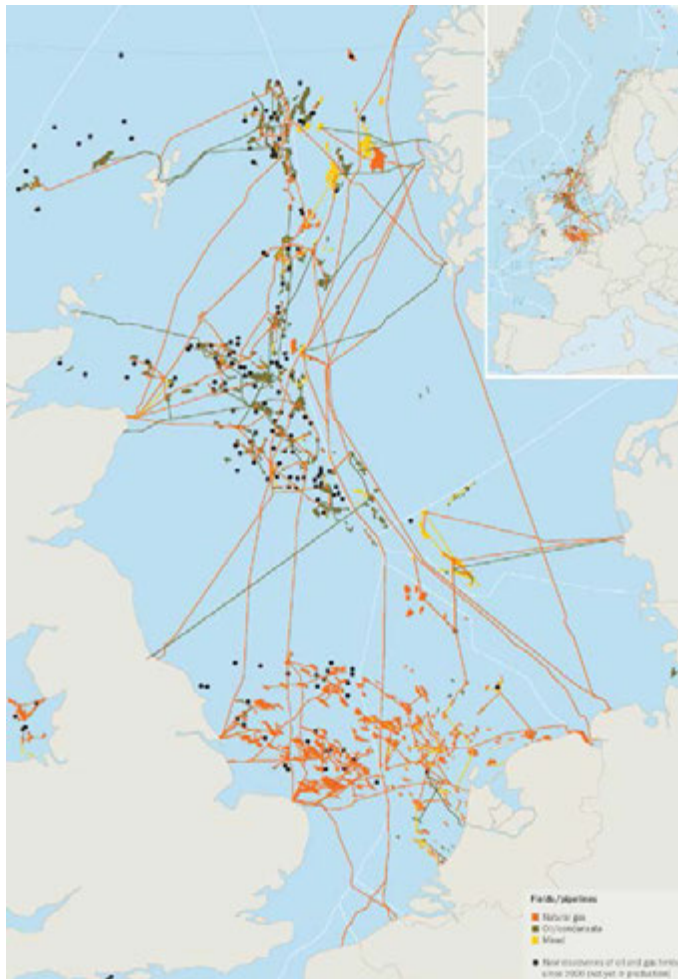

⁶ Partly in response to this conclusion, the Australian Government established, on 1 January 2012, the National Offshore Petroleum Safety and Environmental Management Authority (NOPSEMA; <http://www.nopsema.gov.au>), to be the national regulator for health and safety, well integrity and environmental management for offshore oil and gas operations.

Figures

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Map of offshore oil and gas pipelines in the United States section of the Gulf of Mexico (from NOAA). <http://stateofthecoast.noaa.gov/energy/gulfenergy.html>.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Offshore oil and gas fields under exploitation, new discoveries not yet in production and pipelines in the North Sea in 2009. Figure taken from OSPAR, 2010. (http://qsr2010.ospar.org/en/ch07_01.html).

Figure 3. Global crude oil production, comparing onshore, shallow offshore (<100 m water depth) and offshore deep (>100 m water depth) production (from Infield, 2014).

Whereas onshore production has remained stable at around 50-60 million barrels per day since the early 1970s, offshore production has grown steadily over the last four decades. Deep water production has accounted for nearly all growth since about 2005.

Chapter 22. Other Marine-Based Energy Industries

Contributors: Amardeep Dhanju and Lars Golmen, Peyman Eghtesadi Araghi (Co-Lead member), Peter Harris (Co-Lead member)

1. Marine Renewable Energy Resources: Background

This chapter concerns ocean processes that are viable sources of renewable energy in various forms, such as offshore wind, waves, tides, ocean currents, marine biomass, and energy from ocean thermal differences among different layers (Appiott et al., 2014). Most of these energy forms are maintained by the incoming heat from the sun, so they represent indirect solar energy. Tidal energy is an exception, driven by the varying gravitational forces that the moon and sun exert on both the earth and its oceans (Butikov 2002). Marine renewable energy offers the potential to meet the increasing global energy demand, while reducing long-term carbon emissions. Although some marine renewable energy resources are still in a conceptual stage, other sources have been operational with varying degrees of technical and commercial success. The following section briefly discusses various forms of marine renewable energy sources that are currently in operation or in a demonstration phase.

1.1 *Offshore Wind Power: Background*

Offshore wind power relates to the installation of wind turbines in large water bodies. On average, winds blow faster and more uniformly at sea than on land, and a faster and steadier wind means less wear on the turbine components and more electricity generated per turbine (Musial et al., 2006). The potential energy produced from wind is proportional to roughly the cube of the wind speed. As a result, a marginal increase in wind speed results in a significantly larger amount of energy generation. For instance, a turbine at a site with an average wind speed of 25 km/h would provide roughly 50 per cent more electricity than the same turbine at a site with average wind speeds of 22 km/h.

Offshore wind power is also the most developed form of marine renewable energy in terms of technology development, policy frameworks, and installed capacity. Turbine design and other project elements for offshore wind have benefited significantly from research on and experience with land-based wind energy projects and offshore oil and gas development (Steen and Hansen, 2014). It is already a viable source of renewable energy in many regions and is attracting global attention because of its large-scale resource potential, also often close to major electrical load centers in coastal areas. In light of these factors, offshore wind energy appears to have the greatest immediate potential for energy production, grid integration, and climate change mitigation.

1.2 *Ocean Wave Energy: Background*

As the wind flows over the ocean, air-sea interface processes transfer some of the wind energy to the water, forming waves which store this energy as potential energy and kinetic energy (Special Report on Renewable Energy Sources and Climate Change, 2011). The immense power of waves can be observed at the coast, where this energy can have considerable impacts on coastal landscapes, shoreline topography, and infrastructure. Efforts are now underway to tap this resource for electric generation using wave energy conversion (WEC) devices. WECs transform mechanical energy from the surface motion of ocean waves or from velocity fluctuations below the surface into electrical current.

1.3 *Tidal Power: Background*

Tides are regular and predictable changes in the height of the ocean, driven by gravitational and rotational forces between the Earth, Moon, and Sun, combined with centrifugal and inertial forces. Many coastal areas experience roughly two high tides and two low tides per day (called “semi-diurnal” tides); however in some locations there is only one tidal cycle per day (these are “diurnal” tides Special Report on Renewable Energy Sources and Climate Change, 2011). Tidal power can be harnessed either through a barrage or through submerged tidal turbines in straits or sounds. Tidal barrages involve the use of a dam across an inlet. Sluice gates on the barrage allow the tidal basin to fill on the incoming high tides and to empty through the turbine system on the outgoing tide (U.S. EIA, 2013).

Energy extraction using tidal barrages is derived from the potential energy created when elevation differences develop between two water bodies separated by a dam or barrage, which is analogous to the way a turbine operates in a hydroelectric plant on a dammed river. Conversely, submerged tidal turbines that operate without a barrage only rely on the kinetic energy of the freely moving water. Because water is about 800 times denser than air and is more corrosive, tidal turbines must be much sturdier than wind turbines (U.S. EIA, 2013).

1.4 *Ocean Current Energy: Background*

Ocean currents are the continuous flow of ocean waters in certain directions, driven or controlled by wind flows, salinity, temperature gradients, gravity, and the Earth’s rotation or coriolis; (U.S DOE, 2013). Although surface ocean currents are generally wind driven, most deep ocean currents are a result of thermohaline circulation – a process driven by density differences in water due to temperature (thermo) and salinity (haline) in different parts of the ocean. Currents driven by thermohaline circulation move much slower than surface currents (NOAA, 2007). Many large and powerful ocean currents, such as the Gulf Stream off the east coast of the United States and the Kuroshio Current off the east coast of Japan, represent an enormous source of untapped energy that can be harnessed through large underwater turbines.

1.5 *Ocean Thermal Energy Conversion (OTEC): Background*

The OTEC system produces electricity from the natural thermal gradient of the ocean between the surface and subsurface ocean waters in tropical and subtropical regions. Heat stored in warm surface water is used to create vapor to drive a turbine and generator, and cold, deep water pumped to the surface recondenses the vapor (Avery and Wu, 1994). The OTEC heat engine is usually configured to operate as a thermodynamic Rankine vapor cycle in which a low-boiling-point working fluid (such as ammonia) is evaporated by heat transfer from the surface seawater and produces electricity by expanding through a turbine connected to a generator. The vapor exiting the turbine is condensed with the cold deep water. This is the Closed-Cycle process. The Open-Cycle process uses expendable water/seawater as the driving fluid, under low (<0.1 Atmosphere) pressure. After the flash evaporation of the fluid, fresh, potable water may be collected on the condensers, while new seawater is being evaporated upstream. Additional freshwater may be collected in a second exchanger utilizing the remaining Delta-T after the first stage. Thus, the Open-Cycle process generates both electricity and potable water.

The OTEC systems have been demonstrated to work successfully, but no large-scale plant has been built yet. A benefit of OTEC is that it produces constant base-load electricity, in contrast to other forms of ocean energy sources that fluctuate according to varying winds and currents.

1.6 *Osmotic Power: Background*

Salinity gradient energy is an often-overlooked potential source of renewable energy from the ocean. The mixing of freshwater and seawater that occurs where rivers and streams flow into the salty ocean releases large amounts of energy. Various concepts on how to make use of this salinity gradient have existed for over twenty years. One such concept is Pressure-Retarded Osmosis (PRO), in which seawater is pumped into a pressure chamber where the pressure is less than the osmotic pressure difference between fresh river water (low salinity water) and seawater (higher salinity water). Freshwater then flows through a semi-permeable membrane and increases the volume (or pressure) within the chamber; a turbine is spun as the pressure is relieved. Early technologies were not considered to be promising, primarily because they relied on expensive membranes. Membrane technologies have advanced, but they remain the main technical barrier to economical osmotic energy production (Appiott et al., 2014). Also, water on both sides must be low in particulates and other solids, eliminating many rivers from being a potential freshwater source.

1.7 *Marine Biomass Energy: Background*

Some researchers are looking towards marine biomass, including seaweeds and marine algae as a viable source of biofuel. Interest in marine biomass is driven both by the potential productivity of microalgae, which is tenfold greater than that of agricultural crops, and because, unlike first-generation biofuels, microalgae do not require arable land or freshwater, nor do they compete with food production (NERC, 2014). Marine ecosystems are highly productive because they cycle energy and

nutrients much more rapidly and efficiently than terrestrial ecosystems. Marine algae are photosynthetic aquatic plants that use light as the energy source and seawater as a growth medium. Algae can be harvested and processed into biofuels, including biodiesel and bioethanol.

Biodiesel is a non-toxic and biodegradable fuel that is being used in existing diesel engines without requiring significant modification. Bioethanol can also be used as fuel when mixed with gasoline. Algae grown for biofuels can also provide a sink for carbon dioxide, thereby contributing to climate change mitigation (replacing fossil CO₂ with biogenic CO₂ emissions). Algae are an economical choice for biodiesel production because of their wide availability and low cost. Despite these advantages, however, offshore production of algae is still developing and most algae production takes place onshore.

2. Resource Assessment and Installed Capacity (Global and Regional Scales)

2.1 Offshore Wind Capacity

An assessment of the world's exploitable offshore wind resources has placed the estimates around 22 TWa¹ (Arent et al., 2012) which is approximately nine times greater than the International Energy Agency's (IEA) 2010 estimate of average global electricity generation (IEA, 2012). According to a report by the United States National Renewable Energy Laboratory (NREL), offshore wind resource potential for contiguous United States and Hawaii for annual average wind speeds greater than 7.0 m/sec and at 90 m above the surface is 4,150 GWa (Schwartz et al., 2010). Similarly, a report by the European Environmental Agency (EEA) calculated the technical offshore wind power potential, based on the forecasted costs of developing and running wind power projects in 2020 at 2,850 GWa (EEA, 2009). This figure does not account for spatial use conflicts in developing the wind resource offshore.

As of 2012, large-scale commercial offshore wind projects and demonstration-scale or pilot projects are already operational in the Belgium, China, Denmark, Finland, Germany, Ireland, Italy, Japan, Netherlands, Norway, Portugal, Republic of Korea, Spain, Sweden, United Kingdom of Great Britain and Northern Ireland and United States of America (EWEA, 2008; RenewableUK, 2010; 4C Offshore, 2013; WWEA, 2014). Currently, the North Sea region is considered to be the global leader in offshore wind, both in installed and planned capacity and in technical capability. By the end of 2013, the offshore wind industry has achieved a cumulative global installed capacity of 7,357 MW (WWEA, 2014). Offshore wind turbines can be either bottom-mounted or floating. Currently, most offshore wind projects are bottom-mounted; floating wind turbines are still in the demonstration phase. Moreover, most installations are near the shore in relatively shallow waters due to the higher

¹ TWa: The average number of terawatt-hours, not terawatts, over a specified time period. For example, over the course of one year, an average terawatt is equal to 8,760 terawatt-hours, or 24 hours x 365 days x 1 terawatt.

cost of transmission cabling further offshore, and due to the technical and economic challenges of installing turbines in deeper waters.

Figure 1. Photo credit: Principle Power. The WindFloat Prototype (WF1) floating wind turbine, deployed by Principle Power in 2011, 5km off the coast of Aguçadoura, Portugal. The WF1 is outfitted with a Vestas v80 2.0 MW offshore wind turbine. As of December 2015, the system has produced in excess of 16 GWh of renewable energy delivered to the local grid.

2.2 *Wave Energy Capacity*

The global exploitable wave energy resource is estimated at around 3,700 GWh (Mørk et al., 2010), which is large enough to meet the average global electric generation (IEA, 2012). Wave energy can be harnessed using either floating or fixed conversion devices. Floating devices convert the wave energy by coupling it to a hydraulic system as the device is lifted up and down by the movements of the waves. Fixed devices generally use the oscillating water column generated by the wave to push air (or water) through a turbine. Other types of wave energy technology, such as overtopping devices and attenuators, are also undergoing testing and demonstration.

The world's first grid-connected wave energy device, a 500 kW unit in Scotland (United Kingdom) called the Islay Limpet, has been operating successfully since 2000 (UKDTI, 2004). The Aguçadoura Wave Farm, the world's first utility-scale wave energy project, was launched off the coast of Portugal in September 2008. This installation, developed by PelamisWave Power, utilized three 750 kW devices with a total capacity of 2.25 MW (RenewableUK, 2010). The project operated for two months before technical problems forced the developers to abandon it.

Figure 2. Waves4power OWC plant in operation offshore Sweden (Reprinted with permission from Waves4power AB).

2.3 Tidal Energy Capacity

The global tidal energy resource is estimated to be 3,000 GWa by the World Offshore Renewable Energy Report 2004-2008 (UK DTI, 2004), however, less than 3 per cent of this energy is located in areas suitable for power generation. Tidal energy is feasible only where strong tidal flows are amplified by factors such as funneling in estuaries, making it highly site-specific (UK DTI, 2004). Traditionally, tidal energy has been harnessed using large barrages in areas of high tidal ranges. Many countries, such as Canada, China, France, Republic of Korea, Russian Federation and the United Kingdom have sites with large tidal ranges that are viable for tidal energy capture facilities. The Sihwa Lake Tidal Power Station in the Republic of Korea, which has been operational since August 2011, is the world's largest tidal power barrage with a capacity of 254 MW, surpassing the 240 MW Rance Tidal Power Station in France, which has been generating power since 1967. Numerous projects have also been proposed in other areas, including in the Severn Estuary in the United Kingdom (Hall, 2012).

As part of its technology development initiative, the United States Department of Energy (US DOE) has funded research into several new types of technology, including a turbine under development by Verdant Power Inc. Verdant Power was the first company in the United States of America to be granted a license for a commercial tidal energy project, and looks to build upon an earlier demonstration project in New York's East River with an installation of up to 30 turbines along the strait that connects Long Island Sound and the Atlantic Ocean in the New York harbour.

2.4 *Ocean Current Energy Capacity*

There are no commercial grid-connected turbines currently operating, although a number of prototypes and demonstration units are under development. In 2014, the United States Bureau of Ocean Energy Management (BOEM) issued a lease to Florida Atlantic University (FAU) for testing ocean current turbines. FAU's Southeast National Marine Renewable Energy Center (SNMREC) plans to deploy experimental demonstration devices in areas located 10 to 12 nautical miles offshore Florida (Bureau of Ocean Energy Management, 2014).

2.5 *Ocean Thermal Energy Conversion (OTEC) Capacity*

OTEC technologies have been tested as early as the 1930s. However, OTEC has been limited to small-scale pilot projects, and has yet to encourage much investment and commercial development (US DOE, 2008). Research initiatives in the France, India, Japan and United States of America and elsewhere are currently examining and testing different types of OTEC technologies (Lockheed Martin Corporation, 2012). A modern-type, but very small OTEC plant was constructed in Hawaii, United States, in 1979 (Kullenberg et al., 2008), and similar demonstration projects have been proposed by other nations (IOES, 2015). Most experience is derived from land-based plants. For floating installations, reference material is mostly derived from design studies, but with successful demonstrations in Hawaii (MiniOTEC, OTEC-1) and Okinawa, Japan (OTEC Okinawa, 2014).

2.6 *Osmotic Power Capacity*

The world's first complete prototype osmotic power plant was launched in Norway in 2009 by Statkraft. This plant is located in Tofte, southwest of Oslo. According to the company's assessment, osmotic-power technologies remain several years away from commercial viability (Kho, 2010). Statkraft recently (2014) decided to shelve development plans.

2.7 *Marine Biomass Energy Capacity*

Research into algae production has largely been guided down three tracks: open and covered ponds, photobioreactors, and fermenters; the first two are the most widely pursued. Siting algae farms in ocean areas has also been investigated (Lane, 2010). In the United States, the National Aeronautics and Space Administration (NASA) is investigating the feasibility of growing algae in floating photobioreactors on the outer (geomorphic) continental shelf or in the open ocean. The Offshore Membrane Enclosures for Growing Algae (OMEGA) system would use freshwater algae and wastewater in the photobioreactors to produce biofuel while also cleaning wastewater, creating oxygen, and providing a sink for carbon dioxide (NASA, 2012). As the technology is developed further and States with favourable growing conditions begin to look towards marine renewable energy, this option may become commercially viable in the future.

3. Environmental Benefits and Impacts from Offshore Renewable Energy Development

Marine renewable energy installation and generation invariably has environmental impacts, both positive and negative. These impacts depend on the installation size and footprint, location, and the use of specific technology. A major positive impact of ocean renewable energy is the provision of low-carbon electricity. Analysis suggests that the carbon intensity of offshore wind and marine hydrokinetic resources, such as wave and tidal power, is more than an order of magnitude lower than fossil fuel generation. In a life cycle analysis, greenhouse gas emissions from wave energy projects average between 13-50 gCO₂eq/kWh², tidal current projects emit approximately 15 gCO₂eq/kWh, and offshore wind projects between 4-6 gCO₂eq/kWh (Raventós et al., 2010); these are to be compared with emissions closer to 800-1000 gCO₂eq/kWh for coal power plants and 400-600 gCO₂eq/kWh for natural gas power plants (POST, 2006 and 2011).

Other environmental benefits include no emissions of toxic air or water pollutants (such as NO_x [Nitrogen dioxide], SO₂ [sulfur dioxide], mercury, particulate matter, and thermal pollution from cooling water discharge) and minimal land-use disturbance with the exception of land-use changes related to assembly, equipment loading/offloading and cable landfalls along the coast. In addition, there are potential biodiversity benefits from the installation of offshore turbines or marine energy conversion devices. Offshore renewable energy (ORE) structures increase the amount of hard substrate for colonization and provide marine organisms with artificial reefs. Such structures also create increased heterogeneity in the area: this is important for maintaining species diversity and density (Langhamer, 2012). Investigations have found greater fish abundance in the vicinity of offshore turbines compared to the surrounding areas (Wilhelmsson et al., 2006). One negative impact is that invasive species can find new habitats in these artificial reefs and possibly adversely influence the native habitats and associated environment (Langhamer, 2012).

The broader environmental impacts from marine renewable energy can be understood in the context of an ecological risk assessment framework developed by the United States Environmental Protection Agency (EPA). This approach provides a conceptual model for developing a systematic view of possible ecological effects (McMurray, 2008). The terminology needed for this model requires defining stressors and receptors. Stressors are features of the environment that may change due to installation, operation, or decommissioning of the facilities, and receptors are ecosystem elements with a potential for some form of response to the stressor(s) (Boehlert and Gill, 2010). Stressors can be considered in terms of different stages of development (survey, construction, operation, and decommissioning) as well as the duration, frequency, and intensity of the disturbance. Project size and scale are also

² gCO₂eq/kWh : grams of CO₂ equivalent per kilowatt hour of generation.

determining factors in the magnitude of stressors and receptors. Within this framework, we discuss various ecological impacts in the following sections.

