Most of the effort in the Netherlands is focused on the flood protection, because over three-fourths of the Netherlands is less than 5 m above sea level. Approximately 9 million people live in the region at high risk from coastal flooding and over 50 per cent of GDP is generated in this region. In principle, the Netherlands addresses coastal protection activities in a comprehensive (national) approach to counteract flood risk (coast and river flooding). The total amount spent on flood-risk protection is estimated at 550 million euros per year. Over the period 1998-2015, measures to protect the Dutch coast against flooding and erosion and adapt to increased storminess and sea-level rise amount to 3.4 billion euros. The yearly expenditure on beach nourishments under the Sand Nourishment Programme has increased from 22 million euros in 2000 to 70 million euros in 2008 (ec.europa.eu).

Over 50 per cent of the population in the United States live in the coastal region and are more or less affected by changes in coastal processes. In the United States,

coastal erosion is responsible for approximately 500 million United States dollars per year in coastal property loss, including damage to structures and loss of land. To mitigate coastal erosion, the federal government spends an average of 150 million dollars every year on beach nourishment and other shoreline erosion control measures. However, it is estimated that despite the measures, every fourth house within an approximately 500-m-wide coastal zone will be destroyed by erosion by 2050 (NOAA, 2013).

Economic losses related to coastal erosion are more complex to assess. Detailed analyses carried out in Louisiana in the United States show that major disruptions in economic activities caused by coastal erosion and flooding might result in over 70,000 jobs lost in the United States and a long-term loss for the United States economy of approximately 10 billion dollars (dnr.louisiana.gov). Loss of coastal habitat in Louisiana results from three primary processes: control of the Mississippi River, which reduces the amount of replenishing sediment that rebuilds the coast, subsidence, and industrial activity.

The United States Army Corps of Engineers will be spending upward of 5 billion dollars on shore protection projects following Hurricane Sandy. The vast majority of these funds will be spent on pumping sand onto beaches from Delaware to Connecticut, an amount approaching 25 to 35 million m³. This is an adaptation model that cannot be exported to most developing countries due to its cost, and it is doubtful that it can be maintained for an extended period of time in the United States of America (Young et al., 2014).

The use of initially less expensive hard protection measures (which are extremely destructive to surrounding shores and natural habitats) has decreased, whereas the share of soft coastal protection measures has significantly increased in recent decades. However, in light of global sea-level rise, researchers and coastal communities have started the debate on managed realignment. In the United Kingdom, realignment of private property and infrastructure occurred in a 66-km-long stretch of shoreline during 1991-2013. The United Kingdom government plans to reach 550 km (10 per cent of the United Kingdom coastline) by 2030 (Esteves and Thomas, 2014). These zones will function as natural buffer zones and reduce the risk of erosion and coastal defence costs to the surrounding coasts. Furthermore, most of the local communities are in favour of this measure and the strongest opposition is from those whose property will be most severely affected. This topic is also recognized by European Commission, and a new Horizon 2020 call (open until 2014 autumn) was issued on the topic: "Science and innovation for adaptation to climate change: from assessing costs, risks and opportunities to demonstration of options and practices", where realignment is considered as a key solution

(<http://ec.europa.eu/research/participants/portal/desktop/en/opportunities/h2020/>).

Many countries do not have the economic resources to protect their coast actively through engineering solutions, which are very expensive and often not technologically successful. Effective non-engineering solutions are available such as restoring the processes that were in place before human intervention, improved urban planning, and orderly retreat strategies. The cost of not dealing with coastal

erosion can be even more costly over the long-term. For example, in 2006, Mozambique requested 3 million US dollars from the international community to carry out engineering coastal protection countermeasures for potential flooding. This request was turned down in 2007, and since then, the international community has spent over 90 million dollars to address extreme flooding in the region (Ashdown, 2011).

5. Impacts of catchment disturbance

5.1 Decline in marine sedimentation as a result of water management

On a global basis, the natural (pre-Anthropocene) sediment load to the oceans from rivers is estimated to be about 15×10^9 tons; the majority is supplied by mountain rivers with steep catchments (Milliman and Syvitski, 1992; Ludwig and Probst, 1998; Syvitski et al., 2005). Over the last few centuries, the global annual sediment flux into the coastal zone has increased by 2.3×10^9 tons due to anthropogenic soil erosion and decreased by 3.7×10^9 tons due to retention in reservoirs: the net effect is a reduction of sediment input by 1.4×10^9 tons (Syvitski et al., 2005). A major environmental consequence of river sediment starvation is erosion of the coast and attendant loss of habitat; conversely, the consequence of increased sediment input is elevated coastal and estuarine turbidity and smothering and burial of biota. Many examples of the two opposite consequences are documented from different places around the world (Fig. 1).

A well-documented example of the first problem (sediment starvation) is the Mississippi River, which is controlled by the United States Army Corps of Engineers and has one of the most diverse and largest watersheds in the world. Over the Holocene period (the last 10,000 years) the Mississippi deposited the largest deltaic coastal complex in North America. Prior to European settlement of North America, the sediment load of the Mississippi was around 400 million tons per year, but at present it is around 100 million tons per year as a result of the construction of around 45,000 water reservoirs in the catchment (Syvitski, 2008). The decreased sediment load contributes to loss of wetlands in the delta; this loss peaked between 1955 and 1978 at 11,114 ha/year and declined to 2,591 ha per year from 1990 to 2000. Reductions in sedimentation, compounded by sea-level rise, water abstraction (causing subsidence), oil and gas extraction (also causing subsidence), tidal erosion and storm surges, have resulted in an approximate total land loss of 113,300 acres of the coastal Mississippi delta over the past 60 years (Morton et al., 2005).

Figure 1. Change in the sediment load in millions of tons per year (MT/year) delivered to the deltas of five rivers over a period of 1,000 years: (A) Yellow; (B) Po; (C) Mississippi; (D) Nile; and (E) Danube (from Syvitski, 2008). In some cases an initial phase of catchment clearing and disturbance, characterized by increased sediment load, is followed by a reduced sediment load phase attributed to dam building (A, B and C). In other cases the curves indicate only a steady decrease in sediment load attributed to dam building (D and E) (Source: Syvitski, 2008).

Other examples of river systems that have undergone a similar pattern of anthropogenic sediment retention that has reduced the sediment discharge of the river to below pristine conditions include the Yellow, Indus, Colorado, Nile and Danube Rivers (Syvitski, 2008). In extreme cases the sediment load is reduced to near zero (e.g., the Nile, Indus and Colorado Rivers). The Volta River in West Africa had a sediment load of 11 million tons per year prior to the construction of the Akosombo Dam, but after the dam's completion in 1963, this load was reduced to nearly zero (Milliman and Meade, 1983). With the recent construction of another dam on the

Volta River (the Kpong Dam), its sediment yield has diminished further, starving the delta and coast of sediment input.

5.2 Increase in marine sedimentation as a result of catchment disturbance

In many instances, dam building and sediment entrapment in reservoirs does not offset the impacts of land clearing and soil disturbance in the catchment, such that river sediment loads exceed pristine levels in spite of dam building. The data presented in Figure 1 for the Yellow River 10 years ago and for the Po and Mississippi 100 years ago all showed this effect. Another example is the coast of northeast Queensland in Australia adjacent to the Great Barrier Reef; modelling work by Brodie et al. (2003) indicates that the total suspended sediment load of rivers draining into the Great Barrier Reef region is currently about 16 million tons per year, compared with pre-European settlement estimates of around 2 million tons per year. This is in spite of the fact that nearly all of the rivers in the region have been dammed. Consequently, increased sedimentation (with attendant inputs of nutrients and pesticides) to the ecosystem are affecting inshore areas of the Great Barrier Reef, causing increased algal growth, accumulation of pollutants in sediments and marine species, reducing light and smothering corals (GBRMPA, 2009).

One other key point noted by Milliman and Meade (1983, p. 19) is that “much of the sediment probably accumulates on the subaerial parts of subsiding deltas, never really reaching salt water. Along coastlines that include a number of large estuaries, most of the inflowing river sediment is trapped in embayments.” Hence a significant proportion of sediment discharged by most rivers is trapped within the coastal biome. Nevertheless, more widespread impacts of increased sediment loads may occur during flood events, when buoyant river plumes extend across the continental shelf. The input of fine-grained sediment in historical times may also have increased the turbidity of the coastal zone above pristine environmental conditions, affecting some light-dependent species.

5.3 Modelling Coastal Sedimentary Processes

Computer models have assisted in improving our understanding of sedimentation processes in the near shore (Syvitski and Alcott, 1993; Syvitski and Alcott, 1995; Mulder et al., 1997; Syvitski and Milliman, 2007; Chu et al., 2013). Computer algorithms provide process-related information to understand flow dynamics, particulate and chemical distributions, and the overall oceanography of coastal environments.

5.4 Impacts of increased sediment input on coastal habitats

The impact of sediments has been recognized by both global reviews and the United Nations Environment Programme (UNEP/GEMS, 2008). These impacts include:

- Smothering of marine communities and, in severe cases, complete burial leading to suffocation of corals, mangrove stands and seagrass beds.

- Decreases in the amount of available sunlight, which may in turn limit the production of algae and macrophytes, increase water temperatures and reduce growth of natural vegetation.
- Injuring fish by irritating or scouring their gills and degrading fish habitats as gravel containing fish eggs becomes filled with fine particles, thus reducing available oxygen
- Reducing the success of visual predators, and may also harm some benthic macroinvertebrates.
- Infilling watercourses, storm drains and reservoirs, leading to costly dredging and an increased risk of flooding.
- Many toxic organic chemicals, heavy metals and nutrients are physically and/or chemically adsorbed by sediments, so that an increase of sediment loading to the marine environment can also lead to increased deposition of these toxic substances that result in further negative impacts such as eutrophication.

It is important to recall that human impacts on marine habitats rarely (if ever) act in isolation (Lotze et al., 2006; Harris, 2012). Therefore it is difficult, if not impossible, to attribute specific changes in species composition or abundance to single, specific impacts, such as increased sediment loads of rivers caused by human activities. Nevertheless, increased sediment loads of rivers have evidently affected the marine environment, and this section reviews these effects as far as possible.

Coastal habitats and species that are most affected by increased sediment loads of rivers are those which are least tolerant of rapid sediment deposition and high turbidity (in relation to natural background levels), and changes in sediment grain size and composition. Among such ecosystems, coral reefs and estuaries with their associated mangrove, salt marshes and sea grasses are among the most vulnerable habitats.

In the Caribbean, Burke et al. (2004) reported on the assessment of more than 3,000 watersheds across the region that discharged into an area where coral reefs were present. They found that 20 per cent of coral reefs in the region are at high threat, and about 15 per cent at medium threat from damage caused by increased sediment and pollution from agricultural lands and other land modification.

Sediment input to temperate ecosystems also affects habitats and associated species. For example, eelgrass meadows, which provide important near-shore marine habitat for fish, shellfish, and invertebrates, as well as food for waterfowl and detritus feeders, can be buried or fragmented by increased sediment delivery associated with river-delta channelization (Lotze et al., 2006; Grossman et al., 2011). Increased turbidity is a particular problem because seagrasses require some of the highest light levels of any plant group in the world, approaching 25 per cent of incident radiation in some seagrass species, compared with 1 per cent or less for other angiosperm species (Dennison et al., 1993).

Therefore, even small increases in turbidity can cause significant reductions in seagrass cover over a short time span (Orth et al., 2006).

Changes in sediment grain-size composition can also affect ecosystems. For example, many shellfish beds and forage-fish spawning beaches depend on a specific sediment grain-size composition that is linked to land-use activities and hydrological conditions that release and carry sediment into coastal waters (Gelfenbaum et al., 2009). Water quality, near-shore and offshore habitats, and aquatic ecosystem health are affected by contaminants and nutrients that preferentially adsorb to fine sediments. Specialized organisms that have adapted to fine sediments, high sedimentation rates, and mobile substrate utilize estuaries. The macroinvertebrates that are found at the bottom of estuaries are much smaller than those found in streambeds with larger particle sizes, and they tend to be opportunistic species (Schaffner et al., 1987). Within the estuary, the density of fauna is commonly greater in the freshwater tidal areas than in parts of the estuary having (tidally) varying salinity (Schaffner et al., 1987). The species diversity of macroinvertebrates is usually lower in fine sediments than that in sediments with coarser particles. The diversity and evenness of species decline with an increasing percentage of silt/clay and organic matter (Junoy and Vieitez, 1990). However, fine-sediment beds are important for burrowing tube-building invertebrates and other burrowing species (Minshall, 1984).

The impacts of increased sedimentation from river input will differ between deltas and estuaries (Harris and Heap, 2003). Estuaries and deltas formed along coasts at the end of the last Ice Age when sea level reached its present position, around 6,500 years ago. Deltas evolved in places where river sediment discharge filled the palaeo-river valley to form a deltaic protrusion from the coast. The formation of a delta relies on the river supplying sediment to the coast more rapidly than can be redistributed by waves and tides, causing seaward progradation. For estuaries and lagoons, slow rates of sediment delivery to the coast results in the palaeo-valley remaining partially un-filled. Waves and tides produce deltas and estuaries with distinctively different shapes in plain view (e.g., Harris and Heap, 2003; Syvitski, 2008).

Prograding coastlines, characterized by deltas, strand plains and tidal flats, export most of their sediment load to the sea and generally have a naturally low sediment-trapping efficiency. They contain a suite of habitats that will not be significantly affected by sedimentation. In contrast, transgressive coastlines, characterized by estuaries and lagoons, have a high sediment-trapping efficiency (Fig. 2). They are, therefore, more susceptible to the accumulation of particle-associated contaminants such as heavy metals. They also contain a suite of habitats that will change (evolve) as they infill with sediments (Roy et al., 2001), and are therefore more susceptible to catchment perturbations that affect river sediment loads. The water contained in tide-dominated deltaic distributary channels, estuaries, and creeks that drain intertidal flats, is naturally turbid and generally well mixed. In contrast, water contained in wave-dominated deltaic distributary channels, estuaries, and lagoons is naturally clear (low turbidity) and exhibits mainly stratified (estuarine) circulation patterns (Fig. 2).

In arid regions of the Earth, this circulation is often of the inverse (negative) type, driven by high evaporation rates. From a management perspective, therefore, human activities that give rise to higher turbidity levels are likely to have a greater impact in wave-dominated systems (that have naturally low-turbidity, clear water) than in tide-

dominated systems that are naturally turbid (Harris and Heap, 2003).

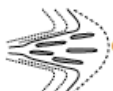

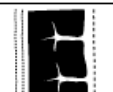

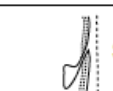

Type of Coastal Environment	Sediment Trapping Efficiency	Turbidity	Circulation	Habitat Change due to Sedimentation
 Tide-dominated Delta	Low	Naturally High	Well Mixed	Low Risk
 Wave-dominated Delta	Low	Naturally Low	Salt Wedge/ Partially Mixed	Low Risk
 Tide-dominated Estuary	Moderate	Naturally High	Well Mixed	Some Risk
 Wave-dominated Estuary	High	Naturally Low	Salt Wedge/ Partially Mixed	High Risk
 Tidal Flats	Low	Naturally High	Well Mixed	Low Risk
 Strand Plains	Low	Naturally Low	Negative/ Salt Wedge/ Partially Mixed	Low Risk
 Lagoon	High	Naturally Low	Negative/ Well Mixed	High Risk

Figure 2. Diagram showing different types of coastal depositional environments in relation to four common management issues: sediment trapping efficiency, turbidity, water circulation and habitat change due to sedimentation (from Harris and Heap, 2003).

5.5 Coastal erosion caused by sediment starvation of coasts attributed to dam building and impacts on habitats

When sediment delivery to the coast is reduced by dam building in the catchment, critical near-shore habitat and beaches can be eroded by natural coastal processes and lost (Malini and Rao, 2004; Warrick et al., 2009). Erosion along pristine sedimentary coastlines will cause a landward retreat of habitats, such that an ecological succession is observed at a fixed observation point. For example, supratidal vegetated dunes give way to intertidal salt marsh and tidal flats. Thus the entire suite of habitats is preserved, but laterally displaced.

Several factors can complicate this simple view. In some cases the space that could allow habitats to retreat is simply not available (so-called coastal squeeze; Doody, 2013; Pontee, 2013) For example, in a modelling study of continental United States coastal habitats, Feagin et al. (2005) found that beach erosion resulted in the disappearance of sand dune plants or in their confinement to a narrow belt because existing coastal development (or coastal defences like seawalls) occupies the

available space landward of the dune zone. This results in a breakdown of the successional process in built-up areas along the coastal zone.

An example of loss of habitat attributed to coastal erosion induced by dam building was reported for mangrove habitat of the Godavari Delta, India (Malini and Rao, 2004). Elsewhere, coastal erosion caused by a combination of factors has been attributed to loss of habitat (see Box 1). For example, loggerhead turtle nesting areas in southern Italy have been affected by coastal erosion (Mingozzi et al., 2008). Although numerous examples exist from around the world where coastal erosion and habitat loss have occurred, it is often not possible to single out dam building as the single (or even the dominant) cause of coastal erosion. This is because of complicating, often related factors, such as subsidence, diversion of freshwater input, coastal development and land-use changes, (e.g., Syvitski, 2008). For example, the loss of wetlands in the Mississippi Delta region is a famous example of habitat destruction caused by human interference with a major river system (see Box 2), but the loss of habitat has not been caused so much by dam building as by diversion of the river channel by the construction of artificial levees and dredging activities (Shaffer et al., 2009).

Other responses to sediment starvation of the coast from dam building also occur (see Box 1). Erosion of a once stable or prograding coast can transform the composition and character of the subtidal habitat such that it no longer supports the original community. For example, erosion of the Elwa River delta in Washington State, USA, transformed a sedimentary terrace in front of the delta from a sandy habitat colonized by molluscs into a cobbled substrate hosting a different ecosystem (Warrick et al., 2009).

Box 1 - Case Study – West African Coastal Erosion

The West African coastal zone stretches from Mauritania to Cape of Good Hope in South Africa and consists of a narrow coastal zone backed by a gradually rising Precambrian landmass that is drained by several rivers. The rivers carry sediments, nutrients and water to the coastal areas. The major rivers responsible for most of the sediment load are the Congo, Niger, Volta, Benue, Gambia, and the Orange. Of these rivers, the Congo, Niger and Orange are classified among the 10 largest rivers in the world in terms of sediment and water yield (Milliman et al., 1983). Minor rivers, such as Senegal, Ouémé, Mono, Bandama and Calvally, collectively contribute significant amounts of sediments and water to the coast because of their basin size, length, and flood plains as compared to rivers such as the Niger, Congo and Orange (Fig. 1).

The ability of these rivers to effectively nourish the coast is hindered by climatic, environmental and anthropogenic factors that determine the amount of sediments, nutrients and water delivered, and include different origins of sediments, and climate variability in the catchment areas. (Folorunsho et al., 1998; Awosika et al., 2013; Awosika and Folorunsho, 2014).