Potential negative impacts on flora and fauna including marine mammals, birds, and benthic organisms, as well as impacts on the larger ecosystem may occur from offshore renewable energy (OREI) development. Some of these impacts are limited to the construction phase, while other impacts span operation and decommissioning phases (Linley et. al., 2009). Potential impacts include habitat loss or degradation at various stages of a project life cycle; injurious noise and displacement of marine mammals from pile driving of wind and tidal-stream generators. Tide power turbines may also induce local seabed scouring and/or changes to the current regime, with unintended consequences for biota. Turbine construction may induce mortality due to physical collision with the OREI structures; effects of operational noise; and electromagnetic field (EMF) impacts from submerged cables (U.S. Department of Interior, 2011).

Noise created during pile-driving operations involves sound pressure levels that are high enough to impair hearing in marine mammals and disrupt their behaviour at a considerable distance from the construction site (Thomsen et. al., 2006). During pile driving for the Horns Rev II offshore wind project in Denmark, a negative effect was detected out to a distance of 17.8 km (Brandt et. al, 2011). Although it has been observed that marine mammals temporarily abandon the construction area, they tend to return once pile driving operations cease. Acoustic impact on marine mammals is a major concern and an important topic of assessment and mitigation strategies in many States. More information is required almost everywhere to understand impacts on and responses by marine organisms to such stresses.

Fixed and moving parts of Ocean Renewable Energy (ORE) devices can lead to fatal strikes or collisions with birds and aquatic fauna. Blades used in marine turbines, such as those in ocean current or tidal energy devices, are relatively slow-moving and therefore not considered to pose a significant threat to wildlife (Scott and Downie, 2003). However the speed of the tip of some horizontal axis rotors could be an issue for cetaceans, fish, or diving strike birds (Boehlert and Gill, 2010). Operation of the SeaGen tidal energy device in Strangford Lough, United Kingdom, considered the presence of seals and porpoises and the potential threat of blade strikes; to minimize strike risk, the turbine was shut down when the presence of seals was observed within 30 meters (Copping et al., 2013). Similarly, investigation of long-tailed geese and ducks in and around the Nysted offshore wind project in Denmark suggests that flocks employ an avoidance strategy. Research suggests that the percentage of flocks entering the wind project area decreased significantly from pre-construction to initial operation. Overall, less than 1 per cent of ducks and geese migrated close enough to be at any risk of collision (Desholm and Kahlert, 2005). This avoidance strategy or adjustment of flight paths, a form of receptor, has also been observed in other projects, such as Horns Rev (NERI, 2006). It is important to highlight that the additional distances travelled by migratory birds to avoid these wind farms were relatively trivial (around 500 m) compared to their total migratory trajectory of 1,400 km. However, construction of further utility-scale projects could have a cumulative impact on the population, especially when considered in combination with other human actions (Masden et. al., 2009).

Submerged cables carrying electricity from ORE devices to onshore substations emit low-frequency Electric and Magnetic Fields (EMF). Marine and avian species are sensitive and responsive to naturally occurring magnetic fields; these are commonly used for direction-finding using the Earth's geomagnetic field. Anthropogenic sources of EMFs are an overlay to naturally occurring sources, and as these sources become increasingly common, there are potential impacts on marine organisms. Industry standards for the design of submarine cables require shielding, which restricts directly emitted electric fields, but cannot shield the magnetic field component of EMFs (Boehlert and Gill, 2010). Moreover, an alternating current (AC) magnetic field has a rotational component that induces an additional electric field in the surrounding environment. There is evidence that EMF's from wind farms can cause disturbance to air traffic control radar systems (De la Vega et al., 2013).

Magnetic fields are strongest over the cables, decreasing rapidly with vertical and horizontal distance from the cables. In projects where the electric current is delivered along two sets of cables that were separated by at least several meters, the magnetic field appeared as a bimodal peak (Normandeau et al., 2011). Studies suggest that behavioural effects of EMF on species occur, although the impacts vary significantly among species.

Thermal aspects of electricity-transmission cables should also be considered. When electric energy is transported, a certain amount is lost as heat, leading to an increased temperature in the cable surface and subsequent warming of the surrounding marine environment (Merck and Wasserthal, 2009). Temperature changes can affect benthic organisms, although data on measureable impacts are sparse. Increased temperatures can also attract marine organisms, exposing them to a higher amount of EMF radiation.

In addition, there are other potential impacts such as chemical effects from potential spills or leaching of anti-fouling paints from ocean renewable energy devices (Boehlert and Gill, 2010), or impacts on benthic creatures and certain fish species which have not yet been fully investigated and assessed. Many such effects are localized, depend on marine and avian biodiversity in a region and can be understood only through comprehensive site-specific environmental impact assessment. Substantial work is proceeding to gather and disseminate available information and data on ecological impacts of ocean energy devices. The International Energy Agency-Implementing Agreement on Ocean Energy Systems (OES) Annex IV³ is maintaining the Tethys database, an important reference for both developers and policy makers (<http://tethys.pnnl.gov/>).

4. Socioeconomic Benefits and Impacts from Offshore Renewable Energy Deployment

³ Annex IV. Assessment of Environmental Effects and Monitoring Efforts for Ocean Wave, Tidal and Current Energy Systems, Tethys.pnnl.gov.

Socioeconomic impacts cover a range of issues, including access to the ocean, visual impacts amenity, impact on coastal and offshore cultural heritage sites, and other uses of the ocean, including recreational tourism and fisheries, related to offshore renewable energy sites. In many regions, these issues have been examined within the context of comprehensive marine spatial planning. Marine spatial planning provides an understanding of the extent to which certain activities take place in an area identified for offshore renewable energy development and provides a baseline assessment of critical ecological and cultural sites.

Sociological surveys of coastal residents, ocean users and other stakeholders have been widely used to assess perceived and experienced impacts from offshore renewable energy facilities. Survey results from two operational offshore wind projects in Denmark, Hons Rev and Nysted, indicate a generally positive attitude among coastal residents (Ladenburg et al, 2006). Relative open access to the projects for marine resource extraction could be a reason for high levels of public approval of the projects. Also, the visual impact of the installations may not have affected those people who were surveyed, since wind farms have caused a loss of amenity in other areas (see below). Both the projects provide access to sailing and fishing within their waters. The Nysted offshore wind project provides access for fishing with net and line, Horns Rev allows only line fishing, and bottom-trawling fishing is prohibited in both projects. Fishing can be further restricted as setting of lobster traps may be limited near cables and turbines. Wave, tidal power, and ocean current energy sources have not yet been commercially deployed at a large enough scale to enable an assessment of potential socio-economic impacts.

The effect of impaired visual amenity from ORE deployment can affect property prices, result in loss of recreational value, and reduce demand for tourism in coastal areas. It can also affect historic and culturally significant resources. These impacts are expected to be more prominent for an offshore wind project than for a wave, tidal, or ocean current installation, as the latter will be underwater and of smaller scale, for similar capacity. Research in the United Kingdom, England and Wales, which have extensive offshore wind capacity, concludes that offshore wind projects have a measureable impact on property prices. The impact is more pronounced in areas which are closest to the wind projects. On the other hand, a small increase in housing value is also seen in areas where wind projects are not visible, indicating a potential economic benefit to landowners near non-visible wind project operations due to an increased rental rate (Gibbons, 2014). This latest assessment is consistent with earlier published studies, which strongly suggest that, given a choice, consumers prefer offshore wind projects sited away from the coast and, in some cases, completely out of sight (Ladenburg and Lutzeyer, 2012).

Utility-scale offshore renewable energy projects can use significant ocean space and impose restrictions for navigational purposes. A large project, if placed along an existing navigational route, can increase the distance that ships and boats would be required to travel. The extent of transit through offshore renewable energy projects depends on safety issues and ease of access. In Denmark, transit through offshore wind energy projects is possible via certain routes; in Germany, navigation is allowed as close as 500 meters (Albrecht et al., 2013). The International Association of Marine Aids to Navigation and Lighthouse Authorities has promulgated

recommendations on how to mark different types of offshore renewable energy installations so that they are conspicuous under different meteorological conditions. This, along with proper charting of installations and associated cables, can limit navigational risks (Detweiler, 2011).

Planning, construction, and maintenance of offshore renewable energy operations have the potential to create direct and indirect employment in various sectors including manufacturing, construction, operation, and maintenance. In 2013, offshore wind represented 3.6 per cent of the United Kingdom's electricity supply, contributed close to 1 billion United Kingdom pounds to the economy and supported 20,000 jobs, including 5,000 direct jobs (Offshore Renewable Energy Catapult, 2014). As the industry continues to grow, it has the potential to add thousands of new jobs, not just in the United Kingdom, but around Europe and other parts of the world that form a critical link to the supply chain. In Europe, offshore wind energy and ocean energy create 7-9 job-years/MW⁴ during construction and installation. In addition, offshore wind projects can generate up to 11 job-years/MW in manufacturing, and 0.2 jobs/MW for operation and maintenance during the operational years of a project. These figures are comparable to those for conventional sources like coal, although offshore wind and other marine renewable sources have no job-creation potential related to fuel extraction, processing, and transportation for the life of a project (Energy [r]evolution, 2012).

Above and beyond the employment generation factor, offshore renewable energy also offers other intrinsic economic and electrical system integration benefits. For instance, many offshore renewable energy projects are sited, or proposed, close to densely populated coastal areas. Proximity to major electrical load centres can significantly reduce the cost of transmission and offset transmission congestion. Moreover, ocean renewable sources, particularly offshore wind power, offers the additional value proposition of load coincidence in many regions (Bailey and Wilson, 2014).

5. Offshore Renewable Energy Assessment Capacity Gaps

A capacity gap is a lack of information that, if available, would or could identify whether environmental effects [of a project] will have substantial negative impacts (McMurray, 2012). In many regions, sufficient knowledge exists in the near-shore and offshore waters to provide an initial baseline assessment, although it is often insufficient to provide a site-specific impact assessment. Significant capacity gaps exist in assessing environmental, social, and economic impacts from deploying devices in the marine environment. Most forms of ocean renewable energies have still not reached commercial scale, although some are at a high Technological Readiness Level (TRL).

⁴ Job-years per MW denote the total amount of labour needed to manufacture equipment or construct a power plant that will deliver a peak output of one megawatt of power (The Energy Policy Institute, 2013).

Certain marine environments and species present additional challenges in addressing capacity gaps. For instance, it is technically difficult to obtain information on benthic biota, as compared to species in the pelagic zone. Due to the lack of high-quality benthic information, resource managers and developers are often required to conduct time-consuming and resource-extensive surveys before siting decisions can be finalized. In the pelagic zone, marine migratory species pose additional challenges for site characterization. Further site-specific research is required to understand migratory species such as whales to ensure that project siting has minimal impact on migratory routes or traditional foraging grounds. Similarly, impacts on avian species in the offshore environment, particularly migratory bird species and bats, have not been fully understood and require further research and assessment.

In the absence of operational utility-scale projects, it is often difficult to determine the socioeconomic impacts of an emerging renewable energy technology. One way to address such capacity gaps is to make long-term monitoring an integral part of the construction and operation phase, though if long-term monitoring regimes are too costly developers may be dissuaded from pursuing commercial projects. Studies and surveys assessing impacts before and during the operation of a project can provide valuable information on impacts, and can suggest substantive mitigation measures to address those impacts.

The knowledge and capacity gaps should be addressed within a comprehensive framework that considers all ecological resources and human uses in an area. This framework, also referred to as marine spatial planning, provides a process for analysing and allocating spatial and temporal distribution of human activities in marine areas to achieve ecological, economic, and social objectives that are usually specified through a political process (UNESCO, 2014). States are increasingly using marine spatial planning as the tool for identifying and siting offshore renewable energy projects. More importantly, the collaborative processes at the heart of marine spatial planning foster relationships and linkages among ocean uses, stakeholders and resources managers to enhance the quality of scientific information and traditional knowledge available. This collaboration and information exchange can lead to better-informed siting decisions and can minimize social and environmental impacts.

6. Conclusion

Offshore renewable energy is an immense resource awaiting efficient usage. Technological progress to harness the resource is steadily increasing around the world. When fully developed and implemented, ocean renewable energy can enhance the diversity of low-carbon energy options and provide viable alternatives to fossil fuel sources. For developing countries and new growing economies, installing renewable energy systems represents a viable path towards a low-carbon future.

To achieve a commercial break-through such that ocean renewable energy becomes cost-competitive, many governments have funded Research and Development (R&D) projects and provided financial support for technological developments and demonstrations within this sector. Traditional commercial funding sources are often insufficient to achieve this goal in the long-term, so innovative strategies are required. In addition, higher education courses on ocean renewable energies must be promoted, and research to understand and mitigate potential environmental and socio-economic impacts of these new technologies must be conducted. Given its immense potential, offshore renewable energy is well positioned to be part of a carbon-constrained energy future.

1. Introduction

Marine mining has occurred for many years, with most commercial ventures focusing on aggregates, diamonds, tin, magnesium, salt, sulphur, gold, and heavy minerals. Activities have generally been confined to the shallow near shore (less than 50 m water depth), but the industry is evolving and mining in deeper water looks set to proceed, with phosphate, massive sulphide deposits, manganese nodules and cobalt-rich crusts regarded as potential future prospects.

Seabed mining is a relatively small industry with only a fraction of the known deposits of marine minerals (Figure 1) currently being exploited. In comparison, terrestrial mining is a major industry in many countries (estimated to be worth in excess of 700 billion United States dollars per year, PWC, 2013). Pressure on land-based resources may spur marine mining, especially deep seabed mining. However, global concerns about the impacts of deep seabed mining have been escalating and may influence the development of the industry (Roche and Bice, 2013).

The exploitation of marine mineral resources is regulated on a number of levels: global, regional and national. At the global level, the most important applicable instrument is the United Nations Convention on the Law of the Sea (UNCLOS). It is complemented by other global and regional instruments. At the national level, legislation governing the main marine extractive industries (i.e. aggregate mining) may be extremely complex and governed in part by national or subnational authorities (Radzevicius et al., 2010). As regards national legislation to regulate deep-sea mining, terrestrial mining legislation often applies to the continental shelf or EEZ, rather than specific deep-sea mining legislation (EU, 2014). However many Pacific Islands States, that are gearing up for deep seabed mining have made significant efforts to adopt concise and comprehensive domestic laws (SPC, 2014).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Global distribution of known marine mineral resources (from Rona, 2008).

2. Scale and significance of seabed mining

2.1 Sand and gravel extraction

Aggregates are currently the most mined materials in the marine environment and demand for them is growing (Bide and Mankelov, 2014). Due to the low value of the product, most marine aggregate extractions are carried out at short distances from landing ports close to the consumer base and at water depths of less than 50 m (UNEP, 2014).

In Europe, offshore sand and gravel mining is an established industry in Denmark, France, Germany, the Netherlands and the United Kingdom of Great Britain and Northern Ireland (Earney, 2005). Marine aggregates are also mined in the tidal channels of the Yellow River China, the west coast of the Republic of Korea, tidal channels between the islands south of Singapore and in a range of settings in the waters surrounding Hong Kong, China (James et al 1999). In many of the Pacific Islands States, aggregates for building are in short supply and the mining of terrestrial sources, principally beaches, has been associated with major increases in coastal vulnerability (e.g. impacts of beach mining in Kiribati and the Marshall Islands are well documented (Webb 2005, McKenzie et al 2006). Therefore, marine sources of aggregates are considered as a preferred source. The Secretariat of the Pacific Islands Applied Geoscience Commission (SOPAC), now part of the Secretariat of the Pacific Community, has been involved in assisting Pacific Island States in the

planning, development and management of sand and gravel resources, (SOPAC, 2007).

Although globally the majority of the demand for aggregates is met by aggregates extracted from land-based sources, the marine-based industry is expanding (JNCC, 2014). However, no figures are available on the global scale of marine aggregate mining.

2.1.1 Case Study: North-East Atlantic

The Working Group on the Effects of Extraction of Marine Sediments (WGEXT) of the International Council for the Exploration of the Sea (ICES) has provided yearly statistics since 1986 on marine aggregate production (ICES 2007, 2008, 2009, 2010, 2011, 2012, 2013; Sutton and Boyd, 2009; Velegrakis et al., 2010). Since 1995, an average of 56 million $\text{m}^3 \text{y}^{-1}$ has been extracted from the seabed of the North-East Atlantic (Figure 2). Five countries account for 93 per cent of the total marine aggregate extraction (Denmark, France, Germany, the Netherlands, and the United Kingdom; OSPAR, 2009). The Netherlands is the largest producer (average 27.3 million $\text{m}^3 \text{y}^{-1}$). There are thirteen landing ports and 17 specialist wharves in Europe (Belgium, France and the Netherlands; Highley et al., 2007).

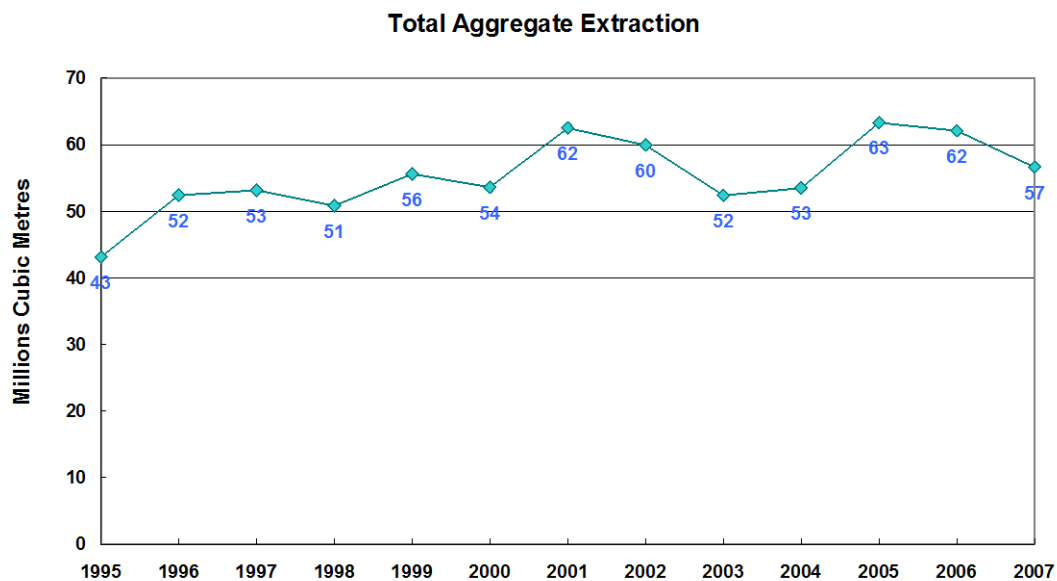

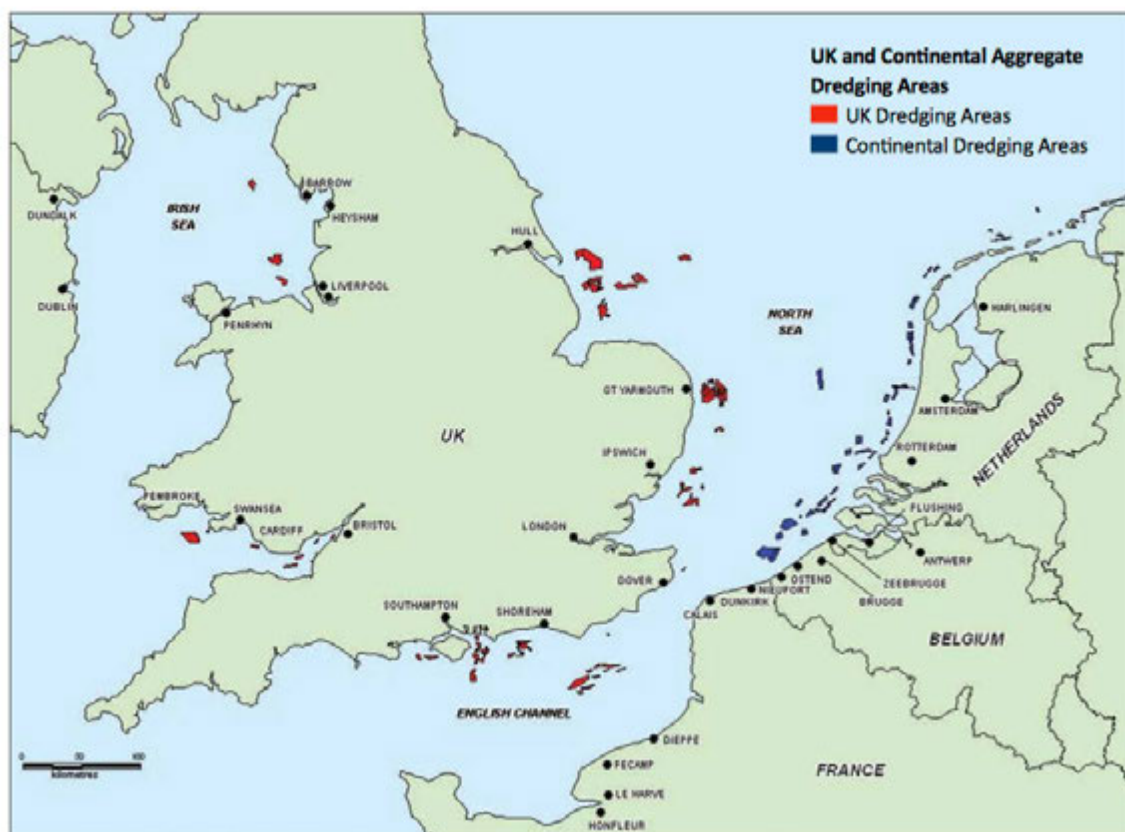

Figure 2. Total marine aggregate extraction in the OSPAR maritime area (in million m^3). Data from: ICES, 2005, 2006, 2007, 2008, 2009 (OSPAR 2009).