Sediments carried to the coast by the major rivers and ephemeral rivers are derived predominantly from the weathered Precambrian rock complex comprised of schist, gneiss, and granite. The rock complex has now been reduced by erosion to piedmonts that dot most of the West African region. Younger sedimentary rock types in the lower Niger River and flood plains have also been eroded along the river courses and carried to the coast. Suspended sediments, comprising fine silt and fine sand blown from the Sahara desert through the savannah and the Equatorial region, constitute another major sediment type in the region.

The large-scale impoundment of upstream reservoirs has reduced downstream flow volumes and velocities. As a consequence, the strength of the Niger River in its downstream segment is reduced. The reduction in flow velocity encourages sediment deposition within river channels, and is reflected in shallower river cross-sections and enlarged sand bars. Assessment of the spatial distribution and relative sizes of sand bars indicates increased deposition over the years of impoundment. The sand bar just north of Patani on the Forcados River increased from 0.1701 km² in 1963 to 0.486 km² in 1988. The sand bar at Anibeze, east of Patani on the same river, increased from 0.3645 km² to 0.9315 km² in the same period. A similar trend is observed on the River Nun, where the sand bar just south of Odoni increased its size by 100 per cent between 1963 and 1988. The sand bar opposite Odi not only increased in size, it also expanded in the upstream direction.

At Sampor, a major river channel completely silted up. Several other sand bars on the river between Onitsha and the bifurcation of the Niger into the Forcados and Nun Rivers have evolved into larger sand bars, thereby significantly modifying the river morphology. The NDES environmental change atlas for this area (NDES, 2000) confirms that changes have largely been confined to the flood plain. This channel modification has adversely affected the economy of the river channel and the Nigerian Federal Government's plan for large-scale dredging of the River Niger.

Box 2: Coastal Louisiana and the Mississippi River Delta, USA, and the Impact of Hurricane Katrina

The Mississippi River Delta provides the primary buffer for inland communities within the State of Louisiana and is a major resource for fisheries. Land loss resulting from subsidence has historically been replenished by the deposition of silt from the Mississippi River. However, human activity, including resource exploitation, such as petroleum extraction and controlling the flow of the Mississippi River by the U.S. Army Corps of Engineers, has resulted in reduced sediment flow and significant loss of land. It is important to note that whereas southeast Louisiana contains 37 per cent of marsh habitat in the United States, it has the highest rate of land loss of any region of the country (Glick et al., 2013).

This land loss resulted in the increased landward incursion of seawater during Hurricane Katrina in 2005, flooding coastal communities and eroding and displacing habitat. In addition, the Mississippi River Gulf Outlet provided a channel through which seawater flowed, overtopping the levees that protected the City of New Orleans, causing billions of dollars of damage to property and economic activities and loss of life (Shaffer et al., 2009).

5.6 Significant environmental, economic and/or social aspects in relation to changes in sediment input

The social and economic aspects of loss of specific habitats include loss of livelihood (where important fish-food sources and access to croplands have been displaced or where tourism assets are lost), homes and communities (for example, where coastal erosion and shoreline retreat have damaged or destroyed buildings), and habitats of cultural or amenity values. The concept of waterfront property value is also linked to tourism, as it is often the case that the aesthetic and cultural aspects driving property values and tourism are the same (Phillips and Jones, 2006). Many of these issues are described in relation to the specific habitats involved in other parts of this Assessment (coral reefs, see Chapter 43 and 44; estuaries and deltas, see Chapter 44; kelp and seagrass, see Chapter 47; mangroves, see Chapter 48; and salt marshes, see Chapter 49).

Shaffer et al. (2009) note in relation to the cost of restoring wetlands on the Mississippi Delta (estimated to be about 5,300 US dollars per hectare) that “the most significant twenty-first century public works projects will be those undertaken to correct environmental damage caused by twentieth-century projects.” In other words, the cost of restoring damaged habitats is often much greater than the cost of the projects that caused the damage in the first place. The cost of maintenance of coastal protection infrastructure is estimated to be about 300,000 dollars per mile (1.8 km) of coast in the United States (Dunn et al., 2000). Along coasts that are eroding, the cost of allowing the coastline to retreat is immense. If the coast of Delaware in the United States were allowed to recede at its present pace (without shoreline defence engineering works), the cost of lost property by 2050 has been estimated by Parsons and Powell (2001) to be about 291 million dollars (year 2000 dollars), which the authors argue justifies the dollar cost of defence.

6. Gaps in Capacity to Assess Land/Sea Physical Interactions

The assessment of land/sea physical interactions is multidisciplinary, requiring expertise in all aspects of oceanography (physical, geological, chemical, and biological) and concomitant terrestrial counterparts. Local, regional, and basin-wide scales must be considered, along with implications of climate change and sea-level rise. Ultimately, the natural sciences must inform and serve the social realities of economic and infrastructural needs. This section is arranged according to gaps in knowledge of coastal processes, gaps in knowledge of ocean processes, and gaps in capacity to apply existing science to effective decision-making. Some examples are taken from the Caribbean; however, the discussion is global, with many areas of extrapolation.

Globally, coastal engineering science has evolved dramatically during the last century, from the application of crude coastal protection measures such as the *ad hoc* placement of rocks and other natural materials, to the well-modelled and sophisticated coastal structures built today. These changes are mainly due to some improvement in understanding of coastal processes, such as the interaction of nearshore waves with littoral sediment transport paths. However, methodologies are still developing, linking changes in sea level to changes in shape, sediment volume, and beach width. New models have been developed, and produce better results when validated than the Bruun model (DECCW, 2010). Since the 1950s, the Bruun model has been used to model coastal retreat caused by increases in sea level, in spite of its apparent limitations as a two-dimensional representation of a multi-dimensional process (Cooper and Pilkey, 2004).

In developed countries, such as the European Union Member States, the United States and Canada, permanent, extensive coastal and nearshore monitoring ensures that the body of data required for modelling coastal processes is readily available. An abundance of information exists on the sources and sinks of sediment, and on sediment transport processes. However, the situation is different in many African and Asian coastal states, and in Small Island Developing States, where capacity and technologies for widespread monitoring are limited. The UNESCO Sandwatch programme has enabled establishment of beach profile monitoring in many developing countries by non-governmental organizations and school students (UNESCO, 2010).

Development of a specific global framework for land/sea physical interaction assessment needs to be initiated. This could include improving capacity of persons who collect and analyze existing and new data at local, regional, and basin-wide levels. Ultimately, a standardized training programme, through an inter-institutional network, should be established. Support is needed for ongoing *in-situ* measurements and for the re-establishment of discontinued data collection programmes, and for initiating new studies. Above all, the scientific questions should be clearly articulated. Forecasting ocean processes is a necessary capability for addressing climate change and sea-level rise.

Many countries, including small island States, are susceptible to climate change impacts, many of which will directly affect land-sea interaction (Carter et al., 2014). Inundation of coastal lowlands and small islands will lead to the loss of mangroves, seagrasses, and coral reef habitats and ecosystems. It is also postulated that rainfall patterns over the region will be altered, changing river discharge and non-point-source sedimentation. It is also thought that hurricanes will become less frequent but more intense, posing a particular threat to the coasts of island States. The global Integrated Coastal Area Management (ICAM) programme of IOC-UNESCO is designed to assist countries in their efforts to build marine scientific and technological capabilities as a follow-up to Chapter 17 of Agenda 21, and to Chapter IV of the Mauritius Strategy. The main objectives of ICAM are to increase capacity to respond to change and challenges in coastal and marine environments through further development of such science-based management tools as marine spatial planning, ecosystem-based management, and the Large Marine Ecosystem (LME) approach.

Activities include syntheses of scientific information and preparation of methodological manuals, a strategic alliance with the International Geosphere-Biosphere Programme (IGBP) and its core project on Land-Ocean Interaction in the Coastal Zone (LOICZ), and a project on the development and application of indicators for integrated coastal and ocean management.

In the same way the SPINCAM (Southeast Pacific Data and Information Network In Support to Integrated Coastal Area Management) project was designed to establish an ICAM indicator framework at national and regional levels in the countries of the Southeast Pacific region (Chile, Colombia, Ecuador, Panama and Peru), focusing on the state of the coastal and marine environment and socioeconomic conditions, to provide stakeholders with information and atlases on the sustainability of existing and future coastal management practices and development. The SPINCAM model is proposed for replication in other regions.

With respect to gaps in knowledge of ocean processes, it is noted that anthropogenic climate change will affect wave climate, sea level and ocean acidification (OA). Impacts of the latter are discussed in chapter 5, and the production of beach sand is discussed in chapter 7. However, given that the science on OA is now developing, significant gaps exist in knowledge of this phenomenon and its effects. Thus far only certain regions of the world's oceans are being studied, e.g. off North America, Canada and New Zealand. The Global Ocean Acidification Observing Network (GOA-ON) is striving to assist in the development of standards, and of capacity for researchers in other countries.

Sea-level monitoring and research is quite mature; almost all coastal States participate in the collection of sea-level data. Instrumentation is easily accessible and States utilize data for early warning of coastal hazards. The Global Sea Level Observing System has improved monitoring in regions not previously monitored. The main gaps in knowledge are in the use of sea-level data in models to determine changes in coastal processes and changes in shorelines.

Other gaps in capacity relate to the application of existing knowledge to inform the development of coastal areas. An understanding of coastal dynamics is vital in design and construction of coastal infrastructure. Diversion of sediment pathways through dam building, port/harbour construction, and infrastructure development constructed on dunes and sand spits may result in losses following coastal erosion.

Land reclamation may destroy habitat and ecosystem services that protect the coast from sea-level-related hazards such as storm surge and tsunamis. One significant gap in capacity is in coastal engineering, especially in Small Island Developing States. Once capacities in physical oceanography and coastal engineering are linked, ocean and coastal processes may be better understood for application by coastal developers.

Even where capacity in Small Island Developing States exists, such as in Barbados, the challenge is to develop a comprehensive succession planning framework that maintains that capacity over time. Additionally, the costs of appropriately located, designed and constructed coastal infrastructure may be prohibitive. Currently, Barbados is undertaking a Coastal Risk Assessment and Management Programme (CRMP) of 42 million US dollars through concessional loan financing. The aim of this project is to conduct diagnostic studies of ocean and coastal processes, in order to determine the impact of sea-level rise and other coastal hazards on the country's coastal assets (IDB, 2011). Thus, the costs of monitoring, including maintenance and calibration of instrumentation, and training, are a factor in the application of existing science for effective coastal planning.

Chapter 27. Tourism and Recreation

Group of Experts: Alan Simcock (Lead member) and Lorna Inniss

1. Introduction

Seaside holidays have a long history. They were popular for several hundred years (100 BCE – 400) among the ruling classes of the Roman Empire: these visited the coast of Campania, the Bay of Naples, Capri and Sicily for swimming, boating, recreational fishing and generally lounging about (Balsdon, 1969). But thereafter seaside holidaying largely fell out of fashion. In the mid-18th century, the leisured classes again began frequenting seaside resorts, largely as a result of the health benefits proclaimed by Dr. Richard Russell of Brighton, England, in 1755 (Russell, 1755). Seaside resorts such as Brighton and Weymouth developed in England, substantially helped by the royal patronage of Kings George III and George IV of Great Britain (Brandon, 1974). After the end of the Napoleonic wars, similar developments took place across Europe, for example at Putbus, on the island of Rügen in Germany (Lichtnau, 1996). The development of railway and steamship networks led both to the development of long-distance tourism for the wealthy, with the rich of northern Europe going to the French Riviera, and to more local mass tourism, with new seaside resorts growing up to serve the working classes of industrialised towns in all countries where industrialisation took place. In England, whole towns would close down for a “wakes week”, and a large part of the population would move to seaside resorts to take a holiday: for example, in 1860 in north-west England, 23,000 travelled from the one town of Oldham alone for a week in the seaside resort of Blackpool (Walton, 1983). Between 1840 and 1969, the population of Blackpool (based almost entirely on the tourist industry) grew from 500 to 150,000 (Pevsner, 1969).

This relatively local mass tourism industry gave way to the modern mass tourist industry from the 1960s onwards. This was facilitated mainly by the introduction of, first, large passenger jet aircraft in the 1960s and, then, large-bodied jet aircraft in the 1970s, which (like the railways a century earlier) enabled relatively cheap mass transit over long distances that were not previously feasible (Sezgin et al., 2012).

2. Present nature and magnitude of tourism

International tourism has grown immensely over the last half century. In 1965, the number of international tourist arrivals worldwide was estimated at 112.9 million. Thirty-five years later, in 2000, this figure had grown to 687.3 million – an increase of 509 per cent, equivalent to an average annual compound growth rate of 5.3 per cent (WTO, 2014). A significant feature of these statistics is the increase in both absolute numbers and as a proportion of world tourist traffic of Asia and the Pacific: in absolute terms, the numbers of international tourist arrivals in that region has more

than doubled, and the share of world traffic has increased by 6 percentage points, from 17 per cent to 23 per cent of the global total. Likewise, tourist numbers in Africa have also risen both in absolute terms and as a proportion, although from a much lower base. Tourist arrivals in Sub-Saharan Africa rose by over a quarter between 2007 and 2012, from 3.5 per cent to 5 per cent of the global total. Nevertheless, Europe continues to dominate international tourism, with 51 per cent of all international tourist arrivals in 2012. Fuller details are in the Appendix to this chapter.

When the origins of the tourists represented by these arrivals are considered, the pattern shown in Figure 1 is not markedly different: European tourists dominate the departures as much as the arrivals; Asian and Pacific tourism is growing strongly, and African tourism is also growing significantly, although from a low base. This is not surprising since most tourists tend to visit countries in their own region (Orams, 2003). It is for small States that the growth in long-distance tourism is most important: taking, for example, the 25 States and territories that cooperate in the Caribbean Tourist Organization, 35 per cent of their 24 million arrivals¹ in 2012 were from the United States of America, 14 per cent from Europe and 12 per cent from Canada, meaning that at least 61 per cent of arrivals were from outside their immediate area (CTO, 2013).

Figure 1. Origins of tourists by WTO region. Source: WTO, 2014.

Although the figures for international tourist arrivals are the standard measure for looking at the tourism industry, they are somewhat misleading. They relate to

¹ This figure differs from that given for the Caribbean in Table 1 because the Caribbean Tourist Organization includes Belize and Cancun, Mexico in Central America and Guyana in South America.

international tourism. In global regions where there are many States (as, for example, in Europe), journeys will count as international when, in other parts of the world, they would be classed as domestic. This means that, for example, that a 1,400 km journey from the Ruhr, Germany to the Costa Brava, Spain in Europe will count towards international tourist statistics, while a 3,000 km journey from Beijing to Hainan Island in China will not. As a measure of global tourism, the statistics for international tourism will therefore exaggerate the proportion of world tourist activity in those global regions where there are relatively numerous States.

Statistics on total tourism (both international and domestic) are difficult to produce, because there is not the opportunity to capture information that arises when tourists cross national boundaries. What is clear, however, is that the numbers of domestic tourists are substantially more in large States than those of international tourists. In Brazil, it has been estimated that, in 2011, 49 million of the inhabitants made one or more visits within the country for the purpose of tourism (FIPE, 2012). This compares with 5.4 million tourists arriving from outside the country (AET, 2012). In China, in 2013, domestic tourism in mainland China was estimated to involve 3,260 million domestic tourists, compared with 129 million from Hong Kong, China, Macau, China and Taiwan Province of China, and 29 million from the rest of the world (NBSC, 2014). In the United States, domestic tourism accounted for 1,600 million person-trips for leisure purposes in 2013, compared with international arrivals of 70 million (US Travel, 2014). On the other hand, in smaller States (particularly Small Island Developing States), international tourist arrivals will be more closely aligned with total levels of tourism.

Even when allowances can be made for domestic tourism, the available statistics tend to be too broad-brush to allow a clear analysis of the impact of tourism on the ocean, since they include tourism of all kinds. The statistics quoted above give the total number of tourists, irrespective of whether they are visiting a country for a beach holiday, to view ancient monuments or to climb mountains. Again, in smaller coastal States (particularly Small Island Developing States), the total number of tourists will be close to the number of tourists who will have an impact on the ocean, since there is only the coastal zone to accommodate them. But the available global figures are not sufficiently differentiated to allow conclusions focused precisely on coastal tourism.

In Europe, efforts have been made to determine the proportion of tourists that are staying in the coastal zone. For 27 countries of the European Union, there were in total in 2009 about 28.1 million “bed-places” (hotels, hostels, camp sites, etc.). Of these, about 60 per cent were in coastal regions (coastal regions being defined as the 447 third-level statistical units (34 per cent out of a total of 1,294) that have either a coastline or more than half their population within 50 km of the sea) (Eurostat, 2014a). Looking at use, rather than supply, surveys showed that, in 2012, for the 28 European Environment Agency countries for which data are available, 599 million tourist person/nights were spent in coastal regions out of the total of 1,416 million tourist person/nights spent in those countries – that is, 42 per cent of all tourism in those countries was in coastal regions, which (as said above) represent only 34 per cent of the total number of regions (Eurostat, 2014b – extracted in

Appendix)². Surveys of the European population have also confirmed a strong wish for seaside holidays: 46 per cent of people in the European Union give a beach holiday as their reason for holiday travel; to this must be added the proportion of the 14 per cent giving a sporting holiday, since this covers scuba diving among other activities (EU, 2014). This factor is made more important by the high proportion of international holiday travel originating in Europe. In Brazil, it was estimated that, in 2011, 78 per cent of domestic tourism destinations were in the coastal Federal Units (although, of course, several of these stretch far inland) (FIPE, 2012). In the United States, surveys of the reasons for domestic travel in 2013 showed that visiting beaches was one of the five main reasons for travel, after visiting relatives, shopping, visiting friends and fine dining (US Travel, 2014). Also in the United States, in 2008, it was noted that Miami Beach attracted more than twice as many visitors than the Grand Canyon, Yellowstone National Park and Yosemite National Park combined, and that California beaches attract more visitors than all 388 National Park Service properties combined (Houston, 2008). Coastal tourism therefore appears to represent a dominant form of tourism generally.

The statistics quoted above do not include Antarctica. Since 1966, a trade has developed both by cruise ships and (to a lesser extent) for airborne tourists. This has grown steadily (with a dip in the 2010/11 season) over the last decade from a total of 27,537 in the 2003/04 season to 37,405 in the 2013/14 season. In 2013/04, 74 per cent of the tourists landed on Antarctica. Four-fifths of the tourists come from the USA (30.1 per cent), Australia (12.6 per cent), China (11.3 per cent), Germany (8.4 per cent), the United Kingdom (7.3 per cent), Canada (4.4 per cent), France (3.4 per cent) and Switzerland (2.4 per cent) (IAATO, 2014). There are obvious concerns about the potential impact (from, among other things, waste, accidents, accidental introduction of organisms and exhausts and oil spills), although the authorities and tour operators attempt to minimise these.