The United Kingdom, one of the largest producers of marine aggregates in the region, currently extracts approximately 20 million tons of marine aggregate (sand and gravel) per year from offshore sites (Figure 3). Production meets around 20 per cent of the demand in England and Wales (Crown Estate, 2013). Around 85 per cent of the mined aggregate is used for concrete, with the remainder used for beach nourishment and reclamation. In 2010, the area of seabed dredged was 105.4 km^2 ,

although 90 per cent of dredging effort was confined to just 37.63 km². Between 1998 and 2007, aggregate extraction produced a dredge footprint of 620 km² (BMAPA, 2014). In 2012, 23 dredging vessels were operating (BMAPA, 2014) and aggregates were landed at 68 wharves in 45 ports in England and Wales. Wharves are mainly located in specific regions where a shortfall in land-derived supplies exists and/or there are economic advantages because of river access and proximity to the market (Highley et al., 2007).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 3. Map of the coastline showing the location of aggregate license areas in the United Kingdom and the adjacent coast of continental Europe (Newell and Woodcock, 2013).

The European Union Marine Strategy Framework Directive (MSFD: 2008/56/EC) requires that its Member States take measures to achieve or maintain Good Environmental Status (GES) by 2020. The Descriptor 6 of the MSFD, referred to as “Sea-floor integrity”, is closely linked to marine aggregate extraction from the seabed – sea-floor integrity is defined as a level that ensures that the structure and functions of the ecosystems are safeguarded and benthic ecosystems, in particular, are not adversely affected (Rice et al., 2010). Descriptor 6 requires immediate actions from Member States to develop suitable pressure indicators (calculated from several parameters such as the species diversity, the number of species and the proportion of different types of species in benthic invertebrate samples) and launch continuous monitoring schemes to contribute to GES achievement.

2.1.2 Case Study: Pacific Islands - Kiribati

The adverse effects of sand mining on the beaches (above the high water mark) of South Tarawa, the main island of Kiribati, were recognized in the 1980s. Removal of the beach sand changes the shape of the beach, increasing erosion and the island's vulnerability to flooding from storm surges and rising sea level. As a consequence of ongoing beach mining, the EU-funded Environmentally Safe Aggregate Project for Tarawa (ESAT) was started in 2008. A purpose-built dredge vessel, the "MV Tekimarawa" was commissioned and a State-owned dredging company was developed to provide marine aggregates for urban construction. The mined material is processed by local people at a processing facility, used on the island for building material and also sold to other islands. The resource area in Tarawa Lagoon (Figure 4), which is currently being mined for coarse sand and gravel, is expected to provide aggregates for 50 to 70 years. ESAT also has a license to excavate access channels on the intertidal reef flats in Beito and Bonriki. This provides fine intertidal silt suitable for road base.

The introduction of marine mining in Tarawa Lagoon has not stopped illegal beach mining. Reviews have found that controlling beach mining by communities is difficult, and that trying to regulate this practice in the absence of a suitable alternative source of revenue is next to impossible (Babinard et al., 2014).

The shoreline and beach profile in South Tarawa has been severely altered, with the almost complete removal of the high protective berm. Mining has now moved on to other untouched beaches. It is estimated that natural recovery of damaged areas will take decades (SOPAC, 2013).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 4. Tarawa Atoll. ESAT resource area in yellow (50-70 year supply). The dot is larger than the absolute maximum surface area that could be mined in any given year (SOPAC, 2013, Figure courtesy Dr. Arthur Webb).

2.2 Placer mining

Placer deposits include minerals that have been concentrated by physical processes, such as waves, wind and currents. Globally, diamonds dominate this sector, but placer deposits also contain valuable minerals. Harben and Bates (1990) identify the most economically important of these minerals (and their associated elements) as: cassiterite (tin), ilmenite (titanium), rutile (titanium), zircon (zirconium), chromite (chromium), monazite (thorium), magnetite (iron), gold and diamonds. About 75 per cent of the world's tin, 11 per cent of gold, and 13 per cent of platinum are extracted from placers (Daesslé and Fischer, 2013).

Table 1. Principal marine placer mining activities (from Murton, 2000)

Placer Minerals	Mined locations
Rutile and ilmenite	South-east and south-west Australia Eastern South Africa South India Mozambique Senegal Brazil Florida
Titanium-rich magnetite	North Island, New Zealand Java, Indonesia Luzon, Philippines Hokkaido, Japan
Tin	Indonesian Sunda shelf, extending from the islands of Bangka, Belitung, and Kunder Malaysia Thailand
Diamonds	West Coast, South Africa Namibia Northern Australia

Diamond placer deposits exist in two distinct areas: a 700-km stretch along the coastal borders of Namibia and South Africa, and an area off the northern coast of Australia (Rona, 2005). Deposits off the coast of South Africa have not been actively mined since 2010 (De Beers, 2012) and Australian operations have not progressed

since discovery. Offshore of Namibia, five vessels operated by NAMDEB (a joint partnership between the Namibian government and De Beers) currently extract approximately 1 million carats/year (De Beers, 2007; 2012). In addition there are diver operated mining activities conducted from smaller vessels. A report from The World Wide Fund for Nature (WWF) South Africa (Currie et al., 2008) identified a number of environmental concerns associated with offshore diamond mining. These included destruction of kelp beds, which provide important habitat for juvenile rock lobsters and the destruction of healthy reefs during the removal of diamondiferous gravels. The authors also suggested that the dumping of tailings back into the ocean or onto the beach (after processing) could also potentially result in the formation of land bridges from some islands to the mainland in the vicinity of islands.

Dredging of tin placers is the largest marine metal mining operation in the world (Scott, 2011). The tin belt, as it is called, stretches from Myanmar, down through Thailand, Malaysia, Singapore and Indonesia. The largest operations are offshore of Indonesia, where submerged and buried fluvial and alluvial fan deposits are mined up to 70 meters below sea level, using large dredgers. P.T. TIMAH, a state-owned enterprise, operates the official tin mine offshore of Bangka and Belitung islands. Their dredges can recover more than 3.5 million cubic meters of material per month (Timah, 2014). Numerous “informal miners” also dredge in the shallow coastal area (see Figure 5). These operations use divers to suck sediment from the seafloor using plastic tubing connected to a diesel pump (which also pumps air to the divers). The Indonesian islands produce 90 per cent of Indonesia's tin, and Indonesia is the world's second-largest exporter of the metal.

Commercial production of tin began in Thailand in the late 1800s. Most of the offshore tin is located off the Malay Peninsula. The major offshore mining operations ceased in 1985 when the tin price collapsed. Prior to that, large-scale operations were located in the Andaman Sea and the Gulf of Siam (now Gulf of Thailand). The Thaisarco tin smelter in Phuket processes tin from inside and outside Thailand. While most of the Thai-sourced tin originates from land-based deposits, a number of privately owned suction boats still work the near shore during the dry season; a typical boat can recover about 15 kg of cassiterite ore per day.

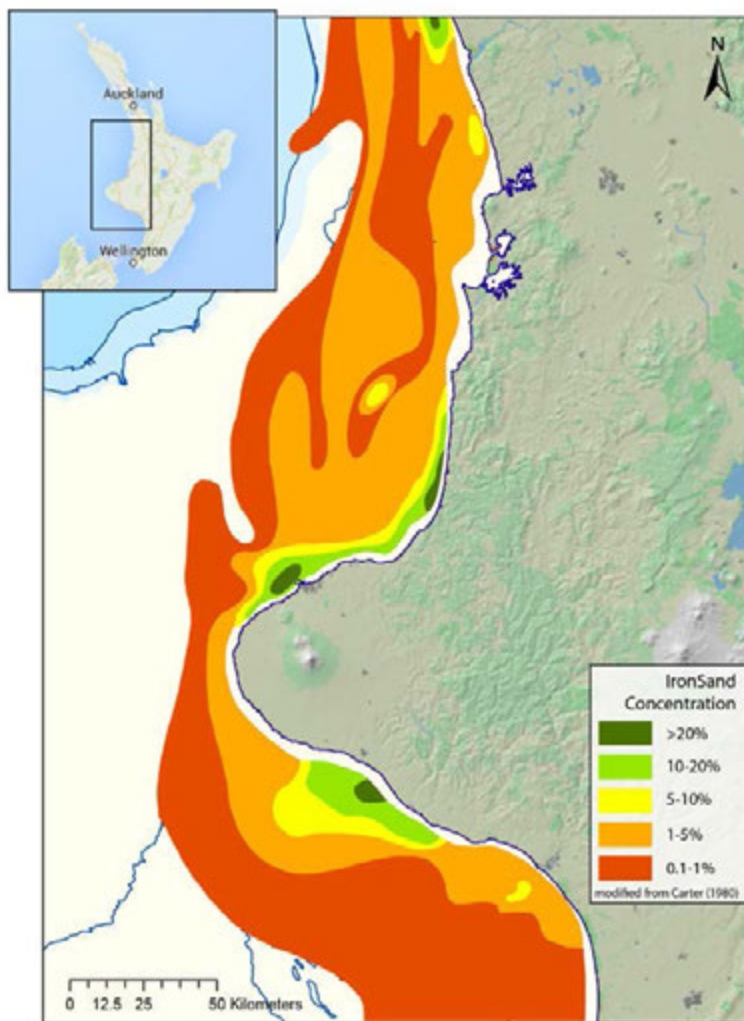

Gold placer deposits along the Gulf of Alaska of the United States of America coast have been worked since 1898. The gold is recovered from sands exposed at low tide, but the gold-bearing sands extend for approximately 5 km offshore to water depths of 20 m (Jewett et al., 1999). The deposit was most recently actively mined from 1987 to 1990, when the lease was terminated. During that period, 3,673 kg of gold were recovered (Garnett, 2000). The Placer Marine Mining Company purchased an offshore lease at Nome from the Alaska Department of Natural Resources in 2011. The AngloGold-De Beers partnership also has an offshore lease and has invested several million US dollars in exploration and baseline studies. They are hoping to have the required permits in place to begin mining by 2017. There are also a number of individual leases, and due to interest from the general public in shallow water gold mining, the Alaska Department of Natural Resources has also established two recreational mining areas offshore of Nome.

Figure 5. Homemade dredges operating offshore Bangka Island Indonesia (Photo Rachel Kent, The Forest Trust).

2.2.1. Case Study: New Zealand

Iron sands constitute a very large potential resource in New Zealand. Iron sands occur extensively in the coastal zone, and exploration off the west coast of the North Island of New Zealand's exclusive economic zone has identified potential resources concentrated on the continental shelf. In 2014, following an exploration phase, Trans-Tasman Resources Limited (TTR) was granted a 20-year mineral mining permit by the New Zealand Ministry of Business, Innovation and Employment for the extraction of iron sand from the South Taranaki Bight (Figure 6). This permit is the first step in a regulatory process that may allow the company to extract iron sand over a 66-km² area of seabed located in water depths of between 20-42 m, up to 36 km offshore. It is estimated that 50 million tons per year of sand could be extracted from the seabed (TTR, 2015). It may still take several years before mining commences and, in addition, the company also needs to obtain consent from the New Zealand Petroleum and Minerals branch of the Environmental Protection Authority (EPA) before any mining can begin (NZ Petroleum and Minerals, 2014). At the time of publication of this report, the decision-making Committee appointed by the EPA has refused to grant the mining consent to TTR (NZ EPA, 2015). The reason for this decision is related in part to the uncertainties about the scope and significance of the potential adverse environmental effects.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 6. Surficial concentrations of iron sand along the west coast of the North Island of New Zealand (Taranaki region) (modified from Carter, 1980, Taylor & Francis, Ltd., www.tandfonline.com).

2.3 Sulphur mining

Sulphur is used in manufacturing and agriculture. Most is produced onshore, but native sulphur is associated with offshore salt domes in the Gulf of Mexico. One offshore mine, the Main Pass 299 facility, located in shallow water off central Louisiana, United States, was operational until 2000 (Kyle, 2002). The sulphur was extracted by the Frasch system, which uses the injection of superheated water through boreholes to melt the sulphur, which is then forced to the surface by compressed air (Ober, 1995). The mine facility is one of the largest platform configurations in the Gulf, with 18 platforms. However, it is unlikely that the mine will resume operations in the near future, due to a glut in the supply of sulphur. This over-supply stems from the fact that sulphur is now extracted in environmental control systems and petroleum refining, which account for 55 per cent of the world sulphur production.

3. Significant environmental, economic and/or social aspects in relation to offshore mining industries

3.1 Environmental Impacts

The current shallow-water seabed mining activities all employ dredging systems to excavate material from the seabed. Dredging techniques vary depending on the nature of the material being mined. They include: a plain suction dredge, which vacuums up unconsolidated material; a rotary cutter dredge, which has a cutting tool at the suction inlet to dislodge more consolidated material; and bucket dredges, which drag a bucket along the sea floor. In marine mining, the dredged material is generally placed into an onboard hopper and excess water and tailings are discharged back into the environment.

Environmental impacts include physical alteration of the benthic environment and underwater cultural heritage. Table 2 summarizes the environmental impacts associated with aggregate mining, which are potentially applicable to all types of shallow water marine mining. Examples of documented impacts are listed in Table 3. The most immediate impacts relate to sediment removal resulting in loss of benthic communities. The removal of the sediment may also affect (re) colonization and recovery rates of impacted communities (Tillin et al., 2011). Most studies on the impact of dredging on marine benthos show that dredging can result in a 30–70 per cent reduction in species variety, a 40–95 per cent reduction in the number of individuals, and a similar reduction in biomass in dredged areas (Newell et al., 1998).

In addition to removal, sediment disturbance can expose marine organisms to increased turbidity and elevated suspended sediment concentrations. This can reduce light availability, which can impact photosynthetic organisms like phytoplankton. Tides and currents can spread turbidity plumes and sediment beyond the mine area. This can be accompanied by changes in water chemistry and contamination (such as algal spores, and from formerly buried substances).

Changes in hydrodynamic processes and seabed geomorphology can also occur. For example, trailer suction dredging, a common form of aggregate dredging, involves dragging the dredge slowly along the seabed, resulting in furrows that are up to 2-3 m wide and 0.5 m deep. These furrows can persist, depending on the local current regime and mobility of the sediments (Newell and Woodcock, 2013). Static suction dredges are employed at sites where deposits are thick and can result in the formation of large pits. Hitchcock and Bell (2004 and references therein) reported that pits within gravelly substrates may fill very slowly and persist after several years, whereas pits in channels with high current velocities have been observed to fill within one year, and those in intertidal watersheds can take 5–10 years to fill.

The European SANDPIT project (Van Rijn et al 2005) aimed to develop reliable techniques to predict the morphological behaviour of large-scale sand mining pits/areas and to understand associated sediment transport processes (Idier et al., 2010). In the study, a baseline pit, based on an actual Dutch pit, was defined as an inverted truncated pyramid 10 m below the seabed, with dimensions at the seabed

of 500m x1300m, an excavated volume of 3.5Mm³, and located 1.5km from shore at a water depth of 10m (Soulsby et al., 2005). Modelling results using this baseline pit indicate that, for example, there could be a reduction of current speed of up to 10 per cent in the pit; an increase in wave height in the centre of the pit of 1-5 per cent, increasing to 10-15 per cent in the areas surrounding the pit; a reduction of sediment transport in the centre of the pit by 40-90 per cent and an increase of 70-200 per cent outside the pit (Soulsby et al., 2005).

Changes in sediment grain size composition can also occur. For example, diamond mining on the continental shelf of Namibia in 130 m depth was shown to have altered the surficial sediments in a mined area, from previously predominantly homogenous well-sorted sediment, to a more heterogeneous mud, coarse sand and gravel. This is because, as part of the on-board processing, cobbles, pebbles and tailings are discarded over the side (Rogers and Li, 2002). Long-term or permanent changes in grain size characteristics of sediments will affect other factors such as organic content, pore-water chemistry, and microbe abundance and composition (Anderson, 2008).

Less well-documented potential impacts include underwater noise. A review by Thomsen et al. (2009) summarized information on the potential risks from dredging noise. They noted that dredging produces broadband and continuous low frequency sound, that studies indicate that dredging can trigger avoidance reaction in marine mammals, and that marine fish can detect dredging noise over considerable distances. They report that the sparse data available indicates that dredging is not as noisy as seismic surveys, pile driving and sonar; but it is louder than most shipping, operating offshore wind turbines and drilling, and should be considered as a medium impact activity. Marine fauna and birds may collide with or become entangled in operating vessels, but this potential impact is also not well studied. Todd et al (2015) noted that collisions with marine mammals are possible, but unlikely, given the slow speed of dredgers.

Because most marine mining currently occurs close to shore there has been considerable concern regarding the potential impact of mining on archaeological sites. Mining activities, particularly aggregate dredging, has been shown to irreversibly damage underwater cultural heritage, including shipwrecks, airplane crash sites and submerged prehistoric sites (Firth, 2006). Individual States, such as the United States have prepared recommendations and guidelines to avoid dredging impacts on cultural sites (Michel et al., 2004). These include improved location of cultural sites using remote sensing technology, the establishment of buffer zones around known sites, and preparation of plans to preserve resources and subsequent monitoring of dredging activity. Government policies in the United Kingdom on marine mineral extraction from the seabed off the coast of England are set out in Marine Minerals Guidance Note 1 (MMG 1; Wenban-Smith, 2002). The MMG 1 states that all applications for dredging in previously undredged areas require an environmental impact assessment. The Office of the Deputy Prime Minister, which approves applications, can request the applicant to provide information relating to potential impacts to archaeological heritage and landscape and provide information on the measures envisaged to prevent, reduce and where possible offset any significant adverse effects. A review by Firth (2013) of marine archaeology in the

United Kingdom recommends that thorough exploration of cultural sites, to constrain their area, may be more cost effective than blanket buffer zones, which can disrupt dredging activity.

Table 2. Spatial and temporal scale of the main effects arising from aggregate extraction activities and the confidence associated with the evidence (from Tillin et al 2011).

Effects arising from aggregate extraction activities	Spatial Scale of Effect	Temporal Scale of Effect	Confidence in Evidence
Direct Impacts: Removal of aggregates:	Impacts on benthic marine organisms and seabed morphology. Confined to footprint of extraction: the active dredge zone.	Recovery may begin after cessation of activity.	Good evidence for impacts on seabed habitats and biological assemblages (Newell et al 2004).
Direct Impacts: Removal of aggregates:	Impacts on cultural heritage and archaeology	May be permanent and irreversible	Good evidence for impacts (Michel et al., 2004)
Direct Impacts: Formation of sediment plumes	From 300-500m for sand particle deposition to 3km where particles are remobilised by local hydrodynamic conditions	Longevity of sediment plumes, up to 4-5 tidal excursions for fine particles (MALSF 2009)	Confidence in understanding of sediment plume has been assessed as high (MALSF 2009)
Indirect Impacts: Visual Disturbance	May affect seabirds and marine mammals, spatial extent of effect depends on visual acuity of organism and response.	Confined to period of extraction activities	Little evidence, unlikely to be different from other forms of shipping.
Indirect Impacts: Noise Disturbance	Changes in noise levels detectable up to several km. Behavioural responses likely to occur over much more limited distances and little	Confined to period of extraction activities	Evidence of hearing thresholds only available for a few species (Cefas 2009).

	risk of hearing damage.		
Indirect Impacts: Collision Risk	Confined to activity footprint	Confined to period of extraction activities	Little evidence, unlikely to be different from other forms of shipping.
Indirect Impacts: Sediment deposition	From 300-500m for sand particle deposition to 3km where particles are remobilised by local hydrodynamic conditions.	Heaviest particles settle almost immediately, lightest particles will settle within 1 tidal excursion (a tidal cycle of ebb and flood) (Cefas 2009).	High (from modelling studies and direct observations at a number of sites).

The scale of impacts will vary depending on the method and intensity of dredging, level of screening (for example in aggregate mining screening may be employed to alter the sand to gravel ratio, in which case significant quantities of sediment, typically unwanted fine sediment particles, can be returned to the seabed), sediment type and local hydrodynamics (Newell and Woodcock, 2013).

Physical and biological impacts (e.g. smothering leading to death or impaired function) may persist well after the mining finishes. Recovery times are likely to vary greatly and be species dependent (Foden et al., 2009). Cumulative impacts such as climate change and other anthropogenic activities may also affect recovery timing.