Land-based tourism in the Arctic is included in the statistics for the different continents above. In addition, there is also a very significant component of cruise ships which do not land their passengers, who therefore are not counted in the statistics. The limited statistics available on Arctic land-based tourism suggest that it is growing quite quickly, but is still only counted in the 100,000s. Cruising is probably growing more quickly, with Arctic seas becoming ice-free in parts during the summer (Lück et al., 2010). The challenges posed for the marine environment are similar to those for the Antarctic.

In spite of the limitations of the available statistics, it is clear that the total amount of tourism has generally been increasing fairly steadily for the last 40 years (with occasional set-backs or slowing down in times of global recession), that the domestic component of tourism is very important in large countries, that international tourism is important in small States, and that coastal tourism is a major component of tourism, if not everywhere the predominant one. Particularly noteworthy is the way in which international tourism is increasing in Asia and the Pacific, both in absolute

² The difference between the 60 per cent for bed-spaces and the 42 per cent for overnight stays in coastal regions is probably due to the fact that much coastal tourism in Europe is highly seasonal, with many bed-spaces being unoccupied during the winter months.

terms and as a proportion of world tourism, with the implication that pressures from tourism are becoming of significantly more concern in those regions.

3. Socioeconomic aspects of the human activities

Movements of people on the scale of the tourism described above require substantial inputs in transportation, accommodation, feeding and recreation. As a study of foreign direct investment in tourism by the United Nations Conference on Trade and Development (UNCTAD) puts it: “A significant part of tourism’s development potential stems from the fact that it links together a series of cross-cutting activities involving the provision of goods and services such as accommodation, transport, entertainment, construction, and agricultural and fisheries production” (UNCTAD, 2007). Tourism has therefore become a major economic activity. (Since it is often difficult to distinguish travel for business purposes from travel for recreational purposes, it is often necessary to describe this economic activity as “tourism and travel”; in the rest of this section, tourism must be understood in this wider sense.)

Even though international tourism is only a part of the picture, it is worthwhile examining the statistics on expenditure from international tourism to see the situation in the different regions of the world. The World Bank World Development Indicator 6.14 (Inbound tourism expenditure) gives details of inbound international tourism expenditure for 2006 and 2012 for 114 coastal States and territories. Table 1 shows an analysis of this data by global regions, showing also the proportion that the inbound tourism expenditure forms of total exports. Fuller details are in the appendix to this chapter.

Table 1. Inbound international tourism expenditure by global region, ranked by regional average percentage of total exports

Region (and number of States and territories covered)	Inbound tourism expenditure (million USD\$)	Regional average % of total exports	Inbound tourism expenditure (million USD\$)	Regional average % of total exports	State or territory with highest % of total exports in region in 2012	State or territory with lowest % of total exports in region in 2012
	2006	2006	2012	2012		
Caribbean Islands (11)	10,467	40.3	12,008	44.2	Aruba (Netherlands) (65.7%)	Haiti (16.3%)
Oceania (7)	26,453	13.7	41,108	11.3	Fiji (61.1%)	Solomon Islands (10.5%)
Sub- Saharan Africa (16)	14,981	7.8	20,740	5.9	Cabo Verde (60.6%)	Democratic Republic of the Congo (0.1%)
Western and Central Europe* (18)	378,794	6.9	440,661	6.1	Cyprus (27.8%)	Germany (3.0%)
Central and South America (17)	22,245	4.9	36,606	4.5	Belize (28.9%)	Brazil (2.4%)
North America (3)	163,599	7.4	234,108	7.4	USA (9.0%)	Mexico (3.4%)
Middle East & North Africa (12)	38,092	6.7	53,889	5.3	Jordan (33.0%)	Algeria (0.4%)
East Asia (12)	132,024	4.0	273,708	4.7	Macau, China (94.2%)	Japan (1.8%)
South Asia (5)	11,882	5.0	23,093	4.4	Maldives (79.9%)	Bangladesh (0.4%)
Eastern Europe (13)	17,488	4.0	28,624	3.7	Albania (45.9%)	Russian Federation (3.0%)

* including Cyprus and Turkey

Source: Compiled from World Bank, 2014.

This shows that, on the basis of this sample of 114 States and territories, tourism and travel accounts for about 6 per cent of total exports globally. However, some regions of the world (particularly the Caribbean) are economically very dependent on international tourism in terms of foreign-currency earnings. It also shows that most small coastal States and territories are more dependent on such earnings than larger countries with more diversified and larger industries or resources of raw materials – although it is not unimportant in countries such as Australia or the United States.

Expenditure by international tourists, however, is not the only important aspect of coastal tourism. As shown above, domestic tourism is also very important, particularly in larger States. Although there are no global estimates of the total expenditure in coastal regions by domestic and foreign tourists combined, it is helpful to look at estimates of this total expenditure for countries as a whole, given the evidence (see above) that coastal tourism can be nearly as much as a half or more of total tourism.

In assessing the importance of an economic activity such as tourism for a country, it is important to consider not only the direct expenditure on that activity, but also the “indirect” expenditure on that activity and the resulting “induced” economic activity. The indirect expenditure is that which those active in the economic activity have to spend to buy assets and supplies that they need to carry it out. In the case of tourism, this includes the construction of hotels and other necessary buildings and the purchase of food, power and services, etc. The induced economic activity (sometimes called the multiplier effect) is that which is generated by those supported by the economic activity in question. In the case of tourism, this includes the spending of those who are directly or indirectly employed in tourism. The World Travel and Tourism Council (an industry body) has commissioned research to estimate the scale of the contribution of the tourism sector (in the wider sense explained above) to national economies. Table 2 summarizes the conclusions of this research (unlike Table 1, information on land-locked States cannot be separated out from that for coastal States). The Table also shows estimates of the proportion of employment in the different regions supported directly and in total.

Table 2. Estimated contribution of tourism to GDP and employment 2013, ranked by total contribution to GDP. Source: Compiled from WTTC, 2014.

Region	Direct contribution to GDP US\$ million	% share of total GDP	Total contribution to GDP US\$ million, including the multiplier effect	% share of total GDP	% share of direct employment	% share of total employment, including multiplier effect
World	2,155,500	2.9	6,990,540	9.5	3.3	8.9
Caribbean	15,299	4.3	48,994	13.9	3.6	11.3
South East Asia	121,166	5.0	294,376	12.3	3.7	9.7
North Africa	34,951	5.6	74,998	12.1	5.2	11.6
Oceania	49,606	2.8	188,018	10.8	4.4	12.4
European Union (27)	552,148	3.2	1,512,360	9.0	4.0	9.9
Central and South America	142,476	3.2	387,609	8.8	2.8	7.9
North East Asia	431,742	2.6	1,389,330	8.5	2.9	8.2
North America	544,342	2.7	1,665,850	8.3	4.2	10.4
Remainder of Europe and Central Asia	111,596	2.3	362,120	7.2	NA	NA
Sub-Saharan Africa	36,623	2.6	95,713	6.9	2.3	5.8
Middle East	63,988	2.4	167,598	6.4	2.5	6.4
South Asia	NA	NA	NA	NA	NA	NA

These statistics show that tourism is a significant component of many economies. As a result, many international organizations promote tourism development as a valuable way forward in improving national economies. However, three important factors need to be borne in mind in evaluating its importance:

First, the direct employment provided by tourism in many countries has a very large proportion of female workers. Studies by the World Travel and Tourism Council showed that in four (Australia, France, Germany and South Africa) of the five countries studied, the proportion of women employed in tourism is over 60 per cent of the work force. The exception was Turkey, where the proportion was 27 per cent, no doubt as a result of cultural differences (WTTC, 2014). It has been noted that this predominance of female workers makes tourism significant in giving economic status to women (Wilson, 2008).

Secondly, there will be a “leakage” from the earnings generated by a country’s tourism activity to the rest of the world economy. This leakage will have four main components:

- (a) Goods and services (such as wine or entertainers) must be purchased from abroad to meet demands from tourists (especially international tourists) that cannot be met from indigenous sources;
- (b) Expatriate staff (especially managers) will remit at least part of their earnings to their home countries);
- (c) International hotel companies will remit earnings to their non-resident owners. The terms on which they are able to do so, and the taxation regime to which any such earnings are subject will, in many cases, be the subject of negotiations between the local authorities and the hotel companies, especially where a large investment is concerned. Small States may be at a disadvantage when negotiating such terms with large international companies, especially where there is a credible threat of choosing a site in another country as an alternative; and
- (d) Commissions will be payable to tourism organizers for directing tourists to tourist establishments.

This “leakage” is usually a higher proportion of earnings in developing countries than in developed countries, although it is not easy to quantify (Yu, 2012).

Thirdly, there is a risk that the employment in tourism will be relatively low-grade and/or seasonal. The risk of the employment being low-grade comes largely from the fact that tourists frequently expect routine tasks (such as cooking, cleaning and making beds) to be done for them, although they would commonly perform these tasks themselves in their own homes. In some areas, when managerial staff are expatriates, the grade of work for the local population can be even lower. The extent to which this is the case varies according to the quality of local trained staff that is available. An important factor is therefore the extent to which related training and education are provided: for example, the University of the West Indies

has undertaken specific programmes for this purpose, including a specialist training centre in the Bahamas (UWI, 2002; UWI, 2014).

Tourism has a further socioeconomic significance, going beyond its macroeconomic importance and the effects on those involved in providing services. Where tourist resorts are created, the circumstances of those already living in the area are affected – sometimes adversely. For example, the literature notes cases where (a) the local residents lost access to beaches that they have previously enjoyed, even where the beaches are public property, because hotels or other tourist developments block access to those beaches; (b) local residents lost access to other areas that they have enjoyed for recreation because they are taken for resort building; (c) local residents had their property expropriated without compensation for the erection of hotels; (d) large increases in land values as a result of the erection of tourist establishments effectively prevented local residents from acquiring land; (e) local residents have seen land to which they attach religious or cultural significance diverted to tourism use (Bartolo et al., 2008; Cater, 1995; Wilson, 2008). On the other hand, cases (mentioned in the same literature) are also found where careful planning and collaboration with the local people produced “win-win” situations, in which successful tourist resorts have been created and the local people have benefited substantially. Information is lacking, and would almost certainly be impossible to collect, to make an assessment of the balance of adverse and beneficial effects, even in one country or region, let alone globally.

4. Major impacts on the marine environment

4.1 Coastal built environment

Coastal tourism needs coastal infrastructure. In the first place, transport is needed to get the tourists to the coast. This requires airports, roads, car-parks and (in some cases) railways. All this tends to change the coastal landscape. In addition, tourism demands accommodation. Hotels and restaurants are therefore built in large numbers, with many completely new resorts being developed. These commonly include marine promenades, bathing places and other hard landscape features, which completely change the shoreline (Davenport et al., 2006).

Globally, there are few statistics on the extent to which coastal areas have been built up to meet tourism needs. Many studies of specific areas are available, most using satellite-based photographs or sensing, but a comprehensive overview is lacking. Particular efforts, however, have been made in Europe, making a more general overview possible. Studies by the European Environment Agency have shown that, for the coastal zone up to 1 km from the shoreline, more than 10 per cent was built up in Bulgaria, Germany, Latvia, Lithuania, the Netherlands, Poland, Portugal and Romania, more than 20 per cent in France, Italy, Spain, more than 30 per cent in Slovenia and nearly 50 per cent in Belgium (the last two countries having very short coastlines). Information was not available for the United Kingdom of Great Britain and Northern Ireland. The proportion of the area close to the shoreline covered with urban development has also been growing rapidly: between 1990 and 2000,

nearly 8 per cent of the area within 10 km of the shoreline in the States mentioned (together with Denmark, Estonia, Finland, Greece and Ireland) was changed from agricultural or natural uses to artificial land cover (EEA, 2006). Some regional studies in the United States have shown a similar picture: more than 10 per cent of the estuarine coastlines of Delaware, Maryland, Virginia, and North Carolina now have artificial shorelines (Currin, 2013).

One significant factor is the extent to which built development for tourism is linked to more general urban development. In many parts of the world (for example, Cyprus, Rousillon in France, southern Spain, Costa Rica, the Algarve in Portugal, and California and Florida in the United States), tourist development is linked with the development of residential property. This has often been targeted at the retirement market from colder industrialised areas. The tourist market and the retirement market overlap, and support a variety of land-use demands – in particular golf courses, which create specific pressures from high levels of fertilizer, pesticide and water use and the consequent run-off (see chapter 20) (Honey et al., 2007).

This change from agricultural or natural uses to hard, artificial land cover has been happening wherever coastal tourism has been developed. The fundamental (and normally irreversible) changes that it brings about have significant implications for coastal ecosystems. These changes are most obvious for species that use both land and sea, such as seabirds, marine reptiles and some marine mammals, and for habitats such as mangroves and salt marshes which combine both land and sea (see Chapters 48 and 49). The changes usually introduce a barrier of artificial land cover between the sea and the natural or agricultural land cover in the hinterland, thus preventing animals moving between one and the other, and affecting the plant cover in the marginal zone. The changes also usually introduce night-time illumination, which also affects the way in which animals (particularly nocturnal animals such as bats) can use the terrain.

The impact of these changes is most obvious for sea turtles, which need to come ashore onto sandy beaches to lay their eggs, which are usually deposited near the vegetation fringe at the top of the beach. Such areas are obviously most affected by coastal development. In the Mediterranean, at the beginning of the 19th century, there were significant breeding populations of green turtles (*Chelonia mydas*), loggerhead turtles (*Caretta caretta*) and leather-back turtles (*Dermochelys coriacea*). Because of the transformation of so many Mediterranean sandy beaches into tourist resorts, these breeding areas are now reduced to Cyprus (for the green turtle) and small areas of Greece and Turkey (for loggerhead turtles); breeding by leather-back turtles is now virtually unknown, except for occasional reports from Israel and Syria (Davenport, 1998, and see chapter 39). Night-time lighting of tourist developments is also a significant problem at turtle-hatching time: turtle hatchlings, which emerge at night, are programmed to make for the lightest part of the horizon, which in natural conditions will be the sea; they are confused by street lighting and fail to reach the sea (Tuxbury et al., 2005; Arianoutsou, 1988).

However, the change from natural to artificial shorelines also affects purely marine species. The difference between a naturally sloping beach and a more vertical seawall produces a significantly different environment. There is growing evidence that the biota living on breakwaters, seawall, groynes and similar structures, and the

fish assemblages associated with them, differ from those on natural shorelines. Even where the natural shoreline is rocky, the replacement artificial shoreline will have different effects; for example, replacing natural rock with concrete may provide a different acid/alkali balance as a result of leaching (Bulleri et al., 2010).

The introduction of artificial hard coastal constructions can also affect the longshore movement of sediments, changing the patterns of sand transport and sedimentation. This can result in changes to beaches. The exact pattern will depend on local circumstances: for example, at Nouakchott, Mauritania, the construction of port facilities is resulting in erosion of dune systems, with increased risks of sea flooding of coastal settlements, reduction of beach area and threats of siltation of the harbour (Elmoustaphat, 2007). Even though sophisticated computer modelling of the possible effects of coastal constructions can be used to reduce the risks, a study of the Herzliya marina in Israel has shown that the effects in practice diverged extensively from those predicted by a meticulous prior environmental planning exercise (Klein et al., 2001).

4.2 Waste and sewage

The influx of tourists to coastal resorts inevitably results in problems in the treatment and disposal of the large amounts of solid waste and urban waste water (sewage) that result. Inadequate handling of solid waste often results in marine debris. Indeed, litter dropped on beaches by tourists is itself a significant source of marine debris (see chapter 24 for both these problems). As described in chapter 20, achieving adequate disposal of sewage is a problem in many areas. Not only do the nutrients contained in this sewage add to the enhanced levels of nutrients in the seawater, leading to eutrophication problems in many areas, but inadequate management can also easily result in health risks to tourists bathing or boating in the sea, a problem that is more directly linked to the success of tourist resorts. Such health hazards for tourists can be self-defeating in attracting business in a highly competitive market.

A special case of these problems of waste and sewage is presented by cruise ships, particularly in the Caribbean (as described in chapter 17, one of the major cruising markets), where large cruise ships put into relatively small ports which have limited facilities for handling waste and sewage. Islands with populations in the range of 20,000 to 100,000 are faced with handling the waste and/or sewage from ships with combined passengers and crew of up to 7,000 people. The resulting difficulties were the main reason why it took so long for the Caribbean to be declared a Special Area for garbage under the International Convention for the Prevention of Marine Pollution from Ships (MARPOL), because adequate reception facilities were a precondition of such a designation. A World Bank project in the member States of the Organization of Eastern Caribbean States (OECS), costing about 50 million United States dollars, enabled much progress to be made in tackling both problems. However, problems remain. During the implementation of this project, cruise lines are reported by the World Bank to have warned the individual OECS governments that any island that imposed waste disposal charges would lose cruise tourism because the cruise lines would merely make a substitute call at ports in less

demanding States. The OECS managed to agree a common levy on cruise passengers entering ports, but the World Bank has reported problems in ensuring that these resources are devoted to the waste and sewage management tasks (World Bank, 2003; ECLAC, 2005).

4.3 Beach and shore usage

For many people, the main point of a seaside holiday is the use of a sandy beach for a mixture of sun-bathing, lounging, swimming and surfing. In general, such usage does not require any change to the natural state of the beach. In many places, however, steps have been taken to try to improve the beach. Often this has taken the form of erecting groynes (wood or stone structures perpendicular to the shore) to try to prevent longshore movement of sand and thus maintain a more sandy beach. "Beach feeding" has also frequently taken place, involving the dredging of sand from further out to sea and its deposition on the beach. These efforts are one form of human intervention in the land/sea interaction, which is considered more generally in Chapter 26. In addition, more recently, attempts have been made to use the creation of artificial reefs to improve the size of surf breakers, and thus the attractiveness of beaches to surfers. The first attempt of this kind was the Cables Reef at Mossman, West Australia. This involved dumping large amounts of natural rock to build up the existing reef. The local municipality reports that it has universally been judged a success in improving the surfing (Mossman, 2003). Later attempts, mainly using a technology based on large sand-filled containers, have been less successful. At El Segundo, California, USA, an artificial reef was created in 2000 but did not achieve its purpose, and its removal began in 2008 (CCT, 2008). At Bournemouth, in the United Kingdom, an artificial surfing reef was created in 2009, but the structure has failed and hoped-for economic benefits have not materialized. (Rendle et al., 2012; Rendle, 2014; Bailey, 2012). Other examples at the Bay of Plenty in New Zealand and at Tuvalom, in India, have also not produced the hoped-for improvements in surfing (Mull, 2014).

Protection of bathers from attacks by sharks has been seen as necessary in some parts of the world, notably Australia and the United States. This has had some adverse effects on local populations of rays, dolphins and turtles, because they have become entangled in this netting (Davenport, 2006).

The need to keep beaches attractive to tourists often leads to the local beach managers (either the communal authority or a hotel which has a concession on the beach) to clean up the debris left by the beach users. However, such clean-up operations usually also include the removal of the natural deposits along the high-tide line of seaweed and other marine material (including dead seabirds and other biota). Such removal of natural material has been shown to reduce substantially the biodiversity of sandy shore shorelines, especially seabirds (Llewellyn et al., 1996; Mann, 2000). Mediterranean and Baltic beaches used substantially by tourists have been shown to have lower densities and diversity of marine invertebrates than neighbouring beaches with less use of this kind. This has been attributed to the combination of cleaning and trampling pressure from the tourists (Gheskiere et al., 2005). Nevertheless, such beach cleaning may often be necessary to maintain

tourism, especially where large amounts of seaweed are brought up onto beaches by the sea. A special problem of this kind has recently emerged in the Eastern Caribbean: since 2011, high numbers of large mats of *Sargassum* species have been washed up on beaches. The same problem, which appears to be emerging from north equatorial recirculation region, has been encountered on the island of Fernando de Noronha, Brazil, and in Sierra Leone (Johnson et al., 2012).

Similar usage impacts can be found on rocky shores. Here even a relatively low number of humans walking over rocks where seaweed and barnacles are found can reduce the coverage of these biota significantly, and heavy (more than 200 visitors a day during the tourist season) usage can take more than a year to recover. Such effects have been shown for New Zealand (Schiel et al., 1999), Italy (Milazzo et al., 2002) and the United Kingdom (Pinn et al., 2005).

Dunes are also vulnerable to heavy usage by tourists, since the footfall can disturb the vegetation cover on which the dunes' stability relies. Because of the importance of dunes in coastal protection, this has been studied extensively in Europe, where it has been shown that 200 passages a day over a dune was enough to reduce vegetation cover by 50 per cent (Hylgaard et al., 1981). Fixed dunes also have a relatively low resilience to damage from vegetation removal (Lemauiel et al., 2003).

Use of the near shore for anchoring ships can also result in damage to the seabed. This is particularly important for shores where the immediate underwater habitat is coral reefs or seagrass beds. Damage has been noted from small pleasure vessels, which often anchor over coral areas so that those on board can dive to see the corals. But more serious damage is caused by cruise ships anchoring in such areas. Destruction of corals of up to 300 square metres has been observed from one anchoring of one cruise ship. Recovery from such damage can take a long time (Allen, 1992).

4.4 Enjoyment of wildlife

Over the past few decades, coastal tourism has come to include creating opportunities for the public to enjoy the local wildlife. This has generated a large number of businesses serving tourists. Six major categories of business are involved, though others do occur. Five are non-consumptive (general marine diving, viewing corals, watching seabirds, watching whales and other marine mammals and watching sharks), and one (recreational fishing and hunting) has a direct impact on the marine biota.

4.5 General marine diving

All around the world, tourists (both domestic and international) engage in diving (usually using self-contained underwater breathing apparatus (SCUBA)). The attractions of this activity are both the sense of freedom conveyed by being in the water and the interesting rock and coral formations and biota that can be seen. The scale of this tourist activity can be judged from the activities of the Professional Association of Diving Instructors, a global organization of experts training people in

scuba diving: between 2000 and 2013, the number of firms in its membership grew by 24 per cent to 6,197, and the number of individual trainers by 26 per cent to 135,615. The annual number of people trained in this period has been around 900,000 (PADI, 2014). At low levels of usage, diving sites do not appear to be adversely affected by recreational diving. There are, however, thresholds above which both the divers' experience is affected by over-crowding and the marine environment is adversely affected (by physical damage and disturbance of fish and other biota). The problem lies in establishing where those thresholds lie, particularly in the absence of long-term monitoring (Davis, 1996).

To enhance the experience of recreational divers, artificial reefs have been created in several locations, including, Australia, Canada, Japan, New Zealand, the Cayman Islands (United Kingdom) and the United States. Many of these used former naval ships as the basis of the new reef. These ships were cleaned of potentially polluting material and then sunk at the desired location. Studies have shown that these have brought substantial economic benefits to the areas from increased visits by tourists for the experience of diving around them (SWEC, 2003; Morgan et al., 2009).

4.6 *Coral viewing*

The sheer splendour and variety of tropical and sub-tropical coral reefs has made them a very popular tourist attraction: people are prepared to travel great distances and pay substantial costs to see coral reefs in their native state. This has therefore generated a large component of the tourist trade. The scale of this component can be judged from what is said on tourism and recreation in Chapter 43.

The specific pressures on corals generated by such viewing can be seen from an assessment of the tourism pressures on the Great Barrier Reef of Australia. These cover (in addition to what is said about anchor damage above):

- (a) Damage (particularly to branching corals) by untrained scuba divers – damage by qualified scuba divers is not seen as a problem;
- (b) Damage by trampling at landing points where large concentrations of tourists were landed from boats to walk on the reef – more generally, even in heavily trafficked areas, damage by tourists walking on the reef was not seen as a problem;
- (c) Some reduction in growth caused by shading from pontoons moored to provide facilities (lecture theatres, restaurants, etc.) for tourists – this could be avoided by careful choice of mooring sites, so that the pontoons were moored over sand rather than corals. Likewise, problems from the anchor points could be avoided by correct design and choice of site;
- (d) Fish feeding by tourists: inappropriate types of food can adversely affect the health of fish, and frequent feeding of large volumes of food could promote unduly large and aggressive fish aggregations. Again, such problems can be avoided by proper management;
- (e) Shell collecting: this was not seen as a major problem, provided that operators gave guidance to tourists;

- (f) Glass-bottomed boats and semi-submersible vessels were seen as potentially capable of causing damage through collisions with corals. However, a survey of one heavily used site could find no overt damage caused by operations of semi-submersible vessels over a five-year period.

The conclusion therefore was that coral viewing, even on a major and locally intensive scale, was compatible with sustaining the reef in a good condition, provided that appropriate management steps were taken (Dinesen et al., 1995). Other studies, however, suggest that: (1) diving can, through abrasion, make large massive coral communities more susceptible to other pressures (Hawkins et al., 1999); (2) damage is virtually impossible to avoid (based on studies in St Lucia and the Cayman Islands); (3) substantial damage can still occur even when restrictive and highly-policed management is in place and (4) camera-users do more damage than divers not undertaking photography (Rouphael et al., 2001; Tratalos et al., 2001; Barker et al., 2004). In some places (for example, Eilat in Israel), artificial reefs have been created to reduce pressure on natural coral reefs (Wilhelmson, 1998).

4.7 *Bird-watching*

There are no global statistics to show the extent of coastal tourism based on bird-watching (Balmforth, 2009). This is largely due to two facts. First, it is not easy to identify bird-watching tourism as a distinct activity: many people may spend a day or two bird-watching out of a longer holiday, although many others will go to destinations where they intend to spend much of their time bird-watching. The latter is particularly the case for destinations where the main attraction is the presence of birds, particularly during migration seasons. Secondly, the resources demanded for bird-watching are not elaborate. Although some sites may provide hides to enable closer observation, much bird-watching is done in the open with no more equipment than binoculars. The resource demand is therefore not easy to capture. Nevertheless, bird-watching is a substantial and growing part of the tourism market. As a major source of tourists of this type, the United States' market is worth noting. In the 2012 National Survey on Recreation and the Environment (NSRE, 2012), it is estimated that 19.9 million people in the United States took trips away from home to watch birds, although not all of these will have visited coastal areas. This group is reported to have both higher educational qualifications and higher incomes than the national average. However, the previous rapid increase in the numbers watching birds (a 332 per cent increase between 1983 and 2002) has slowed down or stopped. Some coastal resorts in the United States can rely very substantially on bird-watching: in 1991, Cape May on the Atlantic Coast of New Jersey was estimated to be attracting 100,000 bird-watching visitors a year, who were spending about 10 million dollars a year (Kerlinger et al., 1991). The Caribbean Tourist Organization has accepted an estimate that, worldwide, three million tourist arrivals a year may be primarily for the purpose of bird-watching (CTO, 2014).

The adverse impact of bird-watching arises from the interaction of the tourist and bird populations. On land, tourists entering nesting areas during the breeding

season can disturb breeding birds, potentially leading to the abandonment of nests. On water, boats carrying bird-watchers can disrupt seabird feeding. This is particularly significant at staging-post sites where migrant birds congregate, since the energy balance of migrating birds is often delicate. Such sites are particularly attractive to bird-watchers because of the numbers of birds (often of many different species) passing through them. On both land and water, bird-watchers can cause birds to flush into the air, making them use energy which (particularly during migration) can be in a tight balance. Careful management of bird-watching sites can minimize this kind of problem (Green et al., 2010; Parsons et al., 2006). One survey of the literature has, however, commented on the lack of research in this field (Steven et al., 2014).

4.8 Whale, seal and dolphin watching

As a tourist activity, whale watching dates back to about 1950, when part of Point Loma in San Diego, California, United States, was declared a public venue for observing grey whales and the spectacle attracted 10,000 visitors in its first year. Within a few years, boat trips to see whales from the sea were added to the land-based opportunities for watching whales (Hoyt, 2009). The attraction spread to other areas and countries. A survey in 2008 showed that the activity was by then taking place in 119 countries, all around the world, involved about 13 million people a year taking part in whale-watching, supported about 13,000 jobs and generated expenditure by tourists of about 2.1 billion dollars (IFAW, 2009 – see Table 3). Whale watching involves not just whales in the strict sense, but also dolphins and other marine mammals: in total around 40 species.

Table 3. Whale-watching numbers and expenditure

Region	Whale-watchers 1998	Whale-watchers 2008	Average annual growth rate 1998 - 2008	Number of countries 1998	Number of countries 2008	Jobs supported	Direct expenditure* USD millions	Total expenditure* USD millions
Africa and Middle East	1,552,250	1,361,330	-1.3%	13	22	1,065	31.7	163.5
Europe	418,332	828,115	7.1%	18	22	794	32.3	97.6
Asia	215,465	1,055,781	17.2%	13	20	2,191	21.6	65.9
Oceania, Pacific Islands and Antarctica	976,063	2,477,200	9.8%	12	17	1,868	117.2	327.9
North America	5,500,654	6,256,277	1.3%	4	4	6,278	566.2	1,192.6
Central America and Caribbean	90,720	301,616	12.8%	19	23	393	19.5	53.8
South America	266,712	696,900	10.1%	8	11	615	84.2	211.8
GLOBAL TOTAL:	9,020,196	12,977,218	3.7%	87	119	13,205	872.7	2,113.1

* In this table, "direct expenditure" is the expenditure on whale-watching trips, and "indirect expenditure" covers the other costs of the tourist trip (travel, hotels, food, etc).

Source: Compiled from IFAW, 2009.

Other marine mammals also support tourism based on watching them. Dolphin-watching has developed as a tourism activity since the 1980s, and is now practised around the world (Constantin et al., 1996). Seal-watching has also developed within the ranges of the various species of seals and other pinnipeds. Since seals and other pinnipeds regularly haul themselves out of the water onto rocks and beaches, seal-watching can offer more reliable viewing of the animals to both operators and tourists, and therefore has enhanced popularity where it is feasible (Newsom, 1996; Bosetti et al., 2002).

Whale-watching involves risks to both humans and the animals. For humans, the risks come from their presence, often in relatively small boats, in the vicinity of large marine animals. The risks are enhanced where the activity involves being in the water – "swimming with dolphins". The threats to the animals are various. The most obvious are those of collisions between whale-watching boats and cetaceans. With quite large boats, often travelling at high speeds (in order to minimize the "blank" time to get from the shore to where the cetaceans are), such collisions can often be fatal to whales (IWC, 2007).

In addition, the literature documents many responses by cetaceans to less extreme pressures from whale-watching traffic (whether on the surface or underwater): surfacing or diving (sometimes to considerable depths), slapping the tail on the water, breaching (that is, leaping out of the water), making noises, changing the size

of the group or the way in which the members of a group interact, changing their swimming patterns, changing their patterns of feeding and/or resting (Senigaglia, 2012; Parsons, 2012). The difficult issue to resolve is whether such behavioural changes are having long-term harmful effects. The result of increased demands for energy and/or increases in stress levels and/or changes in patterns of feeding and resting may affect overall health. One study of bottle-nose dolphins (*Tursiops*) suggests that, in the long term, such pressures may lead to reduced reproductive rates (Bejder, 2006). Pressuring cetaceans to move from their chosen feeding grounds may result in them settling in areas providing less (or less appropriate) food, with obvious deleterious effects. Noise from whale-watching boats may disrupt communication between individuals (which may be important for promoting mating or avoiding harm). The cumulative effect of these various pressures may worsen the situation. These were the kinds of considerations that led the whale-watching subcommittee of the International Whaling Commission to state in 2006 that "... there is new compelling evidence that the fitness of individual odontocetes [that is, the toothed whales (such as the sperm whale (*Physeter macrocephalus*), the killer whale (*Orcinus orca*), beaked whales (*Ziphiidae*) and dolphins (*Delphinidae*)] repeatedly exposed to whale-watching vessel traffic can be compromised and that this can lead to population-level effects" (IWC, 2006). The effect of whale-watching on the life-patterns of the majority of species of baleen (plankton-feeding) whales, with feeding and breeding grounds separated by long migrations, is still under study. Nevertheless, action has been taken in some areas, such as South Africa, to prevent whale-watching in nursery areas (Workshop, 2004; IWCSC, 2013)

As a result, the International Whaling Commission has instituted a five-year strategic plan (2011 – 2016) on whale-watching (IWC, 2014). This aims to provide a framework for research, monitoring, capacity-building, development and management by national authorities. The work includes analysis of the methods adopted by various national administrations to control or regulate whale-watching and coordination of scientific research (IWCSC, 2013).

The impact of watching on seals and other pinnipeds is rather different because of their habit of hauling themselves out of the water. This means that they can be observed both on foot and from boats without any interaction in the water. Furthermore a distinction exists between pinniped species which are inherently "tame" and readily allow very close human approach often to less than 20m with little overt response (most fur seals, sea lions and southern phocid seals) and those which are generally wary of human approach and flush to the water when boats may be at a distance of 200m or more (grey and harbour seals). Some seal species can also become habituated to human presence without any adverse reaction (Wilson, 2015).

4.9 Shark watching

Chapter 40 describes the growth of the tourist activity in shark watching and shark diving, resulting in an industry that, on one estimate, exceeds 300 million dollars a year. The activity in many cases involves placing tourists wearing scuba gear in metal cages and lowering them into the water, and then attracting sharks by throwing

“chum” (fish waste and offal) into the water. It therefore has considerable potential both for injury to the tourists and for disturbing the local ecology. On the other hand, strong arguments are made that the potential economic gains for developing economies are large and the environmental risks are low and can be kept within acceptable bounds by suitable management and monitoring (Martin, 2006).

4.10 Recreational fishing

In most countries, marine recreational fishing is less significant than inland recreational fishing. Nevertheless, estimates suggest that recreational fishing is important in 76 per cent of the world’s exclusive economic zones (Mora, 2009). Some coastal marine stocks in more industrialized nations are exclusively exploited for recreation, or intensive co-exploitation for commercial and recreational purposes occurs. Overall, there is a growing recognition of the immense economic, socio-cultural and ecological importance of recreational fishing as a significant component of global capture fisheries (FAO, 2012). One estimate puts the global level of expenditure in 2003 on recreational fishing at 40 billion dollars a year, supporting 954,000 jobs (Cisneros-Montemayor et al., 2009). This includes fishing by people in the localities around their homes, and the proportion that is attributable to tourists (whether international or domestic) is uncertain. Recreational fisheries are most developed in economically developed countries, but they are emerging as a social and economic factor in many other economies (for example, Argentina, Brazil, China, India) and some other developing countries. Where statistics are available, some 4 per cent to 16 per cent of the populations engage in recreational fishing (FAO, 2012). For example, in Brazil in 2007, about 200,000 fishers have amateur angling permits and it was estimated that there were an additional one million unregistered recreational fishers. In addition, sport fishing in Brazil has grown at a rate of up to 30 per cent a year, with a corresponding growth in tourist numbers. This is reflected, among other things, in the growing success of the sport fishing trade that draws thousands of visitors (FAO, 2010). In more detail for one developed economy where recreational fishing is popular, in Great Britain (that is, the United Kingdom less Northern Ireland) in 2012, about 2.2 per cent of the adult population (1.08 million people) went fishing in the sea at least once. Total resident sea-angler spending in that year was estimated at 1,230 million pounds (1,685 million dollars). This directly supported 10,400 jobs (Armstrong et al., 2013).

The environmental impact of this recreational fishing activity is twofold. First, it is a driver increasing the demand for small boats in coastal waters: most marine recreational fishing is carried out from boats, rather than from the shore. This demand is one of the factors underlying the development of coastal marinas (see below). Secondly, the catch from recreational fishing is a component of the total fishing mortality caused by capture fisheries. Traditionally, it has been regarded as of marginal importance in this regard. However, figures are beginning to emerge that show that it can be a significant component and needs to be taken into account in the general management of fish stocks. For example, in the United States, recreational landings in 2002 accounted for 4 per cent of total marine fish landed in the country. When large industrial fisheries (such as menhaden (*Brevoortia spp*) and pollock (*Theragra chalcogramma*)) are excluded, the recreational component was 10

per cent; when only the fish populations are considered where there are concerns about sustainability, recreational landings in that year accounted for 23 per cent of the total nationwide, rising to 38 per cent in the waters of the States on the southern Atlantic coast of the United States and to 64 per cent in the Gulf of Mexico (Coleman, 2004).

The extent to which the effects of recreational fisheries are taken into account in managing fish stocks varies around the world. Of the authorities responsible for managing the world's exclusive economic zones (EEZs), for recreational fishing, 29 per cent impose regulations on the size of fish caught, 15 per cent regulate the number of fish caught, 13 per cent collect data on what is happening and 3 per cent impose a limit on the number of recreational fishers (Mora et al., 2009).

It is therefore likely that the impacts of recreational fisheries are not being taken into account in managing fish stocks in much of the world. The acquisition of information on local impacts of recreational fishing and the skills to incorporate this information into fisheries management (especially since those undertaking the fishing will in most cases be very different from the usual populations of fisherfolk) will therefore represent significant gaps in much of the world.

Large sport fish (marlin (*Makaira nigricans*, *Istiompax indica* and *Tetrapturus spp*), sailfish (*Istiophorus platypterus*), swordfish (*Xiphias gladius*) and similar species) are a special case. Fishing by rod for these large fish requires relatively large and powerful boats. The tourist market for these species is therefore focused on the more wealthy tourists, especially from the USA. It is particularly significant in the American tropics and sub-tropics, but it is also found, for example, off Mozambique. The economic value of the total of the various recreational fisheries of this kind has been estimated at about 143 million dollars (2003 prices) (Ditton et al., 2003; IOTC, 2013). Although some data on recreational fishing around Mexico have been collected, no reliable data are available for catches of sailfish for the other recreational fisheries of Central and South America, one of the main areas for recreational fishing for large sport fish (for which we know of no reliable data on catches of sailfish (Hinton et al., 2013). Similarly, the data for the Indian Ocean are only partial (IOTC, 2013).