Some of the mitigation measures now used with dredging operations include:

- The use of silt curtains to contain dredge plumes;
- The return of overflow waste to the seabed rather than in the water column;
- Locating mining activities away from known migratory pathways and calving or feeding grounds;
- Limiting the number of vessels or operations in given areas;
- Requiring reduced boat speeds in areas likely to support marine mammals;
- Engineering to reduce the noise of the primary recovery and ore-lift operations;
- Limiting unnecessary use of platform and vessel flood lights at night and ensuring that those that are required are directed approximately vertically onto work surfaces to avoid or mitigate seabird strikes;

- Leaving patches within a mining site un-mined to increase the rate of recolonization and recovery of benthic fauna;
- Excluding areas from mining if they support unique populations of marine life;
- Excluding areas of mining if they are potential sites of cultural heritage;
- Depositing tailings within as small an area as possible surrounding the mining block, or onshore; and
- Avoiding the need for re-mining areas by mining target areas to completion during initial mining.

Table 3. Documented environmental impacts of offshore mining

Mining activity	Location	Impact	Reference
Shell and sand extraction	Owen Anchorage, south-west of Fremantle, Western Australia	Dredging in shallow near-shore waters associated with significant conservation values, e.g., seagrass, coral communities; adverse effects on marine habitats due to direct seabed disturbance and indirect effects, such as elevated turbidity levels. Other concerns include changes in near-shore wave and current conditions, which could affect shipping movements and seabed/shoreline stability	Walker et al., 2001
Sand and gravel extraction	European Union	Loss of abundance, species diversity and biomass of the benthic community in the dredged area. Similar effects from turbidity and resuspension of sediment over a wide area. Benthic impact is a key concern where dredging activities may impinge on habitats or species classified as threatened or in decline (such as Maerl or <i>Sabellaria</i> reefs).	OSPAR, 2009
Sand and gravel extraction	Dieppe, France	10-year monitoring programme revealed a change in substrate from gravel and coarse sand to fine sand in the dredged area. The maximum impact on benthic macrofauna was a reduction by 80 per cent in species richness and 90 per cent in both abundance and biomass. In the surrounding area, the impact was almost as severe. Following cessation of dredging, species richness was fully restored after 16 months, but densities and biomass were still 40 per cent and	Desprez, 2000

		25 per cent, respectively, lower than in reference stations after 28 months. The community structure differed from the initial one, corresponding to the new type of sediment.	
Sand and gravel extraction	United States of America	Comprehensive review of impacts from dredging operations identifying the most severe effects: entrainment of benthic organisms; destruction of essential habitat; increased turbidity affecting sensitive fauna like corals and suspension-feeding organisms.	Michel et al., 2013
Sand and gravel extraction	Moreton Bay, Australia	Alteration of the existing tidal delta morphology by the removal of a small area of shallow banks. In most cases, the prevailing sediment transport processes would result in a gradual infill of extraction sites.	Fesl, 2005
Sand and gravel extraction	Puck Bay, Southern Baltic Sea	Benthic re-colonization at a site formed by sand extraction was investigated some 10 years after the cessation of dredging. The examined post-dredging pit is one of five deep (up to 14 m) pits created with a static suction hopper on the sandy, flat and shallow (1–2 m) part of the inner Puck Bay (the southern Baltic Sea). Organic matter was found to accumulate in the pit, resulting in anaerobic conditions and hydrogen sulfide formation. Macrofauna was absent from the deepest part of the pit and re-colonization by pre-mining benthic fauna was considered unlikely.	Szymelfenig et al., 2006
Diamond mining	Benguela Region, Africa (offshore of Namibia and South Africa)	Cumulative impacts of seabed diamond mining assessed over time and as a combination of numerous operations. Four to 15 years for benthic recovery, biodiversity altered in favour of filter feeders and algae, resulting in decreased biodiversity but increased biomass.	Pulfrich et al., 2003; Pulfrich and Branch, 2014
Diamond mining	Offshore Namibia, Orange Delta	Changes in surficial sediment grain size composition from unimodal to polymodal, with increased coarse sand and gravel.	Rogers and Li, 2002
Tin mining	Bangka-	Hundreds of makeshift pontoons	IDH, 2013

	Belitung Province Indonesia	operate alongside a fleet of 52 dredgers belonging to P.T. TIMAH. The island coastline has been altered by tailing dumps, and up to 70 per cent of coastal ecosystems, particularly coral, sea-grass and mangroves, are degraded.	
Gold mining	Norton Sound, northeastern Bering Sea, United States.	Mining with a bucket-line dredge occurred near shore in 9 to 20 m during June to November 1986 to 1990. Sampling a year after mining ceased indicated that benthic macrofaunal community parameters (total abundance, bio- mass, diversity) and abundance of dominant families were significantly reduced at mined stations	Jewett et al., 1999

Several studies have looked at the restoration of seabed habitat after mining activity (e.g., Cooper et al., 2013, Kilbride et al., 2006, Boyd et al., 2004). In the OSPAR region, where damage to protected species and habitat occurs, restoration is identified within the obligations of the Convention for the Protection of the Marine Environment of the North-East Atlantic, various European directives, and in various United Kingdom marine policy documents, (Cooper et al., 2013). A study on seabed restoration identified three issues central to decisions about whether to attempt restoration following marine aggregate dredging. They include: (i) necessity (e.g. a clear scientific rationale for intervention and/or a policy/legislative requirement), (ii) technical feasibility (i.e. whether it is possible to restore the impacts), and (iii) whether is it affordable (Cooper et al., 2013).

A recent study of the Thames Estuary, United Kingdom, an area of aggregate extraction, used the estimated value of ecosystem goods and services to determine if seabed restoration was justifiable in terms of costs and benefits; they concluded that in this case it was not (Cooper et al., 2013). The proposed restoration involved levelling the seabed and restoring the sediment character for an estimated cost of over 1 million British pounds. In order to determine if this expenditure could be justified, the authors assessed the significance of the persistent impacts on the ecosystem goods and services and the cost and likelihood of successful restoration. While the site-specific cost benefit analysis precluded restoration, they suggest that the approach taken could be used at other sites to determine if restoration is practical and effective.

In the United Kingdom a research fund, (the Aggregate Levy Sustainability Fund), was established in 2002 and ran until March 2011, using revenue from the Aggregates Levy introduced in 2002 - a tax of 2.00 British pounds per ton on primary aggregate sales (including land- and marine-derived aggregates; Newell and Woodcock, 2013). There was intense public criticism when the Fund was discontinued in 2011, as previously 7 per cent of the Fund had been directed to communities, non-

governmental organizations and other stakeholders to fund projects delivering conservation, local community and other sustainability benefits (e.g., BBC 2011; MPA 2011). Cooper et al., 2013 also suggest that the fund could have been used to finance seabed restoration projects.

3.2 Social impacts

Social impacts of offshore mining are likely to be complex and different and generally less than that for terrestrial mining (Roche and Bice, 2013). Table 4 details potential social impacts from offshore mining. In countries where offshore mining is relatively new and untested (like Australia), societal expectations set higher standards for its acceptance, particularly with regard to environmental protection and strengthening of the national economy (Mason et al., 2014).

Table 4. Positive and negative potential social impacts identified (after Tillin et al, 2011; Roche and Bice, 2013)

Impact	Effect
Environmental degradation	Loss of ecosystem services that negatively affects livelihoods.
Provision of material	For coastal defence and beach replenishment.
Revenue	Revenue to industry, government and community; Foreign exchange earner.
Reduced pressure on land based resources	Avoidance of social impacts for resource extraction on land, including competing resources, community relocations.
Employment	Employment for local community, accompanied by influx of people to new industry; particularly for small island communities.
Cultural impacts	Loss of cultural sites; changes/loss in resource distribution (food, territory, etc.); ignoring of/loss of traditional knowledge.
Governance and policy	New regulatory regimes; implementation of policy; social and environmental degradation can lead to conflict.

Regional initiatives, targeted at developing a holistic approach to decision-making, that incorporate social, environmental and economic evaluation and stakeholder engagement, are outlined in Table 5. In some areas, such as the Pacific Islands region, emphasis is on making informed decisions about deep-sea mining. Countries which decide to engage in deep sea mining can obtain assistance from the Secretariat of the Pacific Community to develop national regulatory frameworks (offshore national policy, legislation and regulations) in close collaboration with all key stakeholders and in particular, local communities (SPC-EU, 2012). Elsewhere, the framework is focused more on the sustainable management of the marine environment, including non-living resources, and includes ecosystem-based

approaches and valuation of ecosystem services affected by human activity. For example the European Union Marine Strategy Framework Directive (2008) advocates a transition from a sector-specific policy landscape to a system-based one, in which activities are regulated in concert, based on shared space and time across boundaries. Uncertainty remains, however, about how to value coastal assets and quantitatively measure social impact (Beaumont et al., 2007).

Awareness is increasing of the potential social impacts of marine and coastal extractive mineral industries, such as coastal dredging for aggregates and beach re-nourishment schemes (e.g., Austen et al., 2009; Drucker et al., 2004). Strong public sentiments about environmental and social issues already exist around land-based mining (e.g., Mudd, 2010). However, there is currently not the same level of understanding and informed debate around offshore mining (Mason et al., 2014). As offshore mining becomes more commonplace, information and data on the marine environment and impacts will be collected, and it is important that this information is disseminated to stakeholders. It is worth noting that the value of stakeholder participation in developing and implementing policy was included in Principle 10 of the Rio Declaration, which states that: “environmental issues are best handled with the participation of all concerned citizens, at the relevant level...”

Studies suggest that for an informed society to accept a nascent offshore mining industry, stakeholders require: better information (particularly rigorous scientific analysis of potential impacts, costs and benefits); a transparent and socially responsive management process within a consistent and efficient regulatory regime; and meaningful engagement with stakeholders (Boughen et al., 2010; Mason et al., 2010).

Table 5. Relevant regional and national initiatives

	Initiative
European Union	<p>MSFD (2008): “Directive 2008/56/EC on establishing a framework for community action in the field of marine environmental policy”</p> <p>This directive provides a transparent legislative framework for an ecosystem-based approach to the management of human activities; supports the sustainable use of marine goods and services; and integrates the value of marine ecosystem services into decision making.</p>
United Kingdom	<p>Marine Environment Protection Fund 2010: Framework to allow marine aggregates extraction options to be analysed using socio-economic information. The framework analyses the interactions between different uses of the marine environment at both local and regional levels (Dickie et al., 2010)</p>
Pacific Islands	<p>SPC-EU DSM Project (2011-2016): Technical assistance and advisory service for Pacific Island countries choosing to engage in deep sea mining to help them improve governance and management in accordance with international law, with particular attention to the protection of the marine environment and securing equitable financial arrangements for their people.</p>
United States	<p>Executive Order 13547- Stewardship of the Ocean, Our Coasts, and the Great Lakes. The Order adopts the recommendations of the Interagency Ocean Policy Task Force, except where otherwise provided in this Order, and directs executive agencies to implement those recommendations under the guidance of a National Ocean Council. Based on those recommendations, this Order establishes a national policy to ensure, amongst other things, the protection, maintenance, and restoration of the health of ocean and coastal ecosystems and resources.</p>

3.2.1 Case Study: Kiribati

A recent study by Babinard et al. (2014) examined the potential social impacts of offshore aggregate mining in South Tarawa (see section 2.1.3). The authors determined that as the ESAT (Environmentally Safe Aggregates for Tarawa) dredging operation develops, it could have adverse consequences for the welfare of those Kiribati residents who are either sellers or users of aggregates. Sellers of aggregates rely on beach mining for their livelihood (they currently receive 1 Australian dollar per bag). A 2006 household survey found that 206 out of 280 households surveyed were involved in some form of beach mining (Pelesikoti, 2007). There is widespread belief that they are acting within their rights as customary owners of the land, and they will likely lose economic opportunities as a result of the offshore dredging operations. For users of aggregates on the island, the main issue is whether they will be legally able to continue to mine aggregates from their own beaches. Residents

argue that the customary rights to mine are included in the Foreshore Amendment Act of 2006 (Pelesikoti, 2007).

3.3 *Economic benefits from marine mining*

The economic benefits from near-shore mining are difficult to estimate. Marine aggregates are often sourced locally and reporting is scattered, but the marine sector is often distinguished from the land sector, so the value of the resource can be estimated. In contrast, commodities like tin and diamonds are part of a global market, which does not distinguish between land-derived and marine-derived materials. Table 6 gives estimated values where reported.

Table 6. Estimates of marine aggregates and minerals

Locations	Resource	Quantity	Revenue	Employment	References
European Union, United Kingdom, Japan, United States (minor)	Aggregate	~ 50-150+ million m ³ / year (can vary strongly year to year depending on demand)	1-3+ billion US dollars)	5,000–15,000 (estimate)	Ifremer, 2014 Herbich, 2000 Marinet, 2012 Newell and Woodcock, 2013
South Africa, Namibia, Australia (Inactive)	Diamond Placers	1.1 million carats (2012).	3.5 billion US dollars	~1,600	NAMDEB, 2010 NAMDEB, 2014
Indonesia, Malaysia, Thailand; Australia (inactive)	Tin	19,000 tons /yr tin	Indonesia 500 million US dollars	Indonesia ~3,500 Malaysia & Thailand N/A	Timah, 2012
New Zealand (inactive)	Iron Sands	0	0	0	
United States, South America, Australia, New Zealand, Africa, Portugal, India (all inactive)	Phosphates	0	0	N/A	
Mexico (inactive)	Phosphates	Total of 327.2 million ore tons at 18.5% P ₂ O ₅	0	N/A	Don Deigo (2015)
United States (now inactive)	Sulphur	0	0	0	

4. Developments in other forms of seabed mining: current state and potential scale

4.1 Phosphate mining

Phosphorites are natural compounds containing phosphate in the form of cement-binding sediments in tropical to sub-tropical regions (Murton, 2002). They are widely distributed on the continental shelves and upper slopes, oceanic islands, seamounts and flanks of atolls. Deposits have been found off the west coast of Tasmania, Australia; Congo, Ecuador, Gabon, Mexico, Morocco, Namibia, New Zealand, Peru, South Africa, and the United States. They are usually located in less than 1,000 m of water and their formation is linked to zones of coastal upwelling, divergence and biological productivity.

Currently proposals to mine phosphate are under consideration in New Zealand, Namibia and Mexico. In New Zealand, the Ministry of Business, Innovation and Employment has granted a 20-year mining permit to Chatham Rock Phosphate Ltd. for the extraction of rock phosphate nodules from an 820-km² area of the Chatham Rise (Figure 7). Before mining can commence, the company still needs to obtain consent from the Environmental Protection Authority. At the time of publication of this report the Authority had refused an application by Chatham Rise Phosphate limited for a marine consent to mine phosphorite nodules on the Chatham Rise (NZ EPA, 2015). The decision-making committee found that that “the destructive effects of the extraction process, coupled with the potentially significant impact of the deposition of sediment on areas adjacent to the mining blocks and on the wider marine ecosystem, could not be mitigated by any set of conditions or adaptive management regime that might be reasonably imposed.” They also concluded that the economic benefit to New Zealand of the proposal would be modest at best.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 7. Location of Chatham Rise phosphate project area (RSC, 2014).

In Namibia, an Environmental Impact Assessment Report and an Environmental Management Plan were submitted in March 2012 for the Sandpiper Phosphate Project (Figure 8), which proposed to dredge phosphate-enriched sediments south of Walvis Bay, Namibia, in depths of 180-300 m (Midgley, 2012). The company planned to extract 5.5 Mt of phosphate-enriched marine sediments on an annual basis, for over 20 years. The environmental impact assessment (EIA) identified low-level potential adverse impacts including biogeochemical changes, benthic habitat loss, loss of biodiversity and cumulative impacts (Namibian Marine Phosphates, 2012; Midgley, 2012; McClune, 2012). No official decision has been issued on the Sandpiper Phosphate Project application as yet, however in September 2013, an 18-month moratorium on environmental clearances for bulk seabed mining activities for industrial minerals, base and/or rare metals (including phosphorites) was declared by the Government of Namibia. During this period the Ministry of Fisheries and Marine Resources is required to make a strategic impact assessment on the potential impacts of the proposed phosphate mining on the fishing industry. While the Ministry of Mines and Energy is allowing marine phosphate exploration activities to continue during the moratorium period, such activities are not currently being undertaken in areas within the national jurisdiction of Namibia.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 8. The Sandpiper Project (license area shown) includes the zone of highest regional phosphate concentration (Namibian Marine Phosphate, 2012).

A proposed Mexican underwater phosphate mine, the Don Diego project, is located in 60-90m water depth, approximately 40 km off the coast of the Bay of Ulloa, on the west coast of Baja California. The permit area is 912 km² and it is estimated that if the project proceeds the area dredged annually would be around 1 per cent (1.7 km²; Don Diego, 2015). Phosphorite resources at the Don Diego deposit have been estimated to total 327.2 million ore tons at 18.5 per cent P₂O₅. Odyssey Marine Exploration has lodged an environmental impact assessment for the recovery of the phosphate sands with the Mexican Secretary of Environment and Natural Resources and is awaiting a decision (Odyssey Marine Exploration, 2014). Local non-governmental organizations including WildCoast, Centro Mexicano Derecho Ambiental (CEMDA), Grupo Tortuguero, Vigilantes de Bahía Magdalena and Medio Ambiente Sociedad have been vocal in their opposition to the project (Pier, 2014).

4.2 Deep-Sea Mining

Although commercial deep-sea mining has not yet commenced, the three main deep-sea mineral deposit types – sea-floor massive sulphides (SMS), polymetallic

nodules and cobalt-rich crusts – have been the subject of interest for some time (see SPC 2013a,b,c,d). Recent announcements make it seem likely that SMS mining will begin in the Manus Basin of Papua New Guinea (Nautilus Minerals, 2014a and b). Other Pacific Island States (e.g., Fiji, Solomon Islands, Tonga and Vanuatu) have issued exploration licenses to various companies to evaluate the commercial feasibility of mineral resources development in their exclusive economic zones. The economic interest in SMS deposits is their high concentrations of copper, zinc, gold, and silver; polymetallic nodules for manganese, nickel, copper, molybdenum and rare earth elements; and ferromanganese crusts for manganese, cobalt, nickel, rare earth elements, yttrium, molybdenum, tellurium, niobium, zirconium, and platinum.

In addition, the International Seabed Authority (ISA), which regulates deep-sea mining in the Area (the seabed, ocean floor and subsoil thereof beyond the limits of national jurisdiction) has entered into 15-year contracts for exploration for polymetallic nodules, SMS and cobalt-rich ferromanganese crusts in the deep seabed with 26 contractors (composed of companies, research institutions and government agencies) plus 1 contract pending ISA Council action in July 2015 (ISA, 2000; ISA 2001; ISA 2010; ISA 2013).

Seventeen of these contracts are for exploration for polymetallic nodules in the Clarion-Clipperton Fracture Zone (CCZ, 16) and Central Indian Ocean Basin (1). There are six contracts for exploration for SMS in the South West Indian Ridge, Central Indian Ridge and the Mid-Atlantic Ridge and four contracts for exploration for cobalt-rich crusts in the Western Pacific Ocean (3) and Atlantic (1) (ISA 2015a). These licences allow contractors to explore for seabed minerals in designated areas of the Area.

The ISA has called for comments on draft regulations for exploitation licensing in the Area (ISA 2015b). The decision to commence deep-sea mining in the Area will depend in part on the availability of metals from terrestrial sources and their prices in the world market, as well as technological and economic considerations based on capital and operating costs of the deep-sea mining system.

5. Gaps in capacity to engage in offshore minerals industries and to assess the environmental, social and economic aspects.

Despite the importance of marine extractive industries in many developing countries, the environmental, social and economic aspects are often not adequately understood. Therefore it is necessary to strengthen the approach to planning and managing these activities. This includes implementing the precautionary principle and adaptive management, as well as transparent monitoring. There is also a lack of consensus on what is an acceptable condition in which to leave the seabed post mining. Increasing public awareness and engendering a custodial and stewardship attitude to the environment may help curb the most damaging practices.

Unregulated mining often occurs in parallel to regulated mining activities. For example, numerous small operators participate in the marine sector of the tin mining industry in Bangka and Belitung, Indonesia. Many of the practices associated with these workers are unsafe and miners are killed or injured every year; local news reports refer to over 100 fatalities per year (Jakarta Post, 2010). The lack of regulation or the lack of enforcement of regulations, allows mining to take place in critical marine habitats and extensive damage has been done to coral reefs and mangrove environments (IDH, 2013). Improved licensing, regulation, enforcement and monitoring, in conjunction with social programmes to find alternative sources of revenue, would be needed. How the industry is being regulated would also need to be considered. The export data, published by the Bangka Belitung regional administration, showed that P.T. Timah, which owns 473,800 hectares of concession areas, exported 8,899 tons of tin in 2009, and privately owned smelters, which operate concession areas of 16,884 hectares, exported 13,867 tons. These discrepancies highlight the magnitude of the problem. The penalties provided by mining and/or environmental legislation may need to be strengthened to stop these practices.