Waste discarded from recreational fishing boats can cause problems. For example, discarded monofilament fishing lines have been found on 65 per cent of coral colonies at Oahu, Hawaii, United States, apparently causing substantial mortality by abrading polyps when moved by wave surge (Yoshikawa et al., 2004).

Recreational hunting for seabirds and some marine mammals and reptiles also takes place. In many countries, such hunting is prohibited or strictly controlled, especially for species regarded as threatened or endangered. Nevertheless, such recreational hunting can be of some economic significance for local communities. For example, Canada is the only one of the five jurisdictions in which polar bears are found that allows recreational (trophy) hunting for them; in the two other jurisdictions where such hunting is permitted it is restricted to indigenous peoples (Lunn et al., 2002). An average of about 100 bears per year is taken by recreational hunters, representing about 20 per cent of the total number taken in Canada. This has been

estimated to bring an income of about 1.3 million dollars per year (2010 prices) to the 30 or so communities where such hunting is permitted (Écoressources, 2010).

4.11 Boating and personal leisure transport

In North America and Europe a massive growth has occurred over the last fifty years in the numbers of small vessels used for pleasure boating. For example, in the United States (including the Great Lakes and internal waterways), in 2013 just under 12 million such craft were notified to the authorities (USCG, 2014), a slight reduction on the previous year, suggesting that the market may be becoming saturated. A high proportion (82 per cent) is motorized, with consequent pollution problems from oil and noise. This activity is economically significant, with the turnover in the United States estimated at 121,500 million dollars a year. It is estimated that 36 per cent of the adult population take part in recreational boating at least once a year (NMMA, 2013). Such widespread activities are not without their risks; global figures are not available but, for example, in the United States in 2013 4,062 boating accidents occurred, involving 560 deaths. This shows that safety measures and instruction can be effective, because these represent reductions of 50 per cent (accidents) and 31 per cent (deaths) over the last 15 years (USCG, 2014). Although the current level of participation in the rest of the world is much lower, it is expected to grow rapidly over the next few years in the fast-growing economies: in Brazil, sales of leisure boats have been growing at a rate of over 10 per cent per year since 2005 (except in 2009) (FT, 2011); in China, it is forecast that the number of pleasure yachts will increase to over 100,000 by 2020 (CCYIA, 2013).

All these boats require moorings when they are not being used for recreational sailing. There has therefore been a parallel growth in marinas and specialized harbours for small boats. These installations form a significant part of the hard coastal constructions discussed above, and therefore present the problems analyzed there.

The other main environmental problems from yachts and small boats are parallel to those from larger ships (see chapter 17). Apart from the inevitable impact of oil from motor engines, the most significant are the residual problems from anti-fouling paints (especially tributyltin (TBT)), the role of small boats as vectors of non-indigenous species, waste disposal and anchoring and movement impacts.

The use of TBT has been banned since the 1980s for small vessels (under 25 metres) in many parts of the world and, more generally, under the International Convention on Control of Harmful Anti-Fouling Systems on Ships since 2003 for new applications and from 2008 for vessels already treated with TBT (see further in chapter 17). However, some States have still not accepted this prohibition: 16 per cent of the tonnage of the world's shipping is registered in States that have not become parties to this Convention (IMO, 2014). Even where States are parties to the Convention, areas still remain where TBT is being found in small-boat harbours and associated areas – for example, in Brazil, the Ilha Grande Bay, Rio de Janeiro (described as one of the most heavily protected tourist areas in the country) was shown in 2009 to be still heavily affected by TBT (Pessoa, 2009).

As concern has grown over the transport of non-indigenous organisms by ships, the role of small boats as vectors of such biota has been shown to be significant – not so much in long-distance transport, as in the more local distribution of species once they have been introduced into a region. Problems with the transport of non-indigenous organisms by recreational boats are being found in locations as far apart as British Columbia on the Pacific coast of Canada and Cornwall on the Atlantic coast of England. The problem species include shellfish, seaweeds and bryozoa (Davenport, 2006; Murray, 2011; ERCCIS, 2014). In 2012, the International Maritime Organization issued guidance for minimizing the transfer of invasive aquatic species by recreational craft (IMO, 2012).

As with cruise ships, although on a smaller scale, recreational boat anchors can cause damage to coral reefs. Their anchors can likewise cause problems to seagrass beds (Backhurst et al., 2000). Recreational motor boats can cause further damage to seagrass beds from the action of their propellers in shallow water; re-growth after such damage can take up to four years (Sargent et al., 1994; Dawes et al., 1997). Powerboats (high-speed motor-boats) cause disturbance through noise and wake to seabirds, marine mammals and sea turtles, particularly to slower-swimming species that are unable to get away, and by disturbing foraging. They can also affect the enjoyment of beaches and inshore waters by other human users. Other devices can cause similar disturbances. Such devices include Jet-Skis® and Wave-Runners®, sand-yachts and kites and paragliders towed by all-terrain vehicles and motor-boats (Davenport, 2006). In effect, these newer forms of recreation on shore and in inshore waters are competing for marine space with non-motorized uses and the natural ecology.

5. Integration of environmental and socioeconomic trends

Successful management of sustainable tourism requires a complex balancing exercise. Many factors have to be taken into account: the means of access, the urban development of hotels, other accommodation, restaurants, and other support facilities, sewage and waste disposal, the many kinds of recreational activity, the interests of the local inhabitants, the profitability of resorts and, last but by no means least, the maintenance of the local natural ecology. The levels at which such varied interests can be managed will vary, hence a successful balancing exercise will usually require the involvement of a wide range of authorities, residents and commercial interests. Examples show, however, that it is possible for such successful balances to be achieved and – even more difficult – maintained over long periods.

A further factor in this balancing exercise is the cross-effects between different recreational activities and different environmental compartments and species. The impact of bird-watching on nesting and feeding areas for seabirds is explained above. But similar impacts on birds are also caused by other recreational activities: boats used in birds' feeding areas for sea-fishing, whale-watching, shark-watching or simply for sailing will cause the same type of disruption as boats used for bird-watching; coastal walking through nesting areas for simple enjoyment will cause the

same kind of disruption as access for bird-watching. Likewise, all kinds of uses of boats in areas frequented by cetaceans will have similar impacts to the use of boats for whale-watching. For wildlife which is disturbed, it does not matter what the purpose of the recreational use is: it is the cumulative impact which gives rise to a threat. Secondly, the balancing exercise is further complicated where marine protected areas are created, since these add a further set of factors which have to be taken into account.

Tourism generally, however, suffers from the problem that success risks undermining itself. For many tourists, the attraction of a tourist location relies on a combination of a relatively high level of service provision and a feeling of a relatively low level of pressure from other tourists. As a tourist location becomes recognised as providing this desirable combination, the pressure to intensify the provision of tourist services increases, thus undermining the balance. If the balance is maintained, prices are likely to rise as the service providers take advantage of the demand in the market, and the location will become less available to the less well-off. If the balance is not maintained, those who can afford to will look elsewhere, creating pressures for the development of new resorts. The world's supply of good sandy beaches is fixed. As disposable wealth in an increasing number of economies increases, the pressure to open up more and more areas for tourism will also increase.

At the same time, within any specific resort, there will be conflicting demands for marine space: among others, sun-bathing *versus* beach volley-ball, swimming *versus* Jet-Skis® and similar devices, wildlife watchers *versus* water-skiers. All this will require management – alongside the many other demands on coastal marine space from fishing (both commercial and recreational), shipping, ports, sand and gravel dredging and all the other human activities that affect the coastal zone. The management of ecotourism is particularly important, because it is essential to ensure that the pressures on the wildlife from it are not more than can be accepted: once a natural ecology is damaged, it is often impossible to restore. Since maintaining a good quality of local environment will be essential for the success of a tourist location, tourism management will be one of the first areas to feel these combined pressures.

6. Capacity-building gaps

Any successful management process will rely on a combination of good information about what is happening and the skills needed to integrate and apply that information. Successful management of sustainable tourism has therefore to be based on a wide-ranging collection of all the relevant information and the development of the necessary skills. The information and skills should include: (a) knowledge about the main features of the local marine environment and their vulnerability to the tourist and recreational activities that affect the marine environment; (b) information about the location, scale and economic significance of those tourist and recreational activities; (c) the relationships between those tourist and recreational activities and the other uses of the marine environment in the

locality; and (d) skills to evaluate what would be the most appropriate balance between the various interests involved (including the conservation of the local marine environment and any formally protected coastal or marine areas) and to broker or settle an acceptable agreement between all those interests.

In many parts of the world, much progress has been made in developing the skills necessary to monitor local ecosystems, and in training local residents in managing hotels and the many other trades necessary for the proper functioning of tourist services, although there is scope for improvement. Less progress has been made in integrating these two sides of a successful sustainable tourist operation. Since so many branches of administration are relevant, a focus on ensuring that general administrators understand the importance of an integrated approach to tourism and are willing to implement it is necessary.

Chapter 28. Desalinization

Contributors: Abdul-Rahman Ali Al-Naama (Convenor), Alan Simcock (Lead member)

1. Introduction

Desalinization of seawater is an essential process for the support of human communities in many places around the world. Seawater has a salt content of around 35,000 parts per million (ppm) depending on the location and circumstances: to produce the equivalent of freshwater (with around 1000 ppm (AMS, 2014) therefore requires the removal of over 97 per cent of the salt content. The main purpose of desalinization is to produce water for drinking, sanitation and irrigation. The process can also be used to generate ultra-pure water for certain industrial processes. This chapter reviews the scale of desalinization, the processes involved and its social and economic benefits. Issues relating to discharges from desalinization plants are considered in Chapter 20 (Coastal, riverine and atmospheric inputs from land).

2. Nature, location and magnitude of desalinization

As figure 1 shows, desalinization capacity has grown rapidly over the past half-century. About 16,000 desalinization plants were built worldwide between 1965 and 2011. About 3,800 of these plants are thought to be currently out of service or decommissioned. The current operational capacity is estimated to be about 65,200 megalitres per day (65,200,000 cubic metres per day (m^3/d) – in comparison, the public water supply of New York City, United States of America, delivers in total about 3,800 megalitres per day) (GWI, 2015; NYCEP, 2014).

Figure 1. Global desalination capacity 1965 – 2015. Source: GWI, 2015. “Contracted” covers plant that is complete or under construction; “commissioned” covers plant that is in operation or is available for operation.

Historically, human settlements have tended to grow up where freshwater was available, and their growth has been conditioned by freshwater availability and the possibilities of bringing it to serve the settlement. As long ago as 312 BCE, the Romans had had to build a 16.4-kilometre aqueduct to bring water to Rome in order to avoid this constraint (Frontinus). Desalination represents an alternative technology for avoiding this constraint on the growth of human settlements in areas with very limited availability of freshwater. That capability, however, comes at the price of considerable capital investment and energy consumption. Gleick et al. (2009) give an overview of the worldwide distribution of desalination capacity in 2009.

The nature of the industry, however, varies in many ways between the different regions, particularly in respect of the technology used: the Middle East has relied more on thermal processes, while the United States has relied more on membrane processes. Thermal processes (mainly Multi-Stage-Flash (MSF) and Multiple-Effect-Distillation (MED)) evaporate the water and then re-condense it. At peak performance these distillation processes produce a freshwater output of about 30-40 per cent of the seawater taken in. The residue has to be discharged as brine. Membrane-based processes (such as reverse osmosis (RO), electro-de-ionization (EDI) and electro-dialysis (ED)) force feed-water through a semi-permeable membrane that blocks various particulates and dissolved ions, leaving the feed-water behind as an enhanced brine, with or without further refinements. (Details of these processes can be found in WHO, 2007 and in GCC, 2014). The energy needed for all forms of desalination is usually obtained from fossil fuels. However, combined plants for nuclear power generation and water desalination have been developed in a number of places (for example, Argentina, India, Japan and Pakistan), and the International Atomic Energy Agency has conducted studies on how far this might be developed (IAEA, 2007). At present, very little desalination is powered by solar energy.

One estimate puts it as low as 1 per cent (Kalogirou, 2009). Projects are emerging, however, to develop this form of desalinization. For example, in Abu Dhabi, United Arab Emirates, the Environment Agency completed 22 small (25 m³/day) solar desalinization plants for brackish groundwater in 2012 (The National, 2012). In Chile, Fundación Chile started a small pilot project partly powered by solar energy in Arica in 2013 (Arica, 2013).

Many countries have installed major amounts of desalinization capacity over the past 70 years: the largest amounts of capacity have been installed in Saudi Arabia (capable of producing over 10 million m³ per day), the United States of America (over 8 million m³ per day (but see below), the United Arab Emirates (about 7 million m³ per day) and Spain (about 5 million m³ per day). . More recently, Algeria, Australia, India and Israel also substantially

increased their capacities (GWI, 2014).

2.1 *The Persian Gulf area*

The Persian Gulf area has the biggest concentration of installed desalination capacity in the world. In total, the desalination capacity of the area is around 9.2 million megalitres a year. Ninety-six per cent of this capacity is located in the six countries that form the Gulf Cooperation Council (GCC - Bahrain, Kuwait, Oman, Qatar, Saudi Arabia and the United Arab Emirates).

2.2 *The GCC States*

These six States have a common approach to desalination. They are located in an arid, hot desert region, characterized by an average rainfall ranging between 75 and 140 mm a year and by limited, non-renewable groundwater resources. Surface freshwater resources comprise only 0.6 per cent of their total area. Natural freshwater resources range from 60 to 370 cubic meters a year per head across the GCC countries (World Bank, 2005). The resources *per capita* are expected to decrease in the future by up to 20 per cent, due largely to population growth. The total GCC population in 2012 was 44,643,654, of which Saudi Arabia constituted 62 per cent. This population is increasing at an average rate of 14 per cent annually. The discovery of oil and gas resulted in the GCC countries being the world's top fossil-fuel exporters with the highest *per capita* incomes and the fastest-growing economies in the world, which underlies the population growth. From 1998 to 2008, real GDP for GCC countries grew at an average rate of 5.2 per cent annually.

Bridging the gap between demand for, and supply of, freshwater has remained a major issue. To meet the need for freshwater, desalination of seawater has been one of the main water-supply alternatives that the GCC countries have adopted. Desalination has become the backbone of many GCC States. For example, Qatar draws as much as 99 per cent of its drinking water from this source. In Saudi Arabia, 50 per cent of municipal water supplies are obtained from desalination: in 2012 this represented deliveries of 955,000 megalitres per year (SWCC, 2014). The total desalination capacity installed in the GCC States in 2012 for water production was 8.9 million megalitres a year. This production capacity was divided: Saudi Arabia (KSA) 39 per cent, United Arab Emirates (UAE) 18 per cent, Kuwait 18 per cent, Qatar 15 per cent, Bahrain 6 per cent, and Oman 4 per cent (GCC, 2012). This is shown in Figure 4.

Figure 4. Desalination capacity in the GCC States, 2012. Source GCC, 2012.

The practice of desalination in the GCC States is heavily influenced by the high local level of electricity consumption, which is largely due to the demand for air-conditioning and cooling, necessary in the hot desert climate, and to the energy-intensive petro-chemical industries. The demand for electricity and water is also influenced by the pricing policy. Water and electricity subsidies are a commonplace practice among the GCC countries. The shared rationale behind energy and water subsidization includes: cultural considerations, expanding access to energy and water, protecting the poor, consumption smoothing, fostering industrial development, avoiding inflationary pressures, and political considerations. The result of the lower prices is to increase demand for both electricity and water. However, there is widespread recognition of the harmful effects caused by the current water and electricity tariff rates (Saif, 2012).

The high level of use of thermal technologies for desalination in the GCC States is mainly due to the predominant method of electricity generation, which is through gas-fired power plants. A by-product of the electricity generation process is steam, which can be utilized by MSF and MED thermal desalination plants for their energy needs. The two plants need to be co-located in order for the desalination plant to capitalize on the power stations' by-product of steam. This co-location of power and plants is referred to as co-generation. Roughly 60 per cent of the MSF plants in the United Arab Emirates are co-generation, while that percentage stands at 70 per cent in Qatar. The quality of the water available for desalination also plays a role. It has the 4 Hs: high salinity, high turbidity, high temperature and high marine life. These factors have in the past made it less suitable for membrane technology (Al Hashemi et al. 2014).

The thermal technology most used in the GCC States is the MSF, which is characterized by a high consumption of energy. Reverse osmosis (RO) is the next most used, and the least used is MED: see figure 5. The GCC States constitute around 88 per cent of the world's use of desalination by thermal processes.

Figure 5. Use of the different Desalination Technologies in GCC States. Source: GCC, 2012.

Although this was the balance between thermal and membrane technologies in the GCC States in 2012, the situation is changing quickly, because the GCC States will in future be adopting more RO projects, as a step towards minimizing energy consumption and decreasing environmental impacts. Most of the desalination plants under construction in 2012 were RO or combined RO/MSF, and the balance is expected to change even more in the future (GCC, 2012).

The GCC States are continuing to invest heavily in their water and energy sectors as shown by many independent water and power plant (IWPP) projects. For example, in 2009, Qatar initiated a 30-year water and electricity master plan that will see major investments in desalination, water infrastructure and wastewater treatment (GWI, 2015). Between 2010 and 2015, Qatar plans to invest approximately 5,470 million United States dollars in desalination projects, with an additional 1,100 million dollars investment in IWPP production facilities between 2013 and 2017. Likewise, the UAE plans to invest 13,890 million dollars in new desalination plants and distribution networks between 2012 and 2016.

Generally, this investment in further desalination is counterbalanced by a new interest in adopting an integrated water policy that uses wastewater and drainage water as a valuable source of water and to augment the water supply by enforcing recycling and re-use in agricultural and industrial activities. To this are added an interest in increasing water storage, particularly through groundwater recharge, and attempts to educate the public on the need for water conservation (Darwish and Mohtara, 2013; Al Hashemi et al. 2014). For example, Qatar has also created a National Food Security Program (QNFSP), with a mandate to manage water resources efficiently in agriculture and food production through the use of technologies to minimize water consumption. As well as supplying the agricultural sector with freshwater, a core objective of the QNFSP is to use the solar desalination of water to replenish the country's aquifers (QNFSP, 2012). Similarly, Abu Dhabi, United Arab Emirates, has already invested to increase water storage capacity (EAD, 2009).

2.3 *Other States in the Persian Gulf area*

The other States in the Persian Gulf area (the Islamic Republic of Iran and Iraq) make significantly less use of desalination than the GCC States, although it still plays a part in their water supply arrangements.

It is assumed that the Islamic Republic of Iran has a desalination capacity of about 400 megalitres per day (this is about 4.5 per cent of that installed in the GCC States). In terms of technology, the Islamic Republic of Iran's existing desalination plants use a mix of thermal processes and RO. MSF is the most widely used thermal technology, although MED and vapour compression (VC) also feature (GWI, 2014).

Although Iraq is believed to have about the same amount of installed desalination capacity as the Islamic Republic of Iran (Iraq is reported to have a capacity of 430 megalitres per day), it is used in a quite different way. Much of the water of the Euphrates and Tigris Rivers has a salinity above 1,000 parts per million. The Iraqi authorities therefore use desalination mainly to improve the poor quality of the river water, and only undertake a modest amount of seawater desalination (ESCWA, 2009).

2.4 *United States of America*

Outside the Persian Gulf area, the United States has the largest installed desalination capacity in the world. This is concentrated in California, Florida and Texas. However, desalination of seawater is only a small part of the desalination carried out in the United States. In 2010, seawater desalination represented only 10 per cent of the desalination capacity – 82 per cent was for brackish-water desalination (largely from brackish groundwater, but also from rivers) and 8 per cent for waste-water re-use (Shea, 2010).

In California, however, the situation is changing. In November 2002, California voters adopted by the initiative procedure (by-passing the State legislature) Proposition 50, the “Water Security, Clean Drinking Water, Coastal and Beach Protection Act, 2002”. This legislation allocated the sum of 50 million dollars for grants for brackish-water and ocean-water desalination projects. This grant programme - administered by the State Department of Water Resources - aimed to assist local public agencies to develop new local water supplies through the construction of brackish water and ocean water desalination projects and help advance water desalination technology. Two rounds of funding were conducted in 2004 – 2006. A third funding round announced eight further grants in August 2014, totalling nearly 9 million dollars for a mix of plant construction, pilot projects and research (DWR, 2014).

Statistics on desalination in California show that there are 10 seawater desalination plants in California, with a daily capacity of about 23 megalitres. Not all these plants are in regular operation, but are used only when other water supplies need to be supplemented. Currently, there are proposals for a further 15 seawater desalination plants. If all these plants were built, they would have capacity to provide some 946 – 1,400 megalitres per day

– about 5 - 7 per cent of California’s water demand in the early 2000s. One of these projects (Carlsbad) is expected to become operational in 2016 and will then be the largest seawater-desalination plant in the United States, capable of delivering 190 megalitres per day of drinkable water (SWRCB, 2015).

3. Other countries with large desalination capacities

A review of the countries other than those in the ROPME/RECOFI area¹ and the United States that have recently installed major desalination capacities shows the following picture.

3.1 Algeria

Algeria is invested heavily in seawater desalination capacity during the 2000s. By 2013, ten major plants had been put into service, with a capacity of 1,410 megalitres per day. In addition, 21 smaller plants with an aggregate capacity of 60 megalitres per day have been created. Further plants, with a further aggregate capacity of 850 megalitres per day, are expected to come into service in the near future, including that at Al Mactaa (500 megalitres per day), which will be one of the largest in the world (ADE, 2014)

3.2 Australia

At the start of the 2000s, the only operational seawater desalination plants in Australia were on small islands. A prolonged drought in the middle of the 2000s, affecting most of the most heavily populated areas, led in 2007 to the creation of a National Urban Water and Desalination Plan, estimated to cost 840 million dollars, together with a National Centre of Excellence in Desalination, based in Perth, Western Australia. Desalination is one of the options to be regularly considered under this plan. A major desalination plant, with a capacity of 144 megalitres per day, has been in operation near Perth since 2006. Another major desalination plant was built, partly financed by this plan, at a cost of 1,500 million dollars, for the city of Adelaide, South Australia, with a capacity of 280 megalitres per day. This is said to give the city a climate-independent source of water. In the light of the operating costs and the recovery of the local river system, the plant has, however, been placed on stand-by (ANAO, 2013). Similarly, major desalination plants have been built to service Brisbane, Melbourne and Sydney, but have been placed in stand-by because of the recovery of other sources of supply (BT, 2010; ABC, 2012; SDP, 2015).

¹ Regional Organization for the Protection of the Marine Environment (ROPME) Members: Bahrain, Iran, Iraq, Kuwait, Oman, Qatar, Saudi Arabia, and the United Arab Emirates. Regional Commission for Fisheries (RECOFI) Members: Bahrain, Iran (Islamic Rep. of), Iraq, Kuwait, Oman, Qatar, Saudi Arabia, United Arab Emirates.

3.3 *China*

In 2012, the Chinese National Development and Reform Commission (NDRC) said that, under a first plan covering 2011-2015, China aims by 2015 to produce 2,200 megalitres per day of freshwater from desalinization. This compares with 660 megalitres per day in 2011. The NDRC said it will encourage innovation and upgrade desalinization facilities, as well as cultivate a number of desalinization facility manufacturers with international competitiveness. The NDRC will also encourage the use of desalinated seawater. More than half of freshwater provided in the islands of China, and more than 15 per cent of water delivered to coastal factories, is to come from the sea by 2015, according to the plan (PD (E), 2012).

3.4 *Israel*

Israel relies substantially on desalinization of seawater for its water supply. In 2008, desalinization represented 17 per cent (383 megalitres per day) of its water supply. By 2013, this was expected to rise to 32 per cent (4,950 megalitres per day) of the supply (Tenne, 2011).

3.5 *Japan*

Although Japan has relatively limited natural freshwater resources (it has about half the world average of natural freshwater resources per head), desalinization has not so far played a major role in meeting general demand for water: a 2006 World Bank review of water management in Japan does not mention desalinization (World Bank, 2006). The main focus in Japan on desalinization has been in providing suitable cooling water for nuclear power plants – at least 10 such plants have associated desalinization plants (IAEA, 2002). Nevertheless, desalinization is used locally to supplement natural freshwater supplies for domestic and industrial use. For example, the authorities on Okinawa, the main island of the Ryukyu archipelago, installed in 1997 a desalinization plant with a capacity of 40 megalitres per day (about 10 per cent of the island's daily demand for water) (Yamazato, 2006), and the city of Fukuoka on the southern Japanese island of Kyushu, after some major water shortages, installed in 2005 a desalinization plant capable of supplying 50 megalitres per day (Shimokawa, 2008).

3.6 *Spain*

Spain has long had difficulties in providing adequate water supplies in some parts of the country. This is particularly the case along the Mediterranean coast, which has undergone massive development for tourism. In 2001, the Spanish authorities adopted legislation for a National Hydrological Plan. Among other things, this legislation declared a substantial number of desalinization plants as projects being in the public interest (Spain, 2001). In 2005, this National Hydrological Plan was amended, and a new list of projects along the Mediterranean coastline was added, which the Ministry of the Environment and its

associated bodies were to implement as a matter of urgency. This list included about 20 desalination projects (Spain, 2005). The desalination component of the Plan is reported to have had an estimated cost of about 3,000 million dollars. By 2013, 27 of the 51 approved plants had been built at a cost of about 2,200 million dollars. However, the economic recession starting in 2008 is reported to have reduced the demand for water to such an extent that many of the plants are standing idle or working at well below their planned capacity (Cala, 2013).

3.7 *Other States*

Many small islands have very limited natural freshwater resources, and have decided to supplement these with desalination. In the Caribbean, the following use desalination: Antigua and Barbuda, Aruba (the Netherlands), the Cayman Islands (United Kingdom of Great Britain and Northern Ireland), Curaçao (the Netherlands), Cuba and Trinidad and Tobago (Scalley, 2012; CWCL, 2015). Elsewhere, Malta (46 megalitres per day, 57 per cent of supply; (NSO, 2014)) and Singapore (capacity of 455 megalitres per day, 25 per cent of supply; (PUB, 2014)) are examples of island States which derive high proportions of their public water supplies from desalination.

In temperate zones, where natural freshwater supplies are usually adequate, authorities in some places are creating desalination plants as an insurance against long droughts and other disruptions of supply. For example, Thames Water in the United Kingdom has built a plant on the Thames estuary with a capacity of 150 megalitres per day (WTN, 2014).

In Chile, the northern provinces are some of the most arid areas in the world, yet it is here that the main minerals deposits are found that enabled mining to contribute 12.1 per cent of Chilean GDP in 2013 (BdeC, 2014). Since the extraction of metals from ore requires substantial quantities of water, there is a growing pressure in these northern provinces on freshwater resources. Many mines rely on freshwater from local rivers, but such abstractions (also called withdrawals) compete with growing demand from the local population. Some mines use seawater, but this imposes extra costs of safeguards against the corrosion that seawater causes. More recently, some mines have installed desalination plants to provide them with freshwater. There has been debate in the Chilean Chamber of Deputies about making the use of desalinated water compulsory if freshwater is to be used (Moreno et al., 2011; CdD, 2013). It seems likely that further desalination plants will be constructed.

4. Social and economic aspects of desalination

Freshwater is essential to all life on land. Yet 97 per cent of all the water on earth is in the ocean (USGS, 2014). According to the Intergovernmental Panel on Climate Change (IPCC) (IPCC, 2014), about 80 per cent of the world's population already suffers serious threats to its water security, as measured by indicators including water availability, water demand,

and pollution.

As the description of the nature, location and magnitude of desalinization shows, there are parts of the world where desalinization is essential to human populations at present, or greater, levels. The largest area of this kind is the six GCC States, but island States, such as Malta and Singapore, are also in this category. Such States are likely to continue to generate significant growth in population over the coming years, together with the associated economic development. The only source of additional freshwater for such growing populations is likely to remain desalinization.

Climate change is likely to add to the number of States that will wish to explore the use of desalinization. The IPCC Fifth Report (IPCC, 2014) concludes that:

- (a) The spatial distribution of the impacts of climate change on freshwater resource availability varies considerably between climate models, and depends strongly on the projected pattern of rainfall change. There is strong consistency in projections of reduced availability around the Mediterranean and parts of southern Africa, but much greater variation in projections for south and East Asia;
- (b) Some water-stressed areas are likely to see increased runoff in the future, and therefore less exposure to water resources stress;
- (c) Over the next few decades, and for increases in global mean temperature of less than around 2°C above preindustrial levels, changes in population will generally have a greater effect on changes in the freshwater available per head than will climate change. Climate change would, however, regionally exacerbate or offset the effects of population pressures;
- (d) Estimates of future water availability are sensitive not only to climate and population projections and assumptions on usage per head, but also to the choice of hydrological impact model and to the measure of stress or scarcity that is adopted.

As an indication of the potential magnitude of the impact of climate change, one estimate quoted by the IPCC forecasts that

- (a) A 1°C rise in global mean temperature (compared to the 1990s) will mean that about 8 per cent of the global population will see a severe reduction in water resources (that is, a reduction in runoff either greater than 20 per cent or more than the standard deviation of current annual runoff);
- (b) A 2°C rise (on the same basis) will increase that proportion to 14 per cent; and
- (c) A 3°C rise (on the same basis) will increase that proportion to 17 per cent.

The spread across climate and hydrological models was, however, large. The IPCC report includes desalinization as one of the range of adaptive measures that may prove particularly effective but notes that desalinization will increase green-house gas emissions to the extent that it relies on fossil fuel for its energy requirements.

It therefore seems likely that desalination will increasingly be considered as a future adaptation measure for communities suffering increased water stress. Given that;

- (a) Desalination is, at least at present, significantly more expensive than most other forms of water supply when other options are available, and
- (b) Most current forms of desalination are using fossil fuels as an energy source, it is more likely that, outside areas where adequate alternative sources of water are simply not available, desalination plants will be built as a fall-back provision, rather than as a primary source of freshwater.

5. Environmental impacts of desalination

A major environmental impact of the majority of the present desalination plants is the emission of greenhouse gases to generate the required energy. In some cases, especially in the GCC States, this is to some extent reduced through co-generation, by which the waste heat from electricity generation is used to desalinate water, without further major demands for energy. In those States, some 60 – 70 per cent of desalination is done in this way. Where solar or nuclear energy can be used to power the desalination, this impact is reduced or eliminated.

The other main forms of environmental impact arise from the intake of feedwater and the discharge of brine. The discharges are discussed in Chapter 20. Intake pipes create a risk to marine biota. The risk is highly variable, and is dependent on the technology employed for the seawater intake. In particular, it depends on how far the intake pipe is from the shore, as well as how the intake pipes are located with reference to the water column or the seabed. Biota living in the vicinity of a desalination plant's intake pipe can collide with, or be held against, the intake screens (impingement), or be sucked in with the feedwater into the plant (entrainment). Careful planning of the intake arrangements for each desalination plant is needed to minimize this form of impact. For example, the intake arrangement Fukuoka in Japan has the intake pipes buried in a sandy seabed, which acts as a form of sand-filter to prevent non-microscopic biota entering the pipes (Shimokawa, 2008). However, such an arrangement can require substantial disruption of the seabed during construction and also lead to maintenance problems.

6. Significant environmental, social and economic aspects, knowledge gaps and capacity-building gaps

Desalination has become essential to the functioning of many communities around the world. This is most evident in the GCC States and a number of small island States and territories. The impacts of climate change on freshwater supply are likely to increase the usefulness of desalination as one of the effective forms of adaptation to these impacts, at

least as a fall-back provision for periods when natural freshwater supplies are deficient.

There are many commercial firms specializing in the design and construction of desalination plants. The technology is therefore available on the market. States and communities, however, need to have the capacities to negotiate in this market and to obtain the technologies that they need at a fair price.

In several cases, desalination plants have been built which have proved to be inefficient or too large for the eventual requirement. There is therefore a case for more efficient sharing of knowledge on the planning, construction and operation of these plants.

Given their continuing importance, the need exists for better knowledge of how to operate desalination plants with the lowest possible inputs of energy. Considerable progress seems to be possible in this direction: Malta, for example, reports having reduced the energy demand for its desalination by 33 per cent in a decade (NSO, 2014).

Chapter 29. Use of Marine Genetic Resources

Writing team: Michael Banks, Caroline Bissada, Peyman Eghtesadi Araghi (Lead Author and Lead member), Elva Escobar-Briones, Françoise Gaill, S. Kim Juniper, Ahmed Kawser, Ellen Kenchington, Nigel Preston, Gabriele Procaccini, Nagappa Ramaiah, Jake Rice (Co-Lead member) Alex Rogers, Wouter Rommens, Zheng Senlin and Michael Thorndyke

1. Introduction

The natural environment has long been a source of inspiration for new drugs and other products of biotechnology. Until relatively recently, the terrestrial environment, in particular, has been the primary source of genetic material and natural products at the centre of major new developments in biotechnology, including new drugs. Examples of natural products used in drug development include the anti-malarial drug quinine isolated from the bark of the *Chinchona*, the analgesics codeine and morphine from *Papaver somnifetum* latex, and antibiotics such as penicillins and tetracyclines from strains of *Penicillium* sp. and *Streptomyces* sp. The terrestrial environment contains far more known species of plants and animals than are at present known in the oceans (Hendricks et al., 2006; Mora et al. 2011), and has contributed greatly to the development of new biotechnologies, and new drugs in particular (Molinski et al., 2009; Arrieta et al., 2010; Leal et al., 2012). Yet there are many reasons to expect that the marine environment should represent a rich reservoir of novel genetic material and natural products, particularly those derived from animals and their microbiomes. Covering more than 70 per cent of the planet, and constituting 95 per cent of the volume of the biosphere, the oceans are home to a greater diversity of major animal groups (phyla) than the terrestrial environment (34 of 36 known phyla are found in the oceans *versus* 17 found on land). Most marine organisms have a large dispersal potential, either through the movement of adults, or through the dispersal of larvae by ocean circulation, potentially crossing hundreds to thousands of kilometres during their development. It is thus likely for many species that the same genomic background could be sampled both within several exclusive economic zones (EEZs) and in areas beyond national jurisdiction (ABNJ).

The study and utilization of marine genetic resources is a fairly recent human activity and, compared to the terrestrial environment, examples are relatively few and scattered throughout the world ocean. This chapter will therefore provide a general review of marine genetic resources (MGRs) rather than providing a regionally comprehensive and inclusive assessment. We will use a fairly broad definition of marine genetic resources that includes nucleic acid sequences, chemical compounds produced by marine organisms and unrefined materials extracted from marine biomass. Within areas under national jurisdiction, where marine organisms are most abundant and most accessible to researchers, MGRs and marine biodiversity are best known. MGRs in the vast,

offshore oceanic areas beyond national jurisdiction (ABNJ) are, by comparison, poorly documented. The growing appreciation of the diversity and novelty of life in the oceans that has emerged from the results of programs such as the Census of Marine Life, and MicroB3 (Marine Microbial Biodiversity, Bioinformatics and Biotechnology - a European Union 7th Framework Program), have fuelled interest in the commercial possibilities of MGRs. Currently MGRs are important to the economies and sustainability of many sectors including the pharmaceutical industry (new medicines), cosmetics, the emerging nutraceutical industry, and aquaculture (new high-value high nutrition, healthy foods), biomedicine and many other economically and culturally important sectors.

Molinski et al. (2009) noted a decline since the mid-1990s in the interest of large pharmaceutical companies in the development of 'drugs from the sea'. This is likely related to a general decline in all natural product research (Dias et al. 2012; Lahlou, 2012). Some hints of a recent resurgence exist, but it will be several years before it can be determined if this is a sustainable trend. In parallel with large commercial pharmaceutical interests reducing their activity in this sector, activity increased in smaller academic-industry partnerships in developed countries, resulting in the emergence of small-scale, start-up companies. New and affordable developments in analytical technologies (gene sequencing, biomolecule characterization) have helped drive this new trend. Further evidence of increased interest in MGR is found in an analysis by Arrieta et al. (2010), who noted growth over the past decade in the accumulation of patent claims related to marine organism genes (currently increasing by 12 per cent per year) and identified marine natural products. In the context of its work on the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction (ABNJ), the United Nations General Assembly stressed the need for a comprehensive regime to better address the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction. Marine genetic resources, including questions on the sharing benefits, are part of the package of issues to be addressed by the preparatory committee established to make substantive recommendations to the Assembly on the elements of a draft text of an international legally-binding instrument under the United Nations Convention on the Law of the Sea (resolution 69/292).

2. Marine Pharmaceuticals

Marine biodiversity in theory has enormous biotechnological potential. Yet, to date, despite "repeated waves of enthusiasm and much early promise," examples of successful development of commercial products are very few. In the early 1950s, the first marine bioactive compounds, spongouridine and spongothymidine, were isolated from the Caribbean sponge *Cryptotheca crypta*. The 1970s saw the beginning of basic scientific research in chemistry and pharmacology of marine natural products and directed efforts in drug development (Molinski et al., 2009; Mayer et al., 2010).

However, only in the last decade have these research efforts resulted in the production of a first generation of drugs from the sea into clinical trials. Not until 2004 was the first drug from the sea (developed from a neurotoxin produced by a tropical marine cone snail, *Conus magnus*) finally approved for sale on the market under the name Prialt; it is used in the treatment of chronic pain associated with spinal cord injuries. More recently, in 2007, a second drug, the anti-tumour compound trabectedin (known as Yondelis, discovered from the colonial tunicate *Ecteinascidia turbinata*), was approved for the treatment of soft-tissue sarcoma in the European Union. Seven drugs derived from marine organisms are currently approved by the United States Food and Drug Administration (FDA) and on the market (Mayer et al., 2010; <http://marinepharmacology.midwestern.edu/clinPipeline.htm>). An example of a medical but non-pharmaceutical usage of compounds produced by marine organisms are wound treatment 'dressings' made of marine diatom polymers (Marine Polymer Technologies Inc.).