For any State or company planning resource development, integrating coastal and marine ecosystem services into the development process is important; however, information on the services provided or the value of these services is often scarce. In many developing countries the interface between governments and offshore minerals industries needs to be strengthened. Deficiencies exist in the information available and in the institutional capacity to manage non-living marine resources. In summary, the following gaps can be identified:

- Increased capacity in coastal and marine geosciences information systems (including social, cultural, economic, ecological, biophysical and geophysical information) to improve geoscientific advice for management and monitoring of coastal environments to meet the requirements of ecosystem-based management and sustainable development;
- Development and implementation of robust regulatory frameworks for marine mineral extraction industries, which include environmental impact assessments, environmental quality and social laws, environmental liability, and monitoring capacity;
- Increased public awareness of the vulnerability of coastal environments, the benthic habitats and the fishery nursery grounds that may be affected by marine mining; and
- Technology transfer and skills development to ensure best practice in marine mineral extraction.

Chapter 24. Solid Waste Disposal

Contributors: Alan Simcock (Lead member), Juying Wang (Co-lead member)

1. Introduction – the regulatory system

The disposal at sea of waste generated on land and loaded on board vessels for dumping is the object of long-standing global, and (in many areas) regional, systems of regulation. (These systems also cover, for completeness, dumping from aircraft and waste (other than operational discharges) from fixed installations in the sea). Such dumping must be distinguished from discharges into rivers and directly from land into the sea and emissions to air from land-based activities discussed in Chapter 20 (Land-based inputs).

When concerns about the environment developed in the 1960s, growing constraints on the land disposal of waste and discharges into rivers led to pressures to find new routes for waste disposal. Concerns about these pressures led to action in several forums. Several United Nations specialized agencies set up the Group of Experts on the Scientific Aspects of Marine Pollution (GESAMP¹ – later altered to “Marine Environmental Protection”).

The preparatory committee for the 1972 Stockholm Conference on the Human Environment, set up by the United Nations General Assembly, established an intergovernmental working group on marine pollution. At the national level, several countries started developing approaches to control such dumping. The United States of America put forward proposals for an international agreement on the subject. Spurred from the national level by an attempt by the vessel *Stella Maris* to dump 650 tons of chlorinated waste, several countries started developing approaches to control such dumping. States adjoining the North-East Atlantic adopted an international convention regulating dumping in that area in Oslo, Norway, on 15 February 1972 (OSPAR, 1982; IMO, 1991).

Later that year, the Stockholm Conference adopted a set of principles for international environmental law and called, among other things, for an international instrument to control dumping of waste at sea. The United Kingdom, in consultation with the United Nations Secretariat, organized a further conference in London, and the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter 1972 (the 1972 London Convention) was signed on 13 November 1972 in London, Mexico City and Moscow (ICG, 1982, IMO, 2014f).²

¹ At present, it is jointly sponsored by IMO, FAO, IAEA, WMO, UNESCO-IOC, UN, UNDP, UNEP and UNIDO.

² United Nations, *Treaty Series*, vol. 1046, No. 15749.

1.1 The 1972 London Convention

The main provisions of the 1972 London Convention can be summarized as follows:

- (a) A definition of “dumping” to cover the deliberate disposal of waste and other matter at sea from ships, aircraft, platforms or other man-made structures in the sea;
- (b) A ban on dumping at sea of any of the substances on the “black list” (Annex I to the Convention): toxic organohalogen compounds, agreed carcinogenic substances, mercury and cadmium and their compounds, crude oil and petroleum products³ taken on board for the purpose of dumping them, high-level radioactive substances as defined by the International Atomic Energy Agency and persistent synthetic substances (including plastics) liable to float or remain in suspension. Exceptions were allowed for *force majeure* and for trace amounts not added for disposal purposes;
- (c) A requirement for a special prior permit for any dumping of any substances on the “grey list” (Annex II to the Convention) – arsenic, lead, copper and zinc and their compounds, organosilicon compounds, cyanides, fluorides and pesticides not in Annex I, bulky objects and tar likely to obstruct fishing or navigation, medium-level and low-level radioactive waste and substances to be dumped in such quantities as to cause harm;
- (d) A requirement for at least a general prior permit for all other dumping. Such permits were required to follow an approach set out in Annex III to the Convention, which required consideration of alternative land-based disposal and the avoidance of harm to legitimate uses of the sea;
- (e) A requirement to appraise the effectiveness of the regulatory assessment process through compliance monitoring and field monitoring of effects;
- (f) An obligation to report to the Secretariat of the Convention (which is hosted by the International Maritime Organization (IMO) in London) on dumping permits issued and amounts permitted to be dumped (IGC, 1982; LC-LP, 2014a).

When the 1972 London Convention entered into force in 1975, dumping at sea was still a major disposal route for many kinds of waste. Over the years, the meetings of the Contracting Parties have tightened the requirements of the Convention, with the result that the amounts of waste that may be dumped were reduced significantly:

- (a) Guidance was adopted on the approaches to the grant of special and general permits for dumping. In many respects this guidance was gradually made more precise and restrictive (IMO, 2014a);

³ “Petroleum products” includes wastes from crude oil, refined petroleum products, petroleum distillate products, and any mixtures containing these substances.

- (b) In 1972 incineration of hazardous waste at sea was just beginning to be practised. In 1978 an amendment was adopted clarifying that the incineration at sea of oily wastes and organohalogen compounds was permitted as an interim solution, but requiring a special prior permit in accordance with agreed guidelines for this practice. This amendment came into force in 1979 (IGC, 1982). In 1988, the Consultative Meeting of the States parties called for such incineration to be minimized and for a re-evaluation of the practice (LDC, 1988). In 1993 an amendment to prohibit this practice was adopted and entered into force from 1994 (IMO, 2012);
- (c) In 1990, the Contracting Parties adopted a resolution calling for the phasing out of the dumping of industrial waste (LDC, 43(13)). Following this, an amendment to Annex I of the Convention was adopted in 1993, which entered into force in 1994, to prohibit the dumping of industrial waste from the end of 1995 (IMO, 2012; IMO, 2014c).
- (d) Even though the 1972 London Convention, as adopted, prohibited the dumping of high-level radioactive waste, many Contracting Parties remained unhappy with any dumping of radioactive waste of any kind. In 1983, a voluntary moratorium on such dumping was agreed. In 1993 an amendment was adopted to prohibit all dumping of radioactive waste, subject to a review before February 2019, and every twenty-five years thereafter. The Consultative Meeting of the Contracting Parties is beginning preparations for this review (IMO, 2012; LC-LP, 2014).

1.2 *The 1996 London Protocol*⁴

The generally restrictive policy of the Contracting Parties to the 1972 London Convention towards the dumping of waste and other matter at sea resulted in a further development in 1996, when a protocol to the convention was adopted. This Protocol is intended gradually to replace the 1972 London Convention. The London Protocol entered into force in 2006. Among a number of other changes, the fundamental difference between the 1972 Convention and the 1996 London Protocol is that the Protocol adopts a “reverse list” approach. All dumping of waste is prohibited, except for a limited number of categories where dumping could be permitted, in contrast to the 1972 Convention approach, which prohibited dumping only of a specified list of substances, while requiring a permit (general or special) for everything else. The limited number of categories where dumping can still be permitted under the Protocol as originally adopted are:

- (a) Dredged material;
- (b) Sewage sludge;
- (c) Fish waste, or material resulting from industrial fish processing operations;

⁴ 36 *International Legal Materials* 1 (1997).

- (d) Vessels and platforms or other man-made structures at sea;
- (e) Inert, inorganic geological material;
- (f) Organic material of natural origin;
- (g) Bulky items primarily comprising iron, steel, concrete and similar unarmful materials for which the concern is physical impact and limited to those circumstances, where such wastes are generated at locations, such as small islands with isolated communities, having no practicable access to disposal options other than dumping.

Shortly after the Protocol entered into force in 2006, the Meeting of Contracting Parties to the London Protocol adopted an amendment to add “sub-seabed carbon-dioxide (CO₂) streams from CO₂ capture processes for sequestration” to the list of permitted forms of disposal (LP.1(1)). States Parties may therefore issue permits to allow the injection into a sub-seabed geological formation of CO₂ streams from CO₂ capture processes. This amendment entered into force in 2007. In 2012, specific guidelines were adopted to for such disposal activities and the potential effects on the marine environment in the proximity of the receiving formations. In 2009, a further amendment was adopted, allowing the export of CO₂ from CO₂ capture processes for sequestration in sub-seabed geological formations (LP.3(4)). This amendment is not yet in force. Guidance on the implementation of the export of CO₂ streams for disposal in sub-seabed geological formations for the purposes of sequestration was adopted in 2013. The intention of carbon dioxide sequestration in sub-seabed geological formations is to prevent release into the biosphere of substantial quantities of carbon dioxide derived from human activities, by retaining the carbon dioxide permanently within such geological formations.

In 2008, the Contracting States to both the 1972 London Convention and the 1996 London Protocol adopted a resolution agreeing that the scope of the London Convention and Protocol includes ocean fertilization activities, that is, any activity undertaken by humans with the principal intention of stimulating primary productivity in the oceans. (Ocean fertilization does not include ordinary aquaculture, or mariculture, or the creation of artificial reefs). It was further agreed that:

- (a) In order to provide for legitimate scientific research, such research should be regarded as placement of matter for a purpose other than the mere disposal thereof under Article III.1(b) (ii) of the London Convention and Article 1.4.2.2 of the London Protocol;
- (b) Scientific research proposals should be assessed on a case-by-case basis using an assessment framework to be developed by the Scientific Groups under the London Convention and Protocol;
- (c) Such an assessment framework should include, *inter alia*, tools for determining whether the proposed activity is contrary to the aims of the Convention and Protocol;
- (d) Until specific guidance is available, Contracting Parties should be urged to use utmost caution and the best available guidance to evaluate the

scientific research proposals to ensure protection of the marine environment consistent with the Convention and Protocol;

- (e) For the purposes of the resolution, legitimate scientific research should be defined as those proposals that have been assessed and found acceptable under the assessment framework;
- (f) Given the present state of knowledge, ocean fertilization activities other than legitimate scientific research should not be allowed. To this end, such other activities should be considered as contrary to the aims of the Convention and Protocol and should not currently qualify for any exemption from the definition of dumping in the Convention and the Protocol (LC-LP, 2008).

In 2010, the Contracting Parties to the 1972 London Convention and the 1996 London Protocol adopted the Assessment Framework for Scientific Research Involving Ocean Fertilization (LC-LP, 2010). In 2013, the Contracting Parties to the London Protocol adopted amendments to incorporate into the Protocol provisions regulating the placement of matter for ocean fertilization and other marine geo-engineering activities (LP.4(8)). These amendments are not yet in force (LC-LP, 2013). Guidance on implementing the provisions was adopted in 2014 (LC-LP, 2014).

1.3 Acceptance of the system of regulation

As of October 2014, there are 87 parties to the 1972 London Convention, and 45 parties to the 1996 London Protocol. Thirty-four States are parties to both the Convention and the Protocol (IMO, 2014b). There are, however, many regional conventions on marine environmental protection that have specific references to, or contain provisions relating to, the regulation of disposal of wastes into the sea. Most regional conventions (the Abidjan, Antigua, Barcelona, Bucharest, Cartagena, Helsinki, Jeddah, Kuwait, Lima, Nairobi, Noumea, OSPAR Conventions⁵) have specific

provisions that regulate sea dumping. The dumping clauses are largely based on, or are more stringent than, the London Convention or London Protocol. (An overview of Contracting Parties to the London Protocol, London Convention and Regional Agreements that include management of sea dumping issues is set out in IMO 2014e). Most States are therefore Contracting Parties to an international agreement that relates to the management of sea dumping of solid waste or other matter. However, there remain some States, including some of the world's 20 largest economies, which are not party to any of these agreements. It is not known how far such States apply policies along the lines of those required by the 1972 London Convention or the 1996 London Protocol.

2. Amounts and nature of current dumping

Agreements in, and under, the 1972 London Convention and the 1996 London Protocol provide for annual reporting of the number of permits and the quantity and nature of the waste dumped under them. However, reporting under the Convention and the Protocol is not consistent. Figure 1 shows, for 1976 to 2010, the number of States that are Contracting States of the 1972 London Convention, the number submitting reports and the proportion that the latter are of the former.

Figure 1. Contracting Parties to the 1972 London Convention, Contracting Parties submitting reports to the Convention Secretariat and the latter as a proportion of the former, 1976 – 2010. Source: IMO, 2014g.

When the Meeting of Contracting Parties to the 1996 London Protocol set up a compliance mechanism in 2007, the worrying decline in reporting led it to include the issue of reporting in the terms of reference of the Compliance Group, which formed part of that mechanism (LC-LP, 2007). Reports under the London Convention and Protocol take some time to be compiled and submitted. It is usually only in the fourth year after the year being reported on that it is possible to take a final view on the reporting for that year. It is worth noting that non-reporting is the highest amongst London Convention parties, while reporting from London Protocol parties is above 75per cent. It may well be that some or all of the 59 per cent of Contracting States that did not submit reports had not authorized any dumping –like eight of the States in 2010 that did submit reports – but the absence of reports makes it impossible to draw clear conclusions. Also, several non-reporting States are land-locked, and therefore may also not have had any dumping to report. There is also a substantial degree of variation from year to year in which States submit reports.

The Meetings of the Contracting Parties have made efforts to try to improve the level of reporting on the dumping of waste at sea, but so far with limited success. The steps taken include reviews and simplifications of the reporting forms and more recently the introduction of on-line reporting. Improved outreach to Parties and contact with the industrial organizations (such as the International Association of Ports and Harbours) involved in dumping is beginning to produce some results. Some States (such as Nigeria and South Africa) have also sought to assist neighbours to set up reporting systems (LC-LP, 2013).

In spite of these efforts, it is therefore difficult to derive a clear picture of the quantity and nature of wastes and other matter being dumped at sea from the reports under the 1972 London Convention and 1996 London Protocol.

Nevertheless, it is clear that the overwhelming type of dumping is of dredged material. For the last year for which a summary of the national reports is available (2010), 35 of the 38 reports submitted recorded the dumping of dredged material. Most, if not all, of this is derived from dredging for navigational purposes. Some is “capital dredging” for the creation of new berths or shipping channels, but most is “maintenance dredging” for the maintenance of existing harbours and shipping channels. The quantity of material involved is considerable. For example, Belgium reported dumping 52 million tons in 2010: over 200,000 tons per working day. It is not, however, possible to give an overall picture of how much is the result of regular dredging and how much is new construction, because many reports do not differentiate between capital dredging and maintenance dredging.

The impacts of this dumping of dredged material are essentially twofold (although there can be other effects): the smothering of the seabed by the dredged material, and the remobilization of hazardous substances contained in the dredged material. The effects of smothering depend essentially on the nature of the dump area. If the dumpsite were to have a biodiverse benthic life, such smothering would be catastrophic. Where tidal action is very dynamic and there is a sedimentary bottom, effects are limited, because much of the seabed material will be kept in motion by the tidal action. The choice of dumpsite is therefore important. The regular use of the same dumpsites (which is reported to be common) limits adverse effects. The remobilization of hazardous substances is a different matter. The Guidance under the London Convention and Protocol sets out procedures and criteria for deciding whether it is safe to dump contaminated dredged material. Where the harbour from which the dredged material comes is on the estuary of a river with a history of heavy industry (for example, the Rhine), it is frequently contrary to this Guidance (or, in the example quoted, parallel guidance from OSPAR, the local regional organization) to dump the material at sea, and it should be returned to land.

In the past, a substantial number of States dumped sewage sludge or animal slurry at sea. Where this was done, of course, it was an addition to the nutrient input. In many areas, this has now been stopped because it was a potential contributor to eutrophication problems. In 2010, only Australia (up to 20,000 litres) and the Republic of Korea (556,534 tons) reported dumping of this kind (IMO, 2014b). The Republic of Korea has also reported that dumping of sewage sludge will end by the end of 2015 (LC-LP, 2013).

The other substances reported as dumped cover a miscellaneous range. Dumping of fish waste was reported in 2010 by six countries. The total amount dumped was around 100,000 tons (not all reporting was in terms of tonnage). The other categories of material dumped included rock, sand and gravel, spoilt cargoes (for example, wheat, rice and fertilizer), molasses waste and a handful of ships and platforms (some of the latter being intended to create artificial reefs). In addition, permits were granted for a few burials at sea (see Chapter 8 Cultural ecosystem services). The overall impression is that, for the countries submitting reports,

disposal of waste at sea is now a minor impact on the marine environment and human uses of the sea, except for the dumping of dredged material.

3. Dumping of radioactive material

As noted above, the dumping of high-level radioactive waste has been prohibited under the 1972 London Convention since 1975, and dumping of medium- and low-level radioactive waste has been prohibited also under the 1996 London Protocol (subject to a review every 25 years) since 1994. The first reported sea disposal of radioactive waste took place in 1946 and the last authorized disposal appears to have been in 1993. During the 48-year history of sea disposal, 14 countries have used more than 80 sites to dispose of approximately 85,000 terabecquerels of radioactive waste. Some countries used this waste management option only for small quantities of radioactive waste. Two countries conducted only one disposal each and one country conducted only two disposals (IAEA, 1999).

In 1992, reports that the former Soviet Union had dumped large amounts of high-level radioactive wastes for over three decades in shallow waters in the Arctic Ocean caused widespread concern, especially in countries with Arctic coastlines. In 1992, a joint Norwegian-Russian Expert Group was established to investigate radioactive contamination due to dumped nuclear waste in the Barents and Kara Seas. The Russian Federation provided information on the dumping, some of which had taken place before 1975. It arranged exploratory cruises to the dumping areas, with the participation of the International Atomic Energy Agency. The results obtained during the cruises did not indicate any significant radioactive contamination at the dumping sites, although the levels near some dumped objects are slightly elevated compared with elsewhere (IAEA, 1995).

Norway undertook further radiological monitoring of the Barents Sea in 2007, 2008 and 2009. Activity concentrations of the anthropogenic radionuclides usually used to trace the impact of radioactive waste were reported as low, and up to an order of magnitude lower than in previous decades, including in marine biota. Weighted absorbed dose rates to biota from anthropogenic radionuclides were low, and orders of magnitude below a predicted no-effect screening level of 10 micrograys per hour ($\mu\text{Gy/hr}$). Dose rates to man from consumption of seafood and dose rates to biota in the marine environment were found to be dominated by the contribution from naturally occurring radionuclides (Gwynn et al., 2012). In 2012, a further joint Norwegian-Russian project examined radioactive pollution in the Kara Sea (Stråleverninfo, 2012). It concluded that the situation gave rise to no immediate cause for concern, but that further monitoring of the situation is warranted (JNREG, 2014). A further joint Norwegian-Russian study of radioactive contamination in the Barents Sea has been launched.

4. Dumped explosives and military chemicals

After both World Wars, States were faced with the problem of how to dispose of the residues of explosive materials and other warlike stores (“munitions”), including a number of containers of poisonous gases. The solution adopted for substantial quantities was to dump them in the sea. During peacetime, some States have also adopted this method of disposal for unwanted explosives and military chemicals. The dump sites were usually chosen to avoid seabed areas then being used by people, but over time some of these areas have come into use as a result of improved technologies and pressures from other uses of the sea.

In 2010, the United Nations General Assembly adopted a resolution noting the importance of raising awareness of the environmental effects related to waste originating from chemical munitions dumped at sea, and invited relevant international organizations to keep the issue under review (UNGA, 2010).

Munitions dumped at sea present a risk to several classes of users of the sea. Fishers in the location of the dump sites can bring the munitions up in their nets, especially bottom-trawling nets. Construction of offshore installations, submarine cables and submarine pipelines can interact with dumped munitions. Some munitions based on phosphorus can break out from the (often wooden) boxes in which they were stored at the time of disposal, float to the surface, be stranded on beaches and then (as the tide recedes and they dry out) spontaneously burst into flame, and burn at temperatures around 1,000 degrees centigrade. These present potential risks to users of beaches, especially tourists (HELCOM, 2013).

Exercises have been carried out in several parts of the world to map the dump sites and to establish what was dumped there. The Baltic Marine Environment Protection Commission (HELCOM) estimated that 40,000 tons of munitions were dumped in the Baltic at the end of World War II. Some of these munitions are contained in ships onto which they were loaded and which were then scuttled. Others were thrown overboard piece by piece, a process which means that the munitions can end up scattered over a wide area. Similar conclusions about dispersed dumping have been reached in other areas. The four main dumping areas in the Baltic were south-east of the Swedish island of Gotland and south-west of the Latvian city of Liepaja, east of the Danish island of Bornholm and south of the Little Belt between the main Danish islands and Schleswig-Holstein in Germany. There is also evidence that munitions were thrown overboard as the ships left port (HELCOM, 2013). The OSPAR Commission has carried out a similar exercise, resulting in an “Overview of Past Dumping at Sea of Chemical Weapons and Munitions”, together with a database on encounters with dumped conventional and chemical munitions, which it is intended to keep up-to-date. Best estimates suggest that over one million tons of munitions were dumped in Beaufort’s Dyke (a trough in the United Kingdom of Great Britain and Northern Ireland between Scotland and Northern Ireland), some 168,000 tons of ammunition were dumped in the Skagerrak, some 300,000 tons of munitions of various types, such as bombs, grenades, torpedoes and mines, were dumped in the North Sea and an estimated 35,000 tons were dumped off Knokke-Heist, Belgium (OSPAR, 2010).