3. Marine Nutraceuticals

Related to the biopharma industry, attention also increasingly focuses on so-called marine nutraceuticals. These compounds (or 'substances') are found to be beneficial to human health and "delivered" via food or food products (Kim, 2013). Commercial efforts are also underway to synthetically produce some of these substances. Compounds of interest comprise a wide variety, including polysaccharides, polyphenols, bioactive peptides, polyunsaturated fatty acids, and carotenoids; with identified anticancer, anti-inflammatory, anti-oxidant, and antimicrobial activities (Guerard et al., 2010; Ngo et al., 2011; Vidanarachchi et al., 2012). Many of the products derive from marine algae and include, for example, Fucoidan, a sulfonated polysaccharide found in brown algae and shown to benefit immune system and gastrointestinal health by neutralizing free radicals. Other examples are: Vitamin C and carotenoids, anti-oxidants obtained from *Chlorella* sp.; Spirulina (cyanobacteria of the genus *Arthrospira*), used as a natural blue food colorant and contains a wide variety of nutrients, such as B vitamins, minerals, proteins, linolenic acid, and anti-oxidants such as beta carotene and Vitamin E.

In contrast to the more limited development of new drugs from marine organisms, the nutraceutical industry in Europe and Asia is experiencing significant growth. Marine and algal omega-3 products alone accounted for 1.5 billion United States dollars in sales in 2009, and the global nutraceutical industry as a whole is estimated to grow to a 180 billion US dollars business by 2017 (Kim, 2013). This rapidly growing sector often uses marine biomass, such as fish waste or harvested algae, to produce health food products and restorative cosmetics.

4. Marine organism-derived anti-foulants and adhesives

The antifoulant and marine adhesives industries have a long history. The costs of biofouling to the fleets around the world are estimated to run into 100 million US dollars each year. Many biocidal antifoulants are now banned (e.g., copper-based paints) because of their direct toxicity to marine organisms. Tributyl tin-based products, once used extensively, are now banned because of their now well-known impact on sex determination in marine molluscs and other organisms. Naturally derived antifoulants include enzymes, antimicrobials, biomimetics such as novel topographies, and natural chemical signals (Callow and Callow, 2011; Kirschner and Brennan, 2012; Gittens et al., 2013)

Marine algae are an important source of novel antifouling compounds and mangroves and sponges also feature high on the list of exploited marine organisms. Many algal species produce compounds that inhibit growth of marine bacteria. A red algal metabolite has been shown to affect the composition and density of bacterial colonies, and compounds from the mangrove plant reduce larval barnacle settlement. Such identified active natural compounds inspire the commercial synthesis of mimetics that are more stable and easily applied to surfaces, such as ship hulls, docks etc. (Callow and Callow, 2011; Kirschner and Brennan, 2012; Gittens et al., 2013).

Although the antifoulant industry seeks to prevent undesirable attachments, the bio-adhesive industry focuses on marine glues, materials that enable stable and robust adhesion under water. Perhaps not surprisingly, target organisms used as potential sources of novel marine glues are precisely those that the antifoulant community seeks to deter, for example, barnacles, mussels, tube-building worms and echinoderms. All successfully attach to wet surfaces with tenacity and therefore provide a rich source of ideas for novel adhesives. Some (starfish) uniquely have strong yet temporary adhesives used to anchor their feet during locomotion (Kamino, 2010; Stewart et al., 2011; Petrone, 2013). The mechanisms employed often involve complex surface chemistries and physico-chemical three-dimensional properties, but nevertheless often have a simple biochemical basis. For example, one of the most widely employed core substances is L-Dopa, whilst extracellular DNA is also thought to be an important component in some bio-adhesives (Kamino, 2010; Stewart et al., 2011; Petrone, 2013). Bulk harvesting of natural glues from marine organisms is impractical and any economic exploitation will require an extensive research effort directed at the chemical structure and genetic basis of the natural glues produced by marine organisms.

5. Environmental, economic and social aspects of MGR research

Marine scientific research related to MGR involves the collection of ocean data and the collection of biological samples from the water column and the seabed. Most scientific

instruments and sampling devices so far cause negligible harm to marine habitats. Nonetheless, in some parts of the seabed scientific sampling is concentrated in relatively small areas, such as at well-studied hydrothermal vent fields. There, competing uses have arisen between researchers requiring physical samples (biological or geological) and researchers wishing to observe the natural evolution of local ecosystems (Godet et al., 2011). Such use conflicts led to the adoption of codes of best practices by international organizations such as InterRidge (<http://www.interridge.org/publications>) (see Chapter 30 on Marine scientific research).

Although the possibility still exists of direct extraction of new natural products from marine biomass, such as the extraction of compounds from seaweeds and oils from Sargassum or krill, future exploitation of MGR for purposes of developing the genetic resource is unlikely to involve substantial large-scale harvesting of marine organisms and the resultant destruction of habitat and depletion of species populations as caused by fisheries. Indeed, if recent trends can be used as a guide, future MGR products will come from laboratories and larger facilities where genes and biomolecules will be discovered, and then incorporated into industrial processes that may involve the artificial synthesis of biomolecules (e.g. Mizuki et al., 2014; Wilde et al., 2012; Newman and Cragg, 2012), or the insertion of desired genes into microbes that then produce the desired molecule (Newman and Cragg, 2012). However, potential for habitat damage exists even from scientific fieldwork, particularly in vulnerable marine ecosystems and areas of intensive study and sample collection. In addition, the success of nutraceutical extraction from fish waste could lead to the large-scale harvesting of stocks with little or no food value to humans but attractive as sources of biomolecules for commercial products.

Benefits arising from MGR research include improved knowledge of marine biodiversity and the importance of biodiversity to the provision of ecosystem services and the maintenance of ocean health. Related marine natural products research will also result in more efficient, value-added exploitation of marine resources, as described above. Any accelerated growth in the MGR research sector will not only profit the marine pharmaceutical industry, but also result in health and other social benefits from access to the pharmaceutical or other products themselves (Leary and Juniper, 2014; Broggiato et al., 2014).

6. Capacity to engage in MGR research

6.1 Research Vessels

The first step in the process of accessing MGRs is the collection of samples in the field. In inter-tidal and coastal waters, the capacity to collect biological samples does not require advanced technology. Smaller vessels, even sailing vessels, can be used to sample water column organisms. For example, two recent expeditions used the privately owned sailing yachts; Tara (<http://oceans.taraexpeditions.org/index-o.php/en>)

and Sorcerer II (www.jcvi.org/cms/research/projects/gos/overview/) to conduct ocean basin-scale surveys of planktonic microorganisms. Further offshore sampling of deep-water organisms and the seabed requires an offshore-capable ship (defined here as greater than 60 metres in length) and in most cases a specialized research vessel. Operating costs for these larger vessels are typically greater than 25 000 United States dollars per day. At first glance, basic capability to engage in MGRs research appears to be fairly widespread among nations. The International Research Vessel database (www.researchvessels.org) lists 271 vessels greater than 60 metres in length available in more than 40 countries. However, the majority of these vessels belong to a few developed countries, as shown in Figure 1 (Juniper, 2013).

Figure 1. Geographic distribution of offshore research vessels (60 m or greater in length). Source: International Research Vessel Database.

At sea, most biological specimens are collected by lowering or towing sampling devices from the vessel (Juniper, 2013). Heavier gear, e.g., winches, cables, dredges and corers, is required to sample the seabed, where the majority of known marine species are found. This latter requirement reinforces the importance of larger, motorized research vessels for accessing biodiversity at depths of several kilometres. Some sampling devices are highly specialized and not all research vessels have the same collecting capacity. This is especially true for remotely operated vehicles (ROVs), which are used to locate and sample hydrothermal vent ecosystems, a source of novel species adapted to extreme conditions. Hydrothermal vent sites are very small in area, usually tens to hundreds of square meters, and cannot be easily sampled or even located by lowering standard sampling devices from ships. They require precisely navigated diving with ROVs or human-occupied submersibles, although the latter are used less frequently than ROVs. These vehicles are capable of diving to much deeper depths than military submarines, and are equipped with robotic arms, video cameras and various sampling devices. The list of States possessing and operating deep-diving scientific submersibles is limited to a subset of the developed countries currently leading marine scientific research efforts

globally, such as the USA, Canada, the UK, France, the Russian Federation, Japan and most recently China, India and South Korea (Juniper, 2013). ROVs can also be chartered from commercial firms that provide support for the offshore petroleum industry, but most of these vehicles are limited to depths of less than 2,000 metres.

6.2 Biodiversity Expertise

Another important capacity related to accessing and deriving value from marine biodiversity is the specialist knowledge required to identify species, both known species and those new to science (Hendriks & Duarte, 2008; Juniper, 2013). Marine biodiversity specialists are mostly trained in developed countries with a long history of botanical and zoological scholarship in universities and museums. One way to measure the worldwide distribution of marine biodiversity expertise is to examine the level of publication activity in the scientific literature in relation to the country of affiliation of the lead author on these publications. A recent review of the literature revealed that the majority of publications in the field of marine biodiversity come from relatively few developed countries (Hendriks and Duarte, 2008).

Table 1. Geographic distribution of patent claims for genes of marine origin.
Source: Arnaud-Haond et al. (2011).

Country	Marine Organism Patent Claims
USA	199
Germany	149
Japan	128
France	34
United Kingdom	33
Denmark	24
Belgium	17
Netherland	13
Switzerland	11
Norway	9

These specialists are experts in the morphological identification of specimens and, increasingly, the interpretation of DNA sequence information that is used to identify marine plants, animals and microbes. It could be argued that this scientific expertise is of greater importance to the usage and application of MGR than is access to laboratories that can produce gene sequence and biochemical composition information from field samples. Many countries have commercial sequencing and biochemical analysis facilities that serve national and international organizations/institutions, and academic and private clients. The raw data produced by these facilities require expert interpretation before they can be used to identify species, genes and biochemical compounds of interest. Table 1 illustrates the dominance by applicants from a few developed countries in recent patent claims associated with genes of marine origin according to a database undertaken by Arnaud-Haond *et al.* (2011). The top ten

countries account for 90 per cent of filed gene patents, with 70 per cent from the top three (Arnaud-Haond et al. 2011). Relatively new approaches, such as microbial metagenomics, also require sophisticated bio-informatics tools and training and these are most accessible in developed countries. Nevertheless, some (growing?) capabilities in bio-informatics and genomics exist in developing countries, particularly in the health and agricultural science sectors, and these skills could be adapted and applied to the exploitation of MGRs.

6.3 *Deriving Economic Value from MGR*

Few examples exist of a direct developmental path from field collections of marine organisms through to the commercialization of marine natural products or genes from marine organisms. The Vent Polymerase enzyme is one example of a rapid transition from the discovery of a new microorganism in the field to the commercialization of a biomolecule (Mattila et al, 1991). Field research in the marine environment is primarily led by academic or government scientists and is aimed at increasing our knowledge of the ocean and the organisms that it supports. It is this knowledge base that may be later used by laboratory-based scientists in academia, industry and government in research more directly related to the eventual use of MGR for commercial purposes (Brock, 1997; Juniper, 2013). Surprisingly few direct connections are found between these basic and applied research sectors.

A review by the journal *Nature* (Macilwain, 1998) concluded that tens to hundreds of thousands of failed prospects exist for every example of a commercially successful natural product. One measure of success at extracting drugs from the sea is the number of drugs from marine organisms approved for commercialization by the FDA. Currently (June 2014) only seven drugs from marine organisms have received FDA approval (see also above), and approximately twice that number are in clinical trials (<http://marinepharmacology.midwestern.edu/clinPipeline.htm>). Mayer et al. (2010) note that the pre-clinical pipeline “continues to supply several hundred novel marine compounds every year and those continue to feed the clinical pipeline with potentially valuable compounds.”

Among the myriad marine life forms, the greatest unknown potential source of novel bioproducts is marine microorganisms (Gerwick et al., 2001). The advent and applications of genome, proteome, and transcriptome analyses are helping to recognize the enormous extent of marine microbial diversity and deepening our understanding of how the chemistry of the ocean and its interaction with the atmosphere are also mediated by microbial metabolism. From the bioprospecting perspective, the biomolecules produced by marine microbes remain virtually unstudied for potential commercial applications.

Microbial bioproducts will remain undeveloped unless there is a feasible alternative to mass culturing and efficient harvesting. In general, molecular approaches offer particularly promising alternatives, not only to the supply of known natural products

(e.g., through the identification, isolation, cloning, and expression of genes involved in the production of the chemicals), but also to the discovery of novel sources of molecular diversity (e.g., through the identification of genes and biosynthetic pathways from uncultured microorganisms; Bull et al., 2000).

6.4 “Omics” Tools

Recent breakthroughs in marine metagenomics are paving the way for a new era of molecular marine research. Metagenomic studies of marine life are yielding new insights into ocean biodiversity and the functioning of marine ecosystems; for the first time we can explore ecological interrelationships at the gene level. The first study of this type, led by the J. Craig Venter Institute, used these tools to survey marine microbial diversity, discovering thousands of new species, millions of new genes and thousands of new protein families. A seminal 2004 paper described how the analysis of 200 litres of surface water from the Sargasso Sea enabled the identification of about 1,800 genomic microbial species and 1.2 million unknown genes using an environmental metagenomic shotgun approach (Venter et al., 2004). This work led to other marine metagenomic studies, such as those reviewed by Gilbert and Dupont (2011) that show how massive sequencing of environmental samples can lead to the discovery of extraordinary microbial biodiversity and to the unravelling of important components of the pathways of phosphorus, sulphur, and nitrogen cycling. These powerful molecular tools are enabling a new “study it all approach” to discovering organismal, genetic, biomolecular and metabolic diversity in the oceans at an accelerated pace, as exemplified by the recent round-the-world Tara expedition (Ainsworth, 2013) that returned over 25,000 samples of water column organisms for intensive molecular analysis with so-called ‘omics’ tools.

7. The importance of understanding life histories, plasticity and the impact of climate change

Climate change and ocean acidification are widely recognized as increasing threats to marine ecosystems impacting growth, survival, reproduction, and many other phenotypic features of all marine organisms, leading to changes in species abundances and distribution. Many key marine invertebrates, including crabs, echinoderms and molluscs often have equally if not more complex life histories with several, vulnerable, free-swimming planktonic stages before they metamorphose and settle to their adult benthic form. These sophisticated morphological and physiological processes are underpinned by complex gene regulatory networks and genomic pathways (Gilbert, 2013). This is significant because although it is now increasingly clear that predicted climate change events will affect marine biota, it is also now clear that several key organisms exhibit a valuable plasticity in the face of environmental stresses and challenges (Byrne and Przeslawski, 2013; Chan et al., 2015a, b; Dorey et al., 2013; Harley

et al., 2006; Merila and Hendry, 2014; Reusch, 2014; Stumpp et al., 2011a, b; 2012; Thor and Dupont, 2015). Understanding and exploring this potential will be vital if we are to identify resilient and potentially phenotypically plastic populations. Identification of the genetic bases of this plasticity will be an important resource to the future of exploited marine species in a changing ocean.

8. Conclusion

The commercial utilization of MGRs had very modest beginnings in the 20th century, particularly when measured against the estimated potential of the great diversity of species and biomolecules in the sea. More promisingly, the past decade has seen the commercialization of the first drugs derived from marine organisms, and considerable growth in nutraceutical and other non-medical uses of marine natural products. This past decade has also seen an astounding increase in our capacity to discover novel marine organisms and biomolecules and understand the genomic basis of life in the oceans. New technologies are fostering a new wave of optimism about the commercial potential of MGRs that is influencing funding priorities for marine research and has led to the emergence of futuristic terms, such as ‘blue growth’ and the ‘knowledge-based blue economy of tomorrow’. Much of the capacity for discovery and commercialization of MGRs remains in the hands of a few developed countries. Much of the genetic diversity in our seas and oceans remains unknown and relatively unexplored; yet more potential is to be realized, particularly in the context of climate change. While this chapter has emphasized the commercial utilization of marine genetic resources, there are strong arguments to be made for the value to societies and ecosystems of simply protecting and conserving marine genetic resources (e.g. Pearce and Moran, 1994).

Additional Reading

The European Marine Board (<http://www.marineboard.eu/>) has been responsible for generating policy advice, position papers, vision documents, etc., that review the importance of “blue biotechnology;” most are available as free downloads, for example “Marine Biotechnology: a Vision and Strategy for Europe” (<http://www.marineboard.eu/publications/full-list>). This is a review of the state of the art in marine biotechnology and its significant potential to contribute to scientific, societal and economic needs (2010). In addition, the European Commission has hosted several projects that summarize and highlight the needs and advantages of developing coordinated programmes for harnessing and sustainably exploiting products from our seas and oceans; often generically referred to as “Blue Growth,” it includes all aspects of marine and maritime technology (http://ec.europa.eu/maritimeaffairs/policy/blue_growth/index_en.htm).

Other organizations, for example the National Association of Marine Laboratories (NAML) (<http://www.naml.org/>) in North America also produce regular position papers from marine expert groups.

Chapter 30. Marine Scientific Research

Contributors: Patricio Bernal (Lead member), Alan Simcock (Co-Lead member)

1. Introduction

A scientific understanding of the ocean is fundamental to carry out an effective management of the human activities that affect the marine environment and the biota that it contains. This scientific understanding is also essential to predict or forecast, mitigate and guide the adaptation of societies to cope with the many ways the ocean affects human lives and infrastructures at different spatial and temporal scales.

Ideally, in order to manage human activities so as to achieve sustainable use of the marine environment and its resources, we need to know the geology and geophysics of ocean basins, the physical processes at work as the waters of the world's different oceans and seas move around, the input, distribution and fate of substances (both natural and artificial), the occurrence and distribution of flora and fauna (including the assemblages and habitat dependencies that control the different ecosystems), the biological processes that regulate and sustain the productivity of ecosystems and the way in which all these elements interact. Marine scientific research is the main way in which we can move towards this goal.

From a more fundamental perspective, the ocean is still one of the least known areas of the world. Humanity in its search of understanding has reached beyond our solar system and seeks fundamental answers in the infinitely distant and in the infinitely small. It has been said that we know more about the morphological features on the surface of other planets than of our own ocean. A significant effort of ocean exploration, using the most advanced techniques available today, is still probably one of the most rewarding collective efforts for humanity, as is attested to by the series of achievements of major international scientific programmes of the past.

Sustainability has to do with the mode by which humanity make use of nature. The increasing pressures that we impose on natural systems leave no room for complacency. At any point in time it is possible to extract the best advice that science can provide to completely or partially remove uncertainties around a phenomenon. From a scientific point of view, the need for better information always exists, therefore unresolved uncertainties are not a valid ground for delaying action. There are many improvements that can be made to managing human impacts on the ocean on the basis of current scientific knowledge. However, it is not long since the need to effectively communicate scientific results to policy makers has been recognized and is being systematically addressed through internationally validated efforts. At the national level, it is becoming common practice among institutions funding research to request those receiving their grants to undertake explicit initiatives of outreach towards the general public or to summarize the result of

publicly funded research for policy makers. From a more basic perspective, publicly funded projects in data intensive sciences, like earth sciences, geophysics, and genomics are requested to deposit and disseminate the raw data collected through open access repositories.

The traditional knowledge of those who work with the sea has, in many cases, built up over millennia an understanding of many of these elements. It is essential that this traditional knowledge also be incorporated in our overall understanding of the ocean. Marine scientific research has an important role in validating traditional knowledge and identifying emerging issues. Marine scientific research is therefore fundamental to achieving sustainable use of the oceans.

2. The scale and extent of marine scientific research

The scale and extent of marine scientific research are as wide as the scope of the World Ocean Assessment: every field that needs to be covered in an assessment of the state of the world's marine environment needs to be explored scientifically. This Assessment therefore shows the results of the work that is being done in all these fields and assesses the major gaps in information, thus pointing the way to judgements on priorities for further scientific research.

In order to obtain a full picture, it is necessary to consider where, by whom and how the scientific research is being done. This is not an easy task, because until now no systematic collection of this information has occurred, although the Intergovernmental Oceanographic Commission of UNESCO (IOC/UNESCO) has initiated a process to produce regularly a Global Ocean Science Report (GOSR) aiming to conduct a global and regional assessment of capacity development needs in the field of marine science research and ocean observations.

One starting point is the question of who is doing this research. The IOC/UNESCO maintains a database of "ocean and freshwater experts", which can be analysed to help answer this question. The IOC/UNESCO database is compiled on the basis of voluntary self-recording by experts without any independent validation procedure (<http://www.oceanexpert.net>). There is therefore no reason to think that it is comprehensive, and the status and experience of the experts listed may vary. Examination suggests that it contains practically no experts whose expertise is solely in fresh water, and that nearly all experts have chosen to declare a geographic area of study. It therefore enables an initial understanding of research demographics for the various parts of the ocean. Table 1 shows the information on geographic areas of study derived from an analysis of this database. As this information is provided individually by the experts without any independent validation procedure, any analysis based on it may well be affected by biases or incompleteness in the database, and as much of the detail of the information provided is determined by the experts themselves, any analysis is bound to be fairly broad-brush, but this database is the best comprehensive basis available for examining the question of the spread of interests of marine scientists. This appears as a gap of information that needs to be addressed.

Table 1. Regions of study of IOC experts

Area of Study declared by experts	Experts located in a coastal State of Area of Study	Experts located elsewhere	Total number of experts declaring an interest in the Area of Study
Arctic Ocean	59	78	137
North Atlantic Ocean	519	208	807
Baltic Sea	91	7	98
Black Sea	135	11	146
Mediterranean Sea	393	71	464
North Sea	117	4	121
Wider Caribbean	314	12	326
South Atlantic Ocean	169	562	731
Indian Ocean	588	137	625
Red Sea	61	18	79
The Persian Gulf	49	16	65
North Pacific Ocean	375	102	477
- West Pacific ocean and fringing seas	100	34	134
South Pacific Ocean	157	102	259
Southern Ocean	142 ¹	6	148

Source: Analysis of IOC, 2014.

Subject to the reservations explained above about the nature of the evidence, the main conclusions are that:

- (a) Significantly more marine scientific researchers regard themselves as experts on the Atlantic Ocean than on the Pacific Ocean
- (b) The Indian Ocean is relatively well served by marine scientific researchers; and
- (c) The two main Southern hemisphere ocean basins (South Atlantic and Pacific and the Southern Ocean) attract relatively fewer marine scientific researchers.

¹ For the Southern Ocean, the coastal States have been taken to be those States that maintain research stations on Antarctica.

3. Status and trends of scientific output by regions

3.1 *Status and trends relating to personnel*

An alternative approach to assessing the capacities for marine scientific research by region is to review the number of scientific papers published about each region. This approach also suffers from limitations, and care must be exerted in using it. Some of the issues in assessing the numbers of scientific papers published about the different regions lie with the language of publication and the cost per publication. Although most of the international scientific literature is published today in English, a large potential bias remains with regard to scientific papers and reports published in other languages, or in local journals not reported to international data bases. Although some data bases containing full-text articles address these issues, for example, SciELO (Scientific Electronic Library Online; <http://www.scielo.org>) for several geographic areas and CNKI (China Knowledge Resource Integrated Database; <http://www.cnki.net>) for China, the risk of under-reporting of certain countries, languages and regions exists. Another issue is the attribution of the origin of papers. Usually, the attribution is assigned according to the location of the principal, first or corresponding author. This means that the attribution of where work has been done will exclude the location of junior authors in the multi-authored papers, which are now very common.

The analysis below shows the global results analyzed by region of scientific papers published on oceanography from one database for scientific papers which has a wide coverage – ScImago (<http://www.scimagojr.com/>). Although the papers used are classified *sensu lato* as “oceanography”, the data base lists articles in 122 journals with a broader scope than what is usually understood as “oceanography” in the strict sense (Appendix). The journals covered are those that were regularly published in 209 distinct jurisdictions, national or otherwise (described as “countries and territories” in the data base) over the 17 years between 1996 and 2013.

During the 19 years of the data base, a healthy, clear, positive trend of increasing scientific contributions on oceanography each year from around 7,000 to nearly 14,000 altogether is shown (Figure 1). On the other hand, the number of countries from which contributors are drawn has shown only a slight increase of about 20 new countries in 17 years, probably due to the fact that the database is reaching the upper limit of the number of countries.

Figure 1. Increase in number of scientific papers on oceanography. Adapted from Analysis of ScImago, 2014.

When the countries and territories are grouped into eight regions, the following breakdown emerges of the origins of the 213,760 articles published between 1996 and 2013 (Figure 2).

Figure 2. Geographic areas of origin of scientific papers on oceanography 1996 – 2013. Source: Analysis of ScImago 2014.

These proportions per region, with North America and Western Europe having the highest number, do not differ significantly from those obtained when analyzing papers from other scientific disciplines. This suggests that they accurately reflect the level of scientific activity in general, not merely a situation specific to the marine sciences, and therefore that this analysis may reflect common, broad issues on available research infrastructure, investment and institutional development that,

together with appropriate national policies, do control the development of scientific research in general.

3.2 *Status and trends relating to equipment*

Almost as important as the personnel involved in marine scientific research are the facilities available to them. It is even more difficult than with the personnel to gain an overall view of how far researchers studying the marine environment have adequate equipment. Nevertheless, one indication can be gained from the available information about research vessels. The University of Delaware in the USA maintains an online catalogue of research vessels, including both surface and submersible vessels, and their cruise schedules (www.researchvessels.org). This covers 836 research vessels based in 59 countries, including both publicly owned and commercial research vessels. Again, given that it relies on voluntary recording, it is not comprehensive, but gives a general impression of the distribution of research vessels. Judging by their size, many of these vessels are for coastal operations: 224 are less than 20 m length, while only 138 larger than 80 m. Of those with ocean going capabilities 179 are clustered between 40 and 60 m and 139 between 60 and 80 m. The different capabilities of the vessels can be roughly assessed by the type of equipment they have. All vessels in the database have echo-sounding capabilities, while only 187 are equipped with Conductivity, Temperature and Depth probes (CTDs), 124 with Acoustic Doppler Current Profilers (ADCP), 116 with multi-beam mapping systems and 57 with dynamic positioning systems. Of all the reported fleet 129 have icebreaker capabilities and 103 can berth and deploy remotely operated vehicles (ROVs), autonomous underwater vehicles (AUVs) or submersibles. It is likely that many members of the modal classes (40-80 m length) are fisheries R/V or multipurpose platforms capable of fisheries survey capabilities (acoustic or standard trawling). Table 2 shows an analysis of the areas in which these research vessels are based.

Table 2. Marine Research Vessels

Geographic Area of the World	Number of Research Vessels reported	Largest number recorded in the Geographic Area by one State
Africa	6	4 (South Africa)
Asia	179	108 (Japan)
Eastern Europe	153	116 (Russian Federation)
Western Europe	184	39 (United Kingdom)
North America	288	230 (USA)
Oceania	10	7 (Australia)
Latin America and Caribbean	29	7 (Argentina)
Total	849	

Source: Analysis of IRVSI 2014.

Even with the limited information available, this analysis shows a preponderance of research vessels based in the northern hemisphere. Closer analysis suggests that the vessel capacities for research in the Indian Ocean, in other parts of the waters around Africa and in much of the Pacific Ocean are also limited. Anecdotal information suggests that this imbalance is also applicable to other equipment needed for marine scientific research.

4. Collaboration in Marine Scientific Research

One way of overcoming imbalances in national capabilities to undertake marine scientific research is through international joint activities.

Oceanography has always been considered as an international endeavour. The organizers of the Challenger Expedition, that conventionally marks the origin of modern oceanography, took every step necessary to secure the contribution of the best international specialists of the time to produce the fifty volumes of the Challenger Report, containing the results of the Expedition. The first efforts in the study of the North Sea, North Atlantic and the Arctic were also international, and gave rise to the creation in 1902 of the International Council for the Exploration of the Sea (ICES), which plays a fundamental role in codifying the methodologies that enable progress in physical and chemical oceanography.

After the Second World War, the main event that brought together international scientific cooperation was the International Geophysical Year (IGY) of 1957-58. Although the IGY included some oceanographic research, this was not its main focus and the oceanographic community reacted to this situation by planning a major international expedition to the least-known ocean basin at the time: the Indian

Ocean.

These initiatives gave rise to two international institutions: first, the Scientific Committee of Ocean Research (SCOR) under the International Council of Scientific Unions (ICSU) in 1957 to coordinate ocean research in the IGY, and then the IOC/UNESCO in December 1960, following a recommendation of the First Oceanographic Congress held in July 1960 in the Danish Parliament. During the International Indian Ocean Expedition, the IOC coordinated the efforts of 27 nations employing over 40 oceanographic research vessels in more than 70 cruises in the Indian Ocean during 1962-1965.

Later SCOR and IOC, through the regular organization of the Joint Oceanographic Assemblies, kept the focus of the community on the design of international research programmes. For example, the Committee on Climatic Changes and the Ocean, sponsored by SCOR and IOC, is at the origin of two global research projects of primarily physical studies: the World Ocean Circulation Experiment (WOCE) and the Tropical Ocean-Global Atmosphere Study (TOGA) also co-sponsored by the World Climate Research Programme (WCRP). WCRP was established in 1980 under the joint sponsorship of ICSU and the World Meteorological Organization (WMO) and since 1993 the IOC has also sponsored it.

In the 1980s two major international programmes requiring ocean going capabilities were co-sponsored by SCOR, the International Geosphere-Biosphere Programme (IGBP) and jointly with IOC: first the Joint Global Ocean Flux Study (JGOFS), focusing on the role of the ocean in the global carbon cycle, and second the Global Ocean Ecosystem Dynamics (GLOBEC) programme. Over ten years GLOBEC developed seven regional comparative studies to understand marine ecosystem responses to global changes, including both environmental and human pressures, and produced over 3,500 publications, including 30 special issues of primary journals. The Integrated Marine Biogeochemistry and Ecosystem Research (IMBER) programme has followed GLOBEC.

SCOR and IOC/UNESCO have also developed the Global Ecology and Oceanography of Harmful Algal Blooms (GEOHAB) Programme with a focus on obtaining an understanding of the ecological and oceanographic conditions that cause harmful algal blooms and promote their development. Other international programmes are the Global Coral Reef Monitoring Network and the Census of Marine Life, a ten year effort focusing on the biology of the ocean that mobilized more than 2,700 scientists, published 3,100 scientific papers and described 1,200 new species for science, leaving as one of its legacies the Ocean Biodiversity Information System (OBIS), the largest repository of marine biodiversity to date.

In the domain of marine geology and geophysics, the Integrated Ocean Drilling Programme, that initially built and operated the R/V *"Glomar Challenger"* in the seventies, was followed after October 2013 by the International Ocean Discovery Programme (IODP) currently operating the R/V *"JOIDES Resolution"*. These international programmes were instrumental in developing the technology to drill the sea floor and to obtain the long cores that provide a wealth of research activities expanding our knowledge in different areas, including plate tectonics and seismology.

In geochemistry, the Geochemical Ocean Sections Study, GEOSECS, obtained very accurate sections and profiles of the distribution of chemical, isotopic, and radiochemical tracers in the ocean, building a global three-dimensional view of the chemical composition, including alkalinity, of the ocean, enabling the establishment of a solid baseline to measure acidification worldwide. GEOSECS is now being followed by GEOTRACES, which is measuring the distributions of trace elements in the sea.

4.1 The development of a permanent infrastructure to observe the Ocean.

Perhaps one of the most fundamental changes in marine scientific research was the realization that what was needed to underpin many of the more focused or local research efforts was a common infrastructure to observe the oceans at the global but also at other relevant temporal and spatial scales. In the late 1980s, oceanographers had come to realise that the ocean played a tremendously important role in the climate system through its ability to store large amounts of heat and to move this source of energy for the atmosphere slowly around the globe. Accordingly, understanding and forecasting climate change was seen to require observations over much longer periods of time, than the time-limited experiments such as the ocean observations done during the First GARP² Global Experiment (FGGE) during 1978-79 or the TOGA study, which ran from January 1985 to December 1994.

In 1989 IOC's Technical Committee for Ocean Processes and Climate (TC/OPC) recommended the design and implementation of a global operational observing system. The WMO Executive Council endorsed that call in June 1989, as did the 15th IOC Assembly in July 1989. Finally, in June of 1990, the Intergovernmental Panel for Climate Change (IPCC) called for a Global Ocean Observing System (GOOS) which was endorsed by the Second World Climate Conference in September 1990, that saw GOOS as a major component of the proposed Global Climate Observing System (GCOS). In February 1991, the TC/OPC agreed that the concept of GOOS should be broadened to include physical, chemical and biological coastal ocean monitoring; climate was no longer to be the sole focus. In May 1991, WMO's 11th Congress accepted to co-sponsor the GOOS.

Existing physical oceanographic observing systems developed over the years by UNESCO/IOC became fundamental building blocks of GOOS. For example, the IOC's global sea-level observing system (GLOSS) and the joint IOC/WMO Integrated Global Ocean Services System (IGOSS), which included the Ship-of Opportunity Programme and the drifting and other buoys of the Data Buoy Cooperation Panel.

The creation of GOOS reflected the desire of many nations to establish systems of ocean observations dealing with environmental, biological and pollution aspects of the ocean and coastal seas, to raise the capacity of developing nations to acquire and use ocean data effectively and to integrate existing systems of observation and data management within a coherent framework.

² GARP is the Global Atmosphere Research Programme

That desire was reflected in the call made in Rio de Janeiro from the United Nations Conference on Environment and Development in June 1992 to develop GOOS as one of the mechanisms required to support sustainable development. This required that the initial focus on climate research had to be enlarged to include other aspects, like the impact of pollution and the status of marine living resources. The Health of the Ocean (HOTO) Panel was established as an *ad hoc* group in 1993, and became a formal advisory group to J-GOOS in 1994. An *ad hoc* Living Marine Resources (LMR) Panel met in 1993 and in 1996, and an *ad hoc* Coastal Panel met in 1997.

IOC/UNESCO and WMO gave first priority to the implementation of the physical oceanographic component of GOOS, as the ocean component of the climate observing system GCOS. This part of GOOS has been successfully in operation since 2005; however the development of the other parts of GOOS has continued as new technologies emerge and mature, enabling the automatic long-term measurements of chemical and biological variables.

4.2 *Operating Systems of GOOS*

Although fundamentally underpinning most of the research conducted to understand the role of the ocean in climate change, strictly speaking GOOS is not a research project. GOOS should be better recognized as a *large and distributed scientific facility* or infrastructure, equivalent to the large observatories of astrophysics or the big accelerators of particles of physics. This section describes its components (IOC/GOOS, 2015).

4.2.1 *Surface moorings*

Surface moorings are large fixed buoys, moored to the bottom of the ocean, mostly deployed in the Equatorial region. They measure surface winds, air temperature, relative humidity, sea-surface temperature and subsurface temperatures from a 500-m-long thermistor chain hanging below the buoy. Daily data are broadcast to shore through satellite links (TAO, 2015).

4.2.2 *Argo Profiling Floats Programme*

The Argo floats are autonomous observation systems which drift with ocean currents making detailed physical measurements of the upper 2 kilometres of the water column. Floating along at a depth of 2,000 metres, every 10 days an Argo float awakens and increases its buoyancy by pumping fluid into an external bladder. During its journey upward through the water column, it records the conductivity (salinity) of the seawater, its temperature, and pressure. Once at the surface, the Argo float finds its geographical position via global positioning systems (GPS) and transmits its data by satellite to Argo data centres. After completing the upward profile it decreases its buoyancy and sinks again, collecting a similar record on the trip down to 2000 m. The information is joined with data from over 3,000 other Argo floats to form a synoptic 3-D view of the ocean in near real time (<http://www.argo.ucsd.edu/index.html>).

About 800 profiling floats are deployed on a yearly basis by a number of States. Between 2004 and 2009, 26 States deployed at least one float to maintain a global

array of 3,200 units, spaced 3° by 3° of latitude and longitude. Profiling float technology has evolved to reach the initial desired five-year lifetime, and a float deployed today will probably last between 5 and 10 years. Argo floats spend 90 per cent of their time at 2,000-m depth and on average rise to the surface every ten days to transmit their data.

This system has revolutionized oceanography since its inception in 1998 through the Climate Variability and Predictability (CLIVAR) programme and the Global Ocean Data Assimilation Experiment (GODAE).

Argo floats take more than 100,000 salinity and temperature profiles each year, more than 20 times the number of annual hydrography profiles taken from research ships. The Argo array is maintained by the active engagement of 30 countries that contribute floats and ship-time for the deployments. The original engineering specifications of the floats were made available to many research institutions around the world and floats are now made in several countries. The International Argo Steering Team oversees technically the project and operations are monitored at the Argo Information Centre, a part of the IOC – WMO, Joint Technical Commission of Oceanography and Marine Meteorology - operational centre (JCOMMOPS).

Argo data have transformed ocean circulation studies. Today Argo data are routinely assimilated into global circulation models, giving accurate and timely global views of the circulation patterns and heat distribution of the ocean. This product has become an essential element of atmospheric forecast models and greatly improves seasonal climate, monsoon, El Niño forecasts, as well as tropical cyclone simulations. The value of subsurface heat content measurements to the study of global warming and climate change has made the Argo an invaluable component of 21st-century environmental observation systems.

4.2.3 *The Ship-of-Opportunity Programme (SOOP).*

Ships of opportunity are usually ordinary cargo ships on regular routes, whose owners and crew agree to carry and, where necessary, operate oceanographic equipment during their regular voyages. Other types of vessel are also used. The