In other parts of the world, problems have arisen with dumped munitions. For example, in 2006 New Zealand had problems with munitions that had been dumped improperly at the end of the Second World War. An estimated 1,500 tons of munitions had ended up in relatively shallow water and were posing threats to fisheries and recreational uses of the sea. The New Zealand authorities concluded that the best solution was to lift them and re-dump them in much deeper water before they dried out: if they were brought ashore and allowed to dry, there was a high risk that they would become unstable (LC-LP, 2006).

A non-governmental organization, the James Martin Center for Nonproliferation Studies, conducted a general survey of dumped chemical warfare munitions and published an interactive map of 168 munitions dump-sites, with the publicly available information about them, on the internet (<https://www.google.com/maps/d/viewer?mid=zwm9Gb8KEKxl.kMpXo9rjqLZM&hl=en>).

In 2010, the Research and Technology Organization of the North Atlantic Treaty Organization (NATO) reviewed the environmental aspects of the disposal of unwanted munitions. The overall conclusion was that the technology and expertise existed to deal with immediate problems and with the current generation of munitions, including the legacy of munitions dumped at sea, but that the expertise and technology was often lodged in countries where there was no significant problem, and that a mechanism was required to assist in the transfer of the technology and expertise to the places where it was needed. It was noted that this could be significant in measures to control terrorism (NATO, 2010).

5. Illegal dumping

If there are problems in obtaining an overall global picture of dumping authorized under the London Convention and London Protocol, trying to gain an overview of the potential effects of illegal dumping presents much greater problems. While the 1972 London Convention and the 1996 London Protocol have a mechanism for reporting illegal dumping⁶, no report has been received in the recent past. An alleged case of illegal dumping in Canadian waters is currently under investigation with a report expected to be provided to the governing bodies of the London Convention and Protocol in the near future.

Several cases have been reported of illegal export of waste from industrialized countries for disposal in States in Africa. Most of these have concerned disposal on land. There have also been persistent informal reports of dumping of radioactive or toxic waste in the sea off the coast of the Federal Republic of Somalia. Informal information given to INTERPOL suggested that the naval force present off the coast of the Federal Republic of Somalia to combat piracy may have detected vessels suspected of illegal dumping of waste. Following the tsunami on 26 December 2004,

⁶ See <http://www.imo.org/OurWork/Environment/LCLP/Reporting/incidents/Pages/default.aspx>

UNEP responded to an urgent request from the authorities in the Puntland region of the Federal Republic of Somalia for help in assessing potential environmental damage. After an initial UNEP report, an inter-agency mission, which included FAO, UNDP, UNEP and WHO, went to Puntland in March 2005. It investigated three sample sites along a 500-kilometre coastal stretch between the three main populated coastal locations of Xaafuun, Bandarbeyla and Eyl where toxic waste had reportedly been uncovered by the tsunami. No evidence of toxic waste was found by the mission. In June 2010, Greenpeace International claimed to have proof of the dumping of toxic waste in the Federal Republic of Somalia by European and American companies in the period from 1990 to 1997, citing testimony from an Italian parliamentary commission, evidence uncovered by an Italian prosecutor (including wiretapped conversations with alleged offenders) and warnings by the Special Representative of the Secretary-General for Somalia in 2008 of possible illegal dumping in the Federal Republic of Somalia. While INTERPOL and some of the entities cited in the Greenpeace International report have uncovered fragmentary evidence and signs of the dumping of toxins, no international investigation has ever been able to verify the dumping of illegal waste in the Federal Republic of Somalia, largely because of the security situation (UNSC, 2011).

Other evidence of illegal dumping appears from time to time as a result of ocean monitoring. For example, the authorities in Japan have detected within areas under its jurisdiction high levels of polychlorinated biphenyls (PCBs) and butyl tin and phenyl tin compounds. The origins of such pollution could not be identified (Japan MOE, 2009).

6. Conclusions on knowledge gaps and capacity-building gaps

The disposal of solid waste at sea has been regulated under international agreements for the past 40 years. The majority of coastal States have accepted this regime. If the 1972 London Convention and the 1996 London Protocol were effectively and consistently applied, this source of inputs of harmful substances would be satisfactorily controlled. The problem is basically that we do not know whether this regime is generally being fully implemented, since there is substantial under-reporting of what is happening.

There is therefore a major knowledge gap about the implementation of the 1972 London Convention and the 1996 London Protocol, as has been acknowledged by the Meetings of the Contracting Parties to the two agreements. Some capacity-building is available from the International Maritime Organization and some of the Contracting Parties, to promote better implementation of the agreements and better reporting of what is being done. However, a significant capacity-building gap remains.

The information gap about the scale and nature of dumping of waste and other matter that is taking place is further compounded by the absence of information about dumping under the control of States which are subject to any formal reporting system under the 1972 London Convention, the 1996 London Protocol or regional

dumping agreements and which do not publish any national data. This category includes some of the world's largest economies.

Much work has been done to identify the locations where munitions have been dumped. However, some gaps in the knowledge remain on this subject. There are gaps in building capacities to help fishers and other users of the sea to draw on this knowledge, in order to reduce the risks to which they are subjected and to know how they should respond if they bring up dumped munitions in their nets.

Chapter 25. Marine Debris

Contributors: Juying Wang (Lead member), Kim Kiho, Douglas Ofiara, Yuhui Zhao, Arsonina Bera, Rainer Lohmann, Maria Clare Baker

1. Overview

1.1 *Definition of marine debris*

Litter disposal and accumulation in the marine environment is one of the fastest-growing threats to the health of the world's oceans (Pham et al., 2014). Marine debris, also known as marine litter, has been defined by UNEP (2009) as “any persistent, manufactured or processed solid material discarded, disposed of or abandoned in the marine and coastal environment”. Marine debris consists of items that have been made or used by people and deliberately discarded into the sea or rivers or on beaches; brought indirectly to the sea with rivers, sewage, storm water or winds; accidentally lost, including material lost at sea in bad weather (fishing gear, cargo); or deliberately left by people on beaches and shores (UNEP, 2005). In 1997, the United States of America Academy of Sciences estimated the total input of marine litter into the oceans, worldwide, at approximately 6.4 million tons per year (UNEP, 2005). Jambeck et al (2015) recently calculated that 275 million metric tons (MT) of plastic waste was generated in 192 coastal countries in 2010, with 4.8 to 12.7 million MT entering the ocean.

Marine debris is present in all marine habitats, from densely populated regions to remote points far from human activities (UNEP, 2009) from beaches and shallow waters to the deep-ocean trenches (Miyake et al. 2011). The density of marine debris varies greatly among locations, influenced by anthropogenic activities, hydrological and meteorological conditions, geomorphology, entry point, and the physical characteristics of debris items. However, a recent study presented data on detectable floating plastic accumulation with visual observation in the North Atlantic and Caribbean from 1986 to 2008, the highest concentrations (> 200,000 pieces per square kilometre) occurred in the convergence zones (Law et al., 2010). Computer model simulations, based on data from about 12,000 satellite-tracked floats deployed since the early 1990s as part of the Global Ocean Drifter Program (GODP, 2011), confirm that debris will be subject to transport by ocean currents and will tend to accumulate in a limited number of sub-tropical convergence zones or gyres (IPRC, 2008; UNEP and NOAA, (2011)) (Figure 1).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. A model simulation of the distribution of marine litter in the ocean after ten years shows plastic converging in the five gyres: the Indian Ocean gyre, the North and South Pacific gyres, and the North and South Atlantic gyres. The simulation, derived from a uniform initial distribution and based on real drifter movements, shows the influence of the five main gyres over time. Source: IPRC, 2008.

1.2 Types of marine debris

Marine debris comprises of various material types, and can be classified into several distinct categories (ANZECC, 1996; Edyvane et al., 2004; Ribic et al., 1992; Galgani et al., 2010):

(a) **Plastics**, covering a wide range of synthetic polymeric materials, including fishing nets, ropes, buoys and other fisheries-related equipment; consumer goods, such as plastic bags, plastic packaging, plastic toys; tampon applicators; nappies; smoking-related items, such as cigarette butts, lighters and cigar tips; plastic resin pellets; microplastic particles;

(b) **Metal**, including drink cans, aerosol cans, foil wrappers and disposable barbeques;

(c) **Glass**, including bottles, bulbs;

(d) **Processed timber**, including pallets, crates and particle boards;

(e) **Paper and cardboard**, including cartons, cups and bags;

(f) **Rubber**, including tyres, balloons and gloves;

(g) **Clothing and textiles**, including shoes, furnishings and towels.

1.3 Sources of marine debris

Marine debris originates from a wide and diverse range of sources. The majority of marine debris (approximately 80 per cent) entering the seas and oceans is considered to originate from land-based sources (Allsopp, et al., 2006), including sewage treatment, combined sewer overflows, people using the coast for recreation or shore fishing, shore-based solid waste disposal, inappropriate or illegal dumping of domestic and industrial rubbish, poorly managed waste dumps, street litter which is washed, blown or discharged into nearby waterways by rain, snowmelt, and wind, etc. The remaining can be attributed to maritime transport, industrial exploration and offshore oil platforms, fishing and aquaculture (UNEP, 2009) and loss and purposeful disposal (e.g. ballast weights made of steel, lead or cement) of scientific equipment.

2. Environmental Impacts

The incidence of debris in the marine environment is a cause for concern. It is known to be harmful to biota, it presents a hazard to shipping (propeller fouling), it is aesthetically detrimental, and it may also have the potential to transport contaminants over long distances (STAP, 2011). Marine debris, and in particular the accumulation of plastic debris, has been identified as a global problem alongside other contemporary key issues, such as climate change, ocean acidification and loss of biodiversity (CBD and STAP-GEF, 2012).

2.1 Entanglement and Ingestion

Marine debris results in entanglement of and ingestion by organisms, and poses a direct threat to marine biota. Adverse effects of marine debris have been reported for 663 species by reviewing available publications (CBD and STAP-GEF, 2012). Over half of these reports documented entanglement in, and ingestion of, marine debris, representing almost a 40 per cent increase since a review in 1997, which reported 247 species (Laist, 1997). Reports revealed that all known species of sea turtles, about half of all species of marine mammals, and one-fifth of all species of sea birds were affected by entanglement in, or ingestion of, marine debris. Species with the greatest number of individuals affected by entanglement or ingestion were the Northern fur seal, *Callorhinus ursinus*, the California sea lion, *Zalophus californianus*, and the seabird *Fulmarus glacialis*; the most frequently reported species are all either birds or marine mammals. About 15 per cent of the species affected through entanglement and ingestion are on the IUCN Red List (CBD and STAP-GEF, 2012).

Abandoned, lost or discarded fishing gear (including monofilament line, nets and ropes), as well as ropes, netting and plastic packaging, can be a cause of

entanglement for pinnipeds (seals and related genera), cetaceans, turtles, sharks, sirenians (dugongs and related genera) and birds (WSPA, 2012). The effects range from immediate mortality through drowning to progressive debilitation over a period of months or years (Laist, 1997). Pinniped entanglement usually involves plastic collar-like debris which is often referred to as “neck collars”, where the plastic forms a collar around the neck. The animal cannot remove it and it hampers normal feeding or breathing (Allen et al., 2012; Waluda and Staniland, 2013). As the animal grows, the collar effectively tightens and cuts into tissues becoming firmly embedded in skin, muscle and fat (WSPA, 2012) and may cause death. “Ghost fishing” as it is known, can affect many species of fish and invertebrates such as crabs, corals and sponges. For example, several dead and moribund Geryon crabs were found associated with discarded nets in the deep Mediterranean (Ramirez-Llodra et al., 2013). In addition, lost and abandoned traps and the associated by-catch are a global issue with annual trap loss rates approaching 90 per cent in some fisheries (Al-Masroori et al. 2009; Bilkovic et al. 2012).

Marine debris can be mistaken for food items and be ingested by a wide variety of marine biota (Pham et al., 2014). Many species of seabirds, marine mammals and sea turtles have been reported to eat marine debris. Ingestion of sharp debris may damage their guts and result in infection, pain or death. Plastic polymer mass may irritate the stomach tissue, cause abdominal discomfort, and stimulate the animal to feel full and cease eating (Derraik, 2002; Galgani et al., 2010). Two sperm whales (*Physeter macrocephalus*) were found off the coast of northern California in 2008 with a large amount of fishing gear in their gastrointestinal tracts (Jacobsen et al., 2010). A total of 141 mesopelagic fishes from 27 species in the North Pacific Subtropical Gyre, were dissected to examine whether their stomach contents contained plastic particles. The incidence of plastic in fish stomachs was 9.2 per cent (Davison and Ash, 2011). The study of planktivorous fish from the North Pacific gyre found an average of 2.1 plastic items per fish (Boerger et al., 2010). However, the consequences of ingestion are not fully understood, because effects associated with ingestion can mostly be determined by necropsy (CBD and STAP-GEF, 2012; Hong et al., 2013).

2.2 *Transport of chemicals*

Plastics have a wide variety of chemicals, including those from manufacturing and those that accumulate from the marine environment (i.e. ambient seawater).

Plastics contain a wide variety of potentially toxic chemicals incorporated during manufacture which could be released into the environment (Lithner et al, 2011). Research has established that chemicals used in some plastics, such as phthalates and flame retardants, can have toxicological effects on fish, mammals and molluscs (STAP, 2011). Experimental studies show that phthalates and bisphenol-A (BPA) affect reproduction in all the species studied, impairing development in crustaceans and amphibians, and generally inducing genetic aberrations (Teuten et al., 2009).

There is recent evidence that large concentrations of microplastic and additives can harm ecophysiological functions performed by organisms (Browne et al., 2013; Wright et al., 2013).

Because of their small size, microplastics (<1 mm) have a large ratio of surface area to volume that promotes adsorption of chemical contaminants to their surface, and therefore have a high capacity to facilitate the transport of contaminants. An estimated amount of about 35,000 tons, of microplastics are floating in the world's oceans (Cozar et al. 2014; Eriksen et al. 2014). Boerger et al. (2010) found that 35 per cent of the fish sampled in the North Pacific central gyre revealed microplastics in the gut. A range of marine biota are reported to have ingested microplastics, including zooplankton (Cole et al., 2013), amphipods, lugworms and barnacles (Thompson et al., 2004), mussels (Browne et al., 2008), decapod crustaceans (Murray and Cowie, 2011), fish (Boerger et al., 2010; Rochman et al., 2013) and seabirds (Tanaka et al., 2013; van Franeker, 2011). Ingestion of microplastics has caused more and more concern in recent years, as it can provide a pathway for long-distant transport and bioaccumulation of contaminants, and may be compounded by plastic microbead additives in many personal care products (Fendall and Sewell 2009, Kershaw and Leslie 2012).

Plastic debris can accumulate persistent, bio-accumulative and toxic substances (PBTs) that are present in the oceans from other sources, such as PCBs, PAHs, DDTs and HCHs (Mato et al., 2001; Ogata et al., 2009). Within a few weeks these substances can become concentrated on the surface of or in plastic debris by orders of magnitude more than in the surrounding water column (Mato et al., 2001; Teuten et al., 2009; Hirai et al., 2011; Rios et al., 2010). Japanese medaka (*Oryzias latipes*) exposed to a mixture of polyethylene with chemical pollutants absorbed from the marine environment, bioaccumulate these chemical pollutants and suffer liver toxicity and pathology (Rochman et al., 2013). Plastics may provide a mechanism to facilitate the transport of chemicals to remote, pristine locations where they are ingested by biota (Teuten et al., 2007; Hirai et al., 2011). However, it is not yet clear whether chemicals accumulated on plastic debris are effectively transferred to marine biota (Gouin et al., 2011; Koelmans et al., 2013a and b).

2.3 *Habitat Destruction*

Marine debris can cause destruction of habitats in a number of ways, including smothering, entanglement, and abrasion. The extent of the impact depends on the nature of the debris (i.e., size, quantity, composition, persistence) and the susceptibility of the affected environment (i.e., habitat vulnerability and resilience).

In spite of the growing number of studies documenting the distribution and abundance of marine debris, the ecological impacts, including effects on habitats, are not well documented (NRC, 2009). The few studies that do exist looked at the impacts of derelict fishing gear (that is, gear that has been abandoned, lost or discarded) on coral reefs and other structurally complex benthic communities (Bauer

et al., 2008). For example, in the Florida Keys, USA, Chiappone et al. (2005) found that 87 per cent of all debris was recreational hook-and-line fishing gear, but because of low debris density, less than 0.2 per cent of the sessile species were affected. However, Lewis et al. (2009) noted that lost lobster traps, upwards of 100,000 of which are lost each year, represent a significant threat to seagrass beds and coral reefs in the Florida Keys, especially during storms. Also, when gear and other marine debris wash up on shore, especially during storms, they can cause shoreline destruction and smother the underlying substrate where the debris comes to rest.

Although studies of the effects of marine debris on habitat have focused mainly on benthic environments, the presence of floating debris can similarly undermine the quality of pelagic habitats by: (i) affecting the mobility of species, either through entanglement or ghost fishing (that is, entangling fish in lost, abandoned or discarded fishing nets, traps or pots); (ii) reducing the quality of food available in the environment through accidental ingestion of the debris, which may have accumulated toxins on its surface and interfere with digestion and excretion; and (iii) altering the behaviour and fitness of species, as in the case of debris acting as a fish-aggregating device (Hallier and Gaertner, 2008; Hammer et al., 2012; NRC, 2009).

Abandoned and derelict vessels are a widespread problem for the marine environment. Besides the fact that sunken, stranded, and decrepit vessels can be an eyesore and become hazards to navigation, these vessels can pose significant threats to natural resources. They can physically destroy sensitive marine and coastal habitats, sink or move during coastal storms, disperse oil and toxic chemicals still on board, become a source of marine debris, and spread derelict nets and fishing gear that entangle and endanger marine life.¹

2.4 Introduction and Spread of Alien Species

Marine debris can serve as a vector for numerous species. Hence, floating debris can potentially transport and introduce species to new environments (Barnes, 2002; Winston et al., 1997). Donohue et al. (2001) recorded 13 invertebrate and 10 vertebrate species living on or within a tangle of debris comprising mostly derelict fishing gear in the Northwestern Hawaiian Islands. Similarly, Barnes and Fraser (2003) documented 10 species from 5 different phyla on a single plastic packing band floating in the Southern Ocean. Although none of the species documented in these studies were non-native, the results nonetheless point to the potential for marine debris to serve as vectors for alien species.

To date, the establishment of an alien species via marine debris has yet to be documented (Lewis et al., 2005; Barnes, 2002; Barnes and Milner, 2005; Masó et al.,

¹ (<http://response.restoration.noaa.gov/oil-and-chemical-spills/oil-spills/abandoned-and-derelict-vessels.html>).

2003). The absence of such evidence probably reflects the paucity of research rather than the unlikelihood of such events. However, examples of non-native species arriving in new habitat have been well documented. For example, a 180-ton concrete dock cast adrift from Misawa, Japan, by the March 2011 tsunami was carried across the Pacific where it washed ashore in Oregon in the United States in June 2012 carrying at least 90 Japanese species including 6 species of non-native algae, crustaceans, and molluscs known to be invasive species in other parts of the world (Lam et al., 2013; Portland State University 2012). Removal of the dock and its burden of non-native species cost 85,000 United States dollars (Barnea et al., 2014).

A recent study by Goldstein et al. (2013) hints at the possibility of marine debris contributing to habitat expansion for the sea skater *Halobates sericeus* (of the *Hemiptera* order). They showed that abundance of *H. sericeus* was related to the availability of floating marine debris, and that such debris was used by the sea skater to attach its egg masses. This suggests that, in principle, *H. sericeus* and similar species could spread across ocean basins with the aid of marine debris.

Because marine debris is subject to surface and deep-water currents, the geographic spread of alien species by such debris is not expected to be random. For instance, the North Pacific convergence zone, which tends to concentrate marine debris, regularly occurs around the north-western Hawaiian Islands. Thus, the islands are subject to unusually high loads of marine debris, and perhaps associated invasive species.

Marine debris can also support the growth and transport of microbes (e.g., cyanobacteria, fungi, algae) to new habitats (Masó et al., 2003; Thiel and Gutow, 2005a and b; Zettler et al., 2013). Masó et al. (2003) found dinoflagellates, including those responsible for harmful algal blooms, growing on plastic debris, and raised the possibility that the increase in harmful algal blooms may be facilitated by the increasing abundance of marine debris.

2.5 Socioeconomics Impacts

The socioeconomic impacts of marine debris are a difficult problem to quantify, because many pollution problems and biological and environmental effects have taken a long time to identify and quantify, partly because of the diverse sources (lack of awareness, inadequate waste management, etc.), and because data on volume/mass, occurrence and distribution are seldom recorded. Furthermore, the literature is sparse for economic analyses addressing elements of potential effects. The Kommunenes Internasjonale Miljøorganisasjon (KIMO) studies (Hall, 2000; Mouat et al., 2010) are the most thorough, but inconsistencies, missing data, and absence of detail have been noted. In such cases, verifiable data were used for point estimates using a Benefits Transfer Approach (Ofiara and Brown, 1999; Unsworth and Petersen, 1995).

2.6 *Impacts on Beach Communities, Beach Use, Coastal Tourism*

2.6.1 *Beach cleaning*

Several references in the literature cite anecdotal information related to costs of beach cleaning. NRC (1995) reports the 1993 cost of beach cleaning at Virginia Beach, VA, United States of America, was 43,646 euros per km/yr (60,724 United States dollars per km/yr) and for Atlantic City, NJ, United States, was 215,225 euros per km/yr (299,439 US dollars per km/yr) (2011 Euro values given in parentheses; for all the conversions see Appendix). OSPAR Commission (2009) reports this cost for 2004 for the coast of the United Kingdom at 14 million British pounds per year (19.7 million euros per yr), for the Skagerrak coast, Sweden at 5.1 million euros per year (1.87 million euros per yr) for 2006, and Naturvardsverket (2009) reports the cost of cleaning marine debris on five beaches and in two ports in Poland for 2009 at 570,000 euros per year (632,120 euros per yr). Lane et al., 2007, estimated it would cost 286 million dollars per year to remove debris from the wastewater stream in South Africa (311 million dollars per year, 224 million euros per year -2011 values). A recent study by the Natural Resources Defense Council (NRDC) reports beach cleaning costs and waterway debris removal for 43 communities from South San Francisco to San Diego, California, as 10,993,010 dollars spent (Stickel et al., 2013).

2.6.2 *Damage to beach use*

Studies in the United States examined damage to beach use from marine debris and medical waste (see Appendix). A major wash-up of marine debris on the shore in 1976 closed New York beaches and caused 15-25 million dollars in lost revenues (43-71 million euros, 59-99 million dollars, in 2011 values; Swanson et al., 1978). ERA (1979) found that clean beaches in an adjacent state suffered piggyback effects from the 1976 event; the public avoided going to an "open-clean" beach in an adjacent state (Seaside Heights, New Jersey, United States) as if it too had marine debris and was closed, an example of avoidance behaviour resulting in lost revenues (943,638 euros per year, 2011 values). Extensive pollution and medical waste wash-ups occurred in 1987-1988 on New Jersey and New York beaches, with losses estimated at of 201-749 million euros at 2011 values for marine debris and medical waste; an average of 475 million euros (Ofiara and Brown, 1989 and 1999; Kahn et al., 1989; Swanson et. al., 1991) in 2011 values.

2.6.3 *Losses to tourism*

Ofiara and Brown (1989, 1999) found that marine debris wash-ups in New Jersey, United States, decreased beach attendance by 8.9 per cent -18.7 per cent in 1987 and by 7.9 to 32.9 per cent in 1988 (Appendix). A study in South Africa found that a decrease in beach cleanliness could decrease tourism spending by up to 52 per cent (Balance et al., 2000). In Sweden, research found that marine debris on beaches reduced tourism by between one and five per cent (OSPAR, 2009). Hence, even a limited presence of marine debris can decrease coastal tourism by between one to five per cent, and severe events can decrease beach visits by 8.4 per cent to 25.8 per cent (averaged limits).

2.7 Impacts on Commercial Fishing

The Marine Pollution Monitoring Management Group (MPMMG, 2002) reported the cost of marine debris removal in the United Kingdom fisheries at 33 million euros, and Watson and Bryson (Macfayden, 2009) reported a cost for one trap fisherman in the Scottish Clyde fishery of 21,000 dollars in lost gear and 38,000 dollars in lost time. Without more information, it is hard to give these estimates their proper context. Studies for the Kommunenes Internasjonale Miljøorganisasjon (KIMO) have estimated average losses per vessel from marine debris as follows: cleaning marine debris from nets GBP 4,065 or Euro 12,007; contaminated catch GBP 1,686 or Euro 2,183, snagged nets GBP 3,392 or Euro 3,820; fouled propellers Euro 182 euros (Hall, 2000; Mouat et al., 2010 - Appendix; GBP at 1998 values, Euro at 2008 values).

A recent study that examined blue crab ghost fishing from lost/abandoned traps/pots found an average mortality rate of 18 crabs/trap/year were harvested in Virginia-Chesapeake Bay, United States waters (sampled in the winter) (Bilkovic et al. 2014), compared to earlier mortality rate estimates of 20 crabs/trap/year in Maryland-Chesapeake Bay waters (Giordano et al. 2011), and 26 crabs/trap/year in Gulf of Mexico waters (Guillory, 1993). An earlier study examined ghost fishing catch rates during the crabbing season of 50 crabs/trap/year (live catch rate-capture rate) in Virginia-Chesapeake Bay waters (Havens et al. 2006). Bilkovic et al. (2014) further estimated an overall loss of 900,000 crabs or 300,000 United States dollars for Virginia-Chesapeake Bay, United States waters.

Impacts of lesser magnitude are summarized in Table 1.

Table 1. Summary of impacts of lesser magnitude, point estimates

Ghost Fishing:			
Brown et al. (2005)	Cantabrian Sea, Spain	1.46% loss-landings	Monkfishery
NRC (2008)	Not Available	up to 5% EU landings	
Allsopp et al. (2006)	United States	\$250mill/yr loss-landings	Lobster fishery
Macfayden et al. (2009)	Louisiana, United States	4-10mill. Crabs/yr lost	Blue Crab fishery
Hall (2000)	United Kingdom	Avg. Cost cleanup = £L2355/hbr	
Mouat et al. (2010)	United Kingdom	Avg. Cost cleanup = €8034/hbr-harbours, €9492/hbr-marinas; €8253.hbr-composite	
Hall (2000)	Shetland Is. Livestock crofts, United Kingdom	96% reported marine debris caught in fences, 36% reported animals entangled, 20% reported animals ill	
Mouat et al. (2010)	Shetland Is. Livestock crofts, United Kingdom	71% reported marine debris caught in fences, 42% reported animals entangled or ill	
Hall (2000)	United Kingdom	11% reported cleanup costs of €20,199/yr, rest €0	

Table 2. Summary - Projections (2011 values)

Beach Cleaning Costs (KIMO, 2000,2009)	United Kingdom	€14.301mill/yr - €14.487mill/yr (avg. €14.394mill/yr)
Damage to Beach Use (S-O),	New York, New Jersey, United States	All causes: €1,403mill - €5,236mill (avg. €3,319mill) MD, Medical Waste: €201mill - €749mill (avg. €475mill)
Commercial Fishing (KIMO, 2000,2009),	United Kingdom	€8.308mill/yr - €8.935mill/yr (avg. €8.6215mill/yr)
Aquaculture (KIMO, 2000,2009),	United Kingdom	€94,338/yr
Harbors, Marinas (KIMO, 2000,2009),	United Kingdom	€491,641 - €944,510/yr (avg. €718,076/yr)
Damages to Vessels (S-O),	New York Harbour, United States	€749mill
Coastal Agriculture (KIMO, 2000,2009),	United Kingdom	€486,270 - €614,461/yr (avg. €550,366/yr)

Note: KIMO (2000, 2009) = Hall (2000), Mouat et al. (2010), S-O = Swanson et al., 1991, Ofiara and Brown, 1999, NA: not available.

2.8 Impacts from Invasive Species

The literature pertaining to economic impacts of invasive species is silent regarding marine debris, but it does contain some evidence about the dimensions of the impacts from invasive species. The Swedish Naturvardsverket (2009) cites the collapse of the anchovy fishery in the Black Sea due to the introduction of the American comb jellyfish at an estimated 240 million euros per year. Holt (2009) examined control and eradication costs associated with the Carpet sea squirt in Holyhead Harbour, Wales, and estimated those costs at 525,000 pounds over a 10-yr period (2009-2019); the costs of inaction were estimated at 6.87 million pounds for the same 10-yr period.

3. Assessment of the status of marine litter

3.1 Floating Marine Debris

Floating marine debris in the water column has been documented in the open ocean and in coastal waters. Results for densities of floating marine debris in different regions of the world's oceans are shown in Table 3. However, comparisons between

studies or even systematic status and trend analyses are challenging because of differences in the collection and measurement methodology used.

Table 3 Densities of floating marine debris in different regions

Location	Method	Density	Reference
Coastal North Atlantic Ocean	0.333mm mesh net	3537 items/km ² , 286.8 kg/km ²	Carpenter and Smith, 1972
North Atlantic Ocean Caribbean	0.947mm mesh net	1.023 g/cm ³	Colton et al., 1974
Northwest Pacific	0.50mm mesh net	up to 37.6 items/km ²	Day et al., 1990
North Pacific central gyre	0.333mm mesh net	334,271 items/km ² , 5,114 g/km ²	Moore et al., 2001
Southern California's coastal waters	0.333mm mesh net	7.25 items/m ³ , 0.02g/m ³	Moore et al., 2002
California Current	0.333mm mesh net	3.29 items/m ³ , 0.003g/m ³	Lattin et al., 2004
North Pacific Ocean, Kuroshio Current	0.333mm mesh net	174,000 items/km ² , 3600 g/km ²	Yamashita and Tanimura, 2007
California Current	0.505mm mesh net	0.011-0.033 items/m ³ (Median)	Gilfillan et al., 2009
Caribbean Sea	0.335mm mesh net	1414 ± 112 items/km ²	Law et al., 2010
Gulf of Maine	0.335mm mesh net	1534 ± 200 items/km ²	Law et al., 2010
North Atlantic Subtropical Gyre (near 30°N).	0.335mm mesh net	20,328±2324 items/km ²	Law et al., 2010
Cape Cod, Massachusetts, United States to Caribbean Sea	0.335mm mesh net	0.80~1.24 g/ ml, 0.97~1.04 g/ml	Moret-Ferguson et al., 2010
North Atlantic Ocean	0.335mm mesh net	0.808-1.24 g/ml	Moret-Ferguson et al., 2010
Southeast Bering Sea and United States west coast	0.505mm mesh net	0.004-0.19 items/m ³ , 0.014-0.209 mg/m ³	Doyle et al., 2011
Northeast Pacific Ocean	0.333mm mesh net	Summer 2009: 0.448 items/m ² (Median)	Goldstein et al., 2013
	0.202mm mesh net	Fall 2010: 0.021 items/m ² (Median)	
South Pacific subtropical gyre	0.333mm mesh net	Mean: 26,898 items/km ² , 70.96 g/km ²	Eriksen et al., 2013
Australia	0.333mm mesh net	4256.4-8966.3 items/km ²	Reisser et al., 2013
Bay of Calvi (Mediterranean-Corsica)	0.2 mm mesh net	6.2 particles/100 m ²	Collignon et al., 2014
South-East Pacific (Chile)	visual observations	40°S and 50°S : <1 items/km ² ; nearshore waters: >20 items/km ²	Thiel et al., 2003
Ligurian Sea, north-western Mediterranean	visual observations	1997:15-25 items/km ² 2000: 3-1.5 items/km ²	Aliani et al., 2003
Floating marine debris in fjords, gulfs and channels of southern Chile	visual observations	1- 250 items/km ²	Hinojosa and Thiel, 2009
North East Pacific Ocean	visual observations	0-15,222 items/km ²	Titmus and Hyrenbach et al.,

			2011
Northeast Pacific Ocean	visual observations	0.0014-0.0032 items/m ²	Goldstein et al., 2013
Straits of Malacca	visual observations	578 ± 219 items/m ²	Ryan, 2013
Bay of Bengal	visual observations	8.8 ± 1.4 items/m ²	Ryan, 2013

Note: Ship-based trawling surveys and visual observations are used for small and large debris, respectively.

In coastal waters, the type, composition and density of floating debris vary greatly among locations. The spatial distribution is influenced by anthropogenic activities, hydrographic and geomorphological factors, prevailing winds, and entry point (Barnes et al., 2009; Derraik, 2002). Generally, the distribution and composition of marine debris floating at sea depends largely on near-shore circulation patterns (Aliani et al., 2003; Lattin et al., 2004; Ribic et al., 2010; Thiel et al., 2003). Prevailing winds also affect the pattern of debris abundance. Greater quantities of plastics were observed at downwind sites (Browne et al., 2010; Collignon et al., 2012). Collignon et al. (2014) observed that the density of floating debris was five times higher before a strong wind event than afterwards. This was explained by the wind stress increasing the mixing and vertical redistribution of the plastic particles in the upper layers of the water column. However, most land-based litter is carried by water currents through rivers and storm-water (Ryan et al., 2009). The density of the debris in the southern California, United States coast water, after the storm was seven times higher than prior to the storm (Moore et al., 2002). The weight of plastic increased by more than 200 times after a storm in Santa Monica Bay, California, United States (Lattin et al., 2004). Higher densities of debris in coastal waters are also associated with human population density (Lebreton et al., 2012; Thiel et al., 2003).

In the open ocean, spatial patterns of debris are influenced by the interaction of large-scale atmospheric and oceanic circulation patterns, leading to particularly high accumulations of floating debris in the subtropical gyres (Howell et al., 2012; Goldstein et al., 2013; Martinez et al., 2009). A high profile publication in the *Science* journal presented over 20 years of data clearly demonstrating that some of the most substantial accumulations of debris are now in oceanic gyres far from land (Law et al., 2010). The models developed by Martinez et al. (2009) suggest that marine debris deposited in coastal zones tends to accumulate in the central oceanic gyres within two years after deposition. The persistent floating debris will accumulate in mid-ocean sub-tropical gyres, forming so-called garbage patches (Kaiser, 2010; Lebreton et al., 2012) (See Figure 1).

Although the type of litter found in the world's oceans is highly diverse, plastics are by far the most abundant material recorded. Plastic debris was first reported in the oceans in the early 1970s (Carpenter and Smith, 1972; Colton et al., 1974). Plastics are estimated to represent between 60 per cent and 80 per cent of the total marine debris (Derraik, 2002; Gregory and Ryan, 1997). Almost all aspects of daily life

involve plastics, and consequently the production of plastics has increased substantially in the last 60 years and this trend continues. The fragmentation of plastics generates microplastics. For example, in sampling the South Pacific subtropical gyre, 1.0mm - 4.7mm particles accounted for 55 per cent of the total count and 72 per cent of the total weight (Eriksen et al., 2013). Research on the amount, distribution, composition and potential impact of microparticles has received increasing attention.

Plastic debris continues to accumulate in the marine environment. Goldstein et al. (2013) show that the density of microplastics within the North Pacific Central Gyre has increased by two orders of magnitude in the past four decades. In contrast, there is no significant trend in the density of surface water plastics in the North Atlantic from 1986 to 2008, despite increases in plastic production during this time (Law et al., 2010). Some form of loss must be taking place to offset the presumed increase in input of plastics to the ocean. Possible sinks for floating plastic debris include fragmentation, sedimentation, shore deposition, and ingestion by marine organisms (Law et al., 2011).

3.2 Beach debris

Millions of volunteers in more than 150 countries are involved in beach-cleanup activities on International Coastal Cleanup Day every year (Ocean Conservancy, 2011). The volunteers' participation contributes to extensive sampling and helps to obtain more information from a wider range of sites (Rees and Pond, 1995). The density of debris reported from the beaches in different regions of the world is listed in Table 4. For most of the beaches, the major debris is plastic. The spatial distribution of plastic debris is affected by multiple factors, including land uses, human population, fishing activity, and oceanic current systems (Ribic et al., 2010).

Table 4. Density of beach debris in different beaches

Location	Density	Reference
Dominica	1.9-6.2 items/m, 51.5-153.7 g/m	Corbin and Singh, 1993
St. Lucia	4.5-11.2 items/m, 8.2-109.2 g/m	Corbin and Singh, 1993
Panama	3.6 items/m ² (180/50 m ²)	Garrity and Levings, 1993

Beach debris density may be linked to the number of tourists and the cleaning frequency (Bravo et al., 2009; Kuo and Huang, 2014). For example, beach debris densities in central Chile were lower than in northern and southern Chile, which could be due to different attitudes of beach users or intensive beach cleaning in central regions (Bravo et al., 2009). Rodriguez-Santos et al. (2005) found that the quantity of litter depends on beach visitor density. Ocean current patterns, sand types, wave action, and wind exposure have further effects on litter abundance. For example, in Monterey Bay, California, United States, the seasonal variability in debris abundance may be a function of oceanic winds, as well as the possibility that seasonal current patterns may drive debris deposition (Rosevelt et al., 2013).

Although marine debris density is usually associated with population density, a few studies contradict this. Ribic et al. (2010) show no trends over several decades in beach-debris densities along the Eastern Atlantic seaboard of the United States, although large percentage increases in coastal population occurred in the south-east Atlantic region and a smaller percentage increase in coastal population occurred in the north-east region.

3.3 *Benthic marine debris*

The occurrence of litter on the seafloor has been far less investigated than in surface waters or on beaches, principally because of the high cost and the technical difficulties involved in sampling the seafloor. Nevertheless, a few investigations of benthic debris have been recorded, including on the continental shelves, on raised seabed features, such as seamounts, ridges and banks, in canyons and in polar regions. The surveying methods for the density and composition of benthic marine debris include bottom trawling, coring, scuba diving, the use of submersibles, snorkelling, manta tows and sonar (Spengler and Costa, 2008) and more recently, towed camera systems and remotely operated vehicles (ROVs).

Abundances of benthic debris range from dozens to more than hundreds of thousands items per square kilometre. As more areas of Europe's seafloor are being explored, benthic litter is progressively being revealed to be more widespread than previously assumed. Pham et al. (2014) reported data on litter distribution and density collected during 588 video and trawl surveys across 32 sites in European waters (35-4500 m depth). Debris was found to be present in the deepest areas and at locations as remote from land as the Charlie-Gibbs Fracture Zone across the Mid-Atlantic Ridge. The highest litter density occurred in submarine canyons,

reaching an average (\pm SE) of 9.3 ± 2.9 items ha^{-1} . The lowest density was found on continental shelves and on ocean ridges; mean (\pm SE) litter density of 2.2 ± 0.8 and 3.9 ± 1.3 items ha^{-1} , respectively. As for most other marine environments studied, plastic was the most prevalent litter item found on the seafloor. Woodall et al (2015) showed the litter was ubiquitous on deep-sea raised benthic features, such as seamounts, banks and ridges. A total of 56 items was found in the Atlantic Ocean over a survey area of 11.6 ha, and 31 items in the Indian Ocean over 5.6 ha, with a significant difference in the type of litter between areas sampled in the Indian Ocean (where the dominant litter type was fishing gear) and sites in the Atlantic Ocean (which had mixed refuse).

Litter from fishing activities (derelict fishing lines and nets) was particularly common on seamounts, banks, mounds and ocean ridges. A significant source of benthic debris is lost and discarded fishing gear, which is of particular concern due to ghost fishing effects that can kill both commercial and non-commercial species. Laist (1996) reports annual gear loss rates of about one percent for gillnet fisheries and between 5 - 30 percent for trap fisheries in United States fisheries. Whereas trap loss rates in the American lobster fishery are relatively low (5-10 percent), because the fishery involves more than 3 million deployed traps, the lobster fishery alone may account for the loss of more than 150,000 traps per year.

Hydrography, geomorphology, and anthropogenic activities all affect the abundance, type, and location of debris reaching the seafloor (Barnes et al., 2009; Galgani et al., 2000; Schlining et al., 2013). Because they facilitate the transport and deposition of debris, submarine canyons act as conduits for debris, transporting it from the coast to the deep sea (Ramirez-Llodra et al., 2013; Schlining et al., 2013). Ramirez-Llodra et al. (2013) suggest that debris in a canyon mainly originates from coastal areas, that plastic debris can be transported easily by canyon-enhanced currents, whereas heavy debris is usually discarded from ships. Wei et al. (2012) indicate that the debris density was higher in the eastern than that in the western Gulf of Mexico, primarily because of shipping lanes, offshore oil- and gas-installation platforms, as well as fishing activities. The litter density and diversity were independent of depth of water and of distance from land. Galgani et al. (2000) report that only small amounts of debris were collected on the continental shelf, mostly in canyons descending from the continental slope. Ramirez-Llodra et al. (2013) report accumulation of litter with increasing depth, but the mean weight at different depths, or between the open slope and canyons, showed no significant variation. Schlining et al. (2013) found debris clustered just below the edge of canyon walls or on the outside of canyon meanders. Wei et al. (2012) indicated that the total density of anthropogenic waste was significantly different between parallel depth transects. Woodall et al (2015) concluded that the pattern of accumulation and composition of the litter was determined by a complex range of factors both environmental and anthropogenic.

Table 5. Density of benthic debris in different regions

Location	Method	Density	Depth range	Reference
Bay of Biscay, France	trawl	0.263-4.94 items/ha	0-100m	Galgani et al., 1995a
Northwestern Mediterranean	trawl	19.35 items/ha	750m	Galgani et al., 1995b
French Mediterranean coast	trawl	0-78 items/ha	100-1600m	Galgani et al., 1996
European coast	trawl	0-1010 items /ha	<2200m	Galgani et al., 2000
Eastern China Sea and the south coast of the Republic of Korea	trawl	30.6-109.8 kg/km ²	—	Lee et al., 2006
Greek Gulfs	trawl	72-437 items/km ² , 7-47.4 kg/km ²	—	Koutsodendris et al., 2008
Gulf of Aqaba, Red Sea	SCUBA	2.8 items/m ² ; 0.31 kg/m ²	—	Abu-Hilal et al., 2009
submarine canyons and the continental shelf off California, United States	submersible	1.7 items/100m	20-365 m	Watters et al., 2010
West coast of the United States	trawl	67.1 items/km ²	55-1280m	Keller et al., 2010
West coast of Portugal	ROV	1100 items/km ²	850-7400 m	Mordecai et al., 2011
Eastern Fram Strait west of Svalbard	Image observation	3635-7710 items/km ²	2500m	Bergmann et al., 2012
Gulf of Mexico	trawl	<28.4 items/ha	359-3724m	Wei et al., 2012
Antalya Bay, Eastern Mediterranean	trawl	18.5-2,186 kg/km ² , 115-2,762 items/km ²	200-800m	Güven et al., 2013
Belgium	trawl	3125 ± 2830 items/km ²	—	Van Cauwenberghe et al., 2013
Mediterranean Sea	trawl	0.02-3264.6 kg/km ²	900-2700m	Ramirez-Llodra et al., 2013
Monterey Bay, California, United States	ROV	---	25-3971m	Schlining et al., 2013
Atlantic Ocean, Mediterranean Sea and Indian Ocean	Core (microplastic)	1.4-40 pieces/50ml sediment; 13.4±3.5 pieces/50ml sediment;	1000-3500m	Woodall et al., 2014
Atlantic Ocean	ROV	12.23-0.59 items/ha	200-2800m	Woodall et al., 2015
Indian Ocean	ROV	17.39-0.75 items/ha	1320-1610m	Woodall et al., 2015

ROV: Remotely Operated Vehicle; SCUBA: Self-Contained Underwater Breathing Apparatus

Debris continuously accumulates on the deep seabed; some research shows a significant increasing trend. Watters et al. (2010) reported a significant increase in

the amount of litter at some of shelf locations off California, United States, between 1993 and 2007. The debris density has continued increasing, and has doubled during the last decade in the Arctic deep sea (Bergmann and Klages, 2012). The density of microplastics in sediments has been increasing along the Belgian coast (Claessens et al., 2011). However, some studies did not observe significant temporal increases, for example, in litter abundance between 1989 and 2010 in Monterey Canyon, central California, United States (Schlining et al., 2013).

4. Prevention and Clean-up of Marine Debris

Numerous policies, global, international, national and local, address various aspects of marine debris. Some countries have banned outright the use of certain plastic derivative products.

5. Gaps, Needs, Priorities

Marine debris is a complex cultural and multi-sectoral problem that imposes tremendous ecological, economic, and social costs around the world. One of the substantial barriers to addressing marine debris is the absence of adequate scientific research, assessment, and monitoring. There is a gap in scientific research to better understand the sources, fates, and impacts of marine debris (NOAA and EPA, 2011; NRC, 2008). Scalable, statistically rigorous and, where possible, standardized monitoring protocols are needed to monitor changes in conditions as a result of efforts to prevent and reduce the impacts of marine debris. Although monitoring of marine debris is currently carried out within several countries around the world (often on the basis of voluntary efforts by non-governmental organizations), the protocols used tend to be very different, preventing comparisons and harmonization of data across regions or timescales (NOAA and EPA, 2011; Cheshire et al., 2009).

There is a gap in information needed to evaluate impacts of marine debris on coastal and marine species, habitats, economic health, human health and safety, and social values. More information is also needed to understand the status and trends in amounts, distribution and types of marine debris. There is also a gap in capacity in the form of new technologies and methods to detect and remove accumulations of marine debris (NOAA and EPA, 2011), as well as in means of bringing home to the public in all countries the significance of marine debris and the important part that the public can play in combating it.

Besides, the ways in which waste management is conducted are often a barrier. This is a global problem, but waste is managed on a very local level. Truly biodegradable, naturally occurring, biopolymers are becoming more wide spread and commercially

available. There is a need to pursue truly biodegradable biopolymer alternatives to plastic (Chanprateep, 2010).

Notes: Data contact refers to data obtained from authoritative agencies, USEPA, US Coast Guard, state/municipal/beach park data and/or representative-officials responsible.

Abbreviations where not obvious: MD=marine debris, mill.=million, bc=beach clean, ac=average cost, tc=total cost, P=projection, munic=municipality or local authority, avl=average loss per vessel, hbr=harbor, al=average loss, N=universe projections based on, Nbc=no. municipalities beach cleaned for projections, TotalP=total projection, midpt=midpoint, NEV=net economic value, EV=economic value. Totals may not add due to rounding. Mouat et al is abbreviated as KIMO in places for shorthand. One date appears if the study date and year of monetary value were the same, a monetary symbol appears after the date.

All conversions: 1987\$ to 2011\$: 1.9801 from US CPI-U, 1976\$ to 2011\$: 3.9532 using US CPI-U, 1998£ to 2011£: 1.3128 from UK CPI, 2011\$ to 2011€: .71876 exchange rate, 2011£ to 2011€: 1.1525 exchange rate, 2011£ to 2011\$: 1.6041 exchange rate, 2011€ to 2011\$: 1.3926 exchange rate, 1993\$ to 2011\$: 1.5567 from US CPI-U, 1998€ to 2011€: 0.8293 using historical inflation rates for € currency.

Chapter 26. Land-Sea Physical Interaction

Contributors: Julián Reyna (Convenor), Arsonina Bera, Hong-Yeon Cho, William Douglas Wilson, Regina Folorunsho, Sean Green (Co-lead member), Frank Hall, Peter Harris (Co-lead member), Lorna Inniss (lead member), Sung Yong Kim, Teruhisa Komatsu, Renzo Masetti, Kareem Sabir, Wilford Schmidt, Hannes Tönisson, Joshua Tuhumwire (Co-lead member)¹

1. Introduction

This chapter deals with how human activities have changed the physical interaction between the sea and the land. This physical interaction is important because about 60 per cent of the world's population live in the coastal zone (Nicholls et al., 2007). The "coastal zone" is defined in a World Bank publication as "the interface where the land meets the ocean, encompassing shoreline environments as well as adjacent coastal waters. Its components can include river deltas, coastal plains, wetlands, beaches and dunes, reefs, mangrove forests, lagoons and other coastal features." (Post et al., 1996) In some places, natural coastal erosion processes cause damage to property, harm to economic activities and even loss of life. In other places, human activities have modified natural processes of erosion of the coast and its replenishment, through: (1) coastal development such as land reclamation, sand mining and the construction of sea defences that change the coastal alongshore sediment transport system; (2) modification of river catchments to either increase or decrease natural sediment delivery to the coast; and (3) through global climate change and attendant sea level rise changes to surface wave height and period and the intensity and frequency of storm events.

2. Natural coastal erosion and property damage

Coastal erosion is a natural, long-term process that contributes to the shaping of present coastlines, but it can also pose a threat to life and property (Rangel-Butrago and Anfuso, 2009). For example, the total coastal area (including houses and buildings) currently being lost in Europe through marine erosion is estimated to be about 15 km² per year (Van Rijn, 2011). Over 70 per cent of the world's beaches experience coastal erosion, some portion of which is a natural process (Dar and Dar, 2009). Other natural processes influencing coastal sediment dynamics include the supply of biogenic carbonate sand and gravel (see Chapter 7) and volcanism which can provide an important sediment source to some coastal areas, including some continental coasts, such as in Italy (de Rita et al., 2002) and to volcanic islands, such

¹ The writing team thanks Kazimierz Furmanczyk for his substantive contribution to this chapter.

as in Polynesia, Indonesia, the Caribbean, the Azores and sub-Antarctic islands (e.g., Dey and Smith, 1989; Ross and Wall, 1999). Volcanic activity may supply sediments to the coast directly in the form of ash deposited as atmospheric fallout, or as lava flows or debris flows down the flanks of volcanoes that are adjacent to the coast (Fisher and Smith, 1991).

3. Impacts of anthropogenic climate change

The impacts on coastal ecosystems of anthropogenic global climate change (Jaagus, 2006; Jylhä et al., 2004) are associated with sea-level rise (Johansson et al., 2004 and increased storminess (Alexandersson et al., 1998) (Lowe et al., 2001; Masselink and Russell, 2006; Meier et al., 2004; Morton et al., 2005; Tönisson et al., 2011; Suursaar et al., 2006; Wang et al., 1998). Coastal sedimentation and morphology are influenced directly by regional land morphology and composition and anthropogenic activities that affect the amounts and locations of precipitation, run-off from both point and non-point sources, sea level, and storm activity. In addition, aeolian (i.e., wind-blown) dust, especially from deserts in Africa and Asia, affects some coastal communities. Aeolian processes are discussed in Chapter 5 and will not be considered further here.

The Intergovernmental Panel on Climate Change (IPCC) (2013) has shown that the rate of global sea-level rise throughout the 20th century has increased, due to melting ice caps and glaciers and the thermal expansion of the oceans, both resulting from increased global temperatures. Local sea level is further affected by processes including sediment discharge and subsidence (the natural, gravitational sinking of land over time), hydrological management, fluid withdrawal, and tectonic activity (Millman et al., 1989; Reed and Yuill, 2009; Boon et al., 2010). The human response to sea-level rise will include armouring coastlines to protect real estate, thus cutting off the natural (landward) retreat path of coastal and intertidal organisms. Coastal development that has occurred on low-gradient, sandy coastlines is the most vulnerable, since the natural response of such systems is to retreat landward as sea level rises.

Another apparent response to the warming of the Earth's atmosphere is a change in the ocean wave climate, manifested as increased wave heights associated with more intense storm events (Carter and Draper, 1988; WASA Group, 1998; Gulev and Hasse, 1999; Allan and Komar, 2000). Changes in wave regime may affect the stability of sandy shorelines and potentially dramatic changes in coastal geomorphology may occur locally. For example, the transformation from tide-dominated to wave-dominated coastal systems is possible in some locations (Harris et al., 2002). Increased wave height and period translates into an increase in the water depth at which sediments may be mobilized, thereby fundamentally changing the character of the seabed habitat. For example, areas of sandy seafloor previously stable under the prevailing wave and current regime may become transformed into a different habitat type, subject to mobilizing forces of episodic storms (Hughes et al., 2010).

4. Impacts of coastal development

Increasing human encroachment, land reclamation, coastal development and economic activity (e.g., shipping, recreation, mining) are considered to be among the major anthropogenic impacts on the coastal environment. These impacts have both direct and indirect influences on the physical interaction of the ocean with the coast.

4.1 *Land Reclamation*

Land reclamation is a significant component of economic growth and development for many countries around the world. The need for space to accommodate an increasing world population, which is projected to exceed 8.1 billion by 2025 (United Nations, 2013), has been a contributing factor to the growing trend of large-scale reclamation projects in many coastal areas to provide suitable land for housing and recreation, industry, commerce, agriculture and, in some cases, to provide coastal protection for the adjacent coastline. Many land-reclamation projects are also found in coastal cities that are short of space for expansion, particularly for port activities.

Two methods of land reclamation are generally used: infilling and draining of tidal and submerged wetlands. Infilling is most common in coastal areas associated with dredging activities, either indirectly by utilizing dredged material from port and harbour development or directly from offshore sources. Improved dredging technologies over time have increased the scale efficiency, cost-effectiveness and value of the land created in reclamation projects (Kolman, 2012). Previously land reclamation was restricted to shallow near-shore environments; however, with improvements in dredging methods and technologies, land reclamation has progressed to deeper water.

Large-scale land reclamation was pioneered in the Netherlands by the building of “polders” (areas of former swamp or intertidal land enclosed by embankments known as dikes). Since the 11th century, the Dutch have reclaimed marshes and fenland, resulting in some 3,000 polders nationwide enclosing about 7,000 km². About half of the total surface area of polders in northwest Europe is in the Netherlands. With the advent of modern machinery, such reclamation of wetlands is achieved much more readily. In West Bengal, India, 1,500 km² of the coastal Sundarbans wetlands have been reclaimed over the last 100 years (UNEP, 2009). In China, 9,200 km² (16 per cent) of the wetlands present in the 1970s had disappeared by 2007 (Zuo et al., 2013). At a more local level, 28 per cent of the tidal flats around the coast of the Yellow Sea were reclaimed between the 1980s and the late 2000s (Murray et al., 2014). Around the world, polder-type reclamation has been undertaken in Egypt, Morocco, Senegal and Tunisia in Africa, in Bangladesh, China, India, Indonesia, Iraq, Japan, Malaysia, Myanmar, the Republic of Korea, Pakistan, Thailand and Viet Nam in Asia; in Belgium, Denmark, Germany, Italy, Poland, Portugal, Romania, Spain and the United Kingdom of Great Britain and Northern Ireland in Europe; in The Russian Federation; in the south-eastern states of the United States of America in North America; and in Argentina, Colombia, Suriname and Venezuela in South America (MVenW, 1983). This reclamation work has particularly affected

mangroves and salt marshes (see Chapters 48 and 49).

In recent times significant large-scale dredging projects have been undertaken in several countries in Asia and the Middle East. Rapidly emergent economies, such as China, Japan, Singapore, and United Arab Emirates, have all undertaken large-scale reclamation projects as a solution to finding land for economic development (Glaser et al., 1991; Suzuki, 2003). Reclamation is no longer limited to near-shore coastal environments. Technological advances enabled the creation of the international airport of Hong Kong, China, Japan's Kansai airport and resort developments, such as the Palm Jumeirah, Palm Jebel Ali, the Deira Islands and other similar facilities that are now a prominent feature of the coastline of Dubai, United Arab Emirates.

Major projects, such as the creation of Hulhumalé Island in the Maldives between 1997 and 2002, have been used to relieve overpopulated urban areas and to enable urban expansion. More than 10 per cent of the developed land area of Hong Kong, China, is reclaimed from the sea (Jiao et al., 2001). Other examples of such urban land reclamation projects are: Rotterdam in Europe, New York/New Jersey Port Authority and San Francisco in North America, Rio de Janeiro and Rio Grande in South America, Shanghai, Singapore and Tokyo in East Asia, Chennai and Kolkata in South Asia, Bahrain and Dubai in West Asia, and Cape Town and Lagos in Africa. In special cases, such as the Principality of Monaco, reclaimed land forms 20 per cent of the land area of the State (Anthony, 1994).

Several examples of reclamation are found in China, where the primary objective was to provide suitable living space for a growing population and to promote economic development. Between 2003 and 2006, the Shanghai government spent 40 billion yuan (6.5 billion United States dollars) on the so-called Lingang New City Project to reclaim 133.3 km² of artificial land from the sea. From 1949 to 2000, China reclaimed about 12,000 km² of land. Land reclamation has also been used to tackle long-term coastal erosion problems from storm surges and extreme climatic events. For example, significant financial investments have been allocated to reclaim beaches along Florida's eastern coastline in the United States and support a major tourism industry. The Sand Engine² in the Netherlands is also an innovative example of an effort to alleviate long-term coastal erosion problems while at the same time boosting local biological diversity and the economy (Stive et al., 2013).

4.2 *Environmental impacts of land reclamation*

Land reclamation causes significant negative impacts on coastal habitats and the ecosystem services they provide (Wang et al., 2014; Wang et al., 2010). Degradation of wetlands, seagrass beds and coastal water quality is commonly associated with

² The Sand Motor is an innovative method for coastal protection. The Sand Motor (also known as Sand Engine) is a huge volume of sand that has been applied along the coast of Zuid-Holland (the Netherlands) at Ter Heijde in 2011. Wind, waves and currents will spread the sand naturally along the coast of Zuid-Holland. This is called 'Building with Nature'. The Sand Motor will gradually change in shape and will eventually be fully incorporated into the dunes and the beach. The coast will be broader and safer. From: <http://www.dezandmotor.nl/en-GB/>.

large-scale reclamation projects. Examples of studies examining the impacts of coastal wetlands reclamation are available from, e.g., Hong Kong, China (Jiao et al., 2001), the Republic of Korea (Lee, 1998) and the Netherlands (Waterman et al., 1998).

Large-scale reclamation can also affect the regional groundwater regime, causing changes of the groundwater level and the modification of natural groundwater discharge to the coast. For example, Mahamood and Twigg (1995) conducted a statistical analysis of water table data to document a rise in the water table in areas of Bahrain associated with land reclaimed from the sea. Some of the problems related to land reclamation in coastal areas are reported by Jiao (2000) as including:

- Rises in water level will lead to reduction in the bearing capacity of foundations and in the stability of slopes.
- Ground water may also penetrate underground concrete and cause corrosion of steel reinforcements.
- An increase in water level may cause damp surfaces and superficial damage to the floors of residential buildings (Mahamood and Twigg, 1995).

Furthermore, aquifers behave like underground reservoirs and can receive only a certain amount of rainfall before they overflow. If the water level is increased as a result of land reclamation, the additional water storage capacity will be significantly decreased, resulting in increased rainwater run-off. Thus, aquifers that are full will increase the chance of flooding during heavy rainfall periods. As submarine groundwater input to the sea depends on the groundwater level relative to sea level, a change in the groundwater regime may modify the coastal marine environment and ecology (Jiao, 2000).

4.3 Socioeconomic impacts of land reclamation

The significance of land reclamation to the development of local and national economies cannot be overstated. Land development is inextricably linked to rapid economic growth in many countries. For example, Small Island Developing States depend on coastal economies for their growth and development. Several islands rely heavily on the provision of suitable tourism infrastructure and seaports to maintain their development objectives. More generally, growth in international trade entails growth in shipping (see Chapter 17) both in volume and in the size of ships, which makes port expansion necessary (see chapter 18). In many cities, such port expansion can only be achieved by land reclamation.

As well as benefits, interference with other uses of the sea can occur. For example, in Japan, part of Isahaya Bay on the Ariake Sea was cut off from the rest of the bay by a dike to reclaim land for agriculture and to create freshwater storage. Fishers and seaweed growers complained that the effects, especially on tidal flows, have harmed fish, shellfish and seaweed production, a view that a Japanese court upheld in 2010 (JT, 2014; AS, 2013).

4.4 *Habitats, coastal development and coastal squeeze*

Measured normal to the coast, the assemblage of coastal habitats ranges in width from only a few metres to tens of kilometres, offering very diverse environmental conditions to numerous plant and animal species. These habitats formed as a result of long-term stability in ecological conditions influenced by the constant distance from the shoreline. The influence of the sea decreases rapidly towards the land and biodiversity decreases rapidly just a few hundred metres from the shoreline as well. Therefore, it is noted that the loss of the land on the coastal zone often leads to the rapid decrease of biodiversity, especially on the uplifting regions (Kont et al., 2011).

Coastal vegetation (e.g., dune vegetation, reed-beds, mangroves, salt marshes) inhibits erosion, reducing the effect of storm surges and wave attack (Kathiresan and Rajendran, 2005), and serves as natural protection. Removing the vegetation for coastal development can increase coastal erosion (Waycott et al., 2009) and may add to the amount of sediment moving along the shore, causing siltation of harbours and burial of coastal and coastal sea habitats.

One of the most recent and most notable coastal defence structures is the 25-km-long Saint Petersburg Flood Prevention Facility Complex. The estimated cost of this structure was approximately 3.85 billion United States dollars (Reuters, 2011). Recent winter storms have caused extreme erosion events on the surrounding sandy beaches (Tönisson et al., 2012).

Several countries in the world have legislatively defined shoreline locations, and major efforts are made to implement the laws. The most notable examples are Poland, the Netherlands and the United States of America. Today, over one-fourth of the 1032-km-long Polish coast is more or less engineered (www.climateadaptation.eu). For the period 2004-2023 a Long-Term Coastal Protection Strategy was developed for which 249 million euros has been secured (approximately 7.5 million euros per year). Approximately 3.5 million inhabitants live in the region that might be potentially affected by the sea in Poland (ec.europa.eu). This cost is rather big compared to what the Baltic States (which have a shoreline that is four times longer) altogether are spending on coastal protection. The only known cost is the Lithuanian Palanga nourishment project reaching 1.65 million euros per year (Gulbinskas et al., 2009).
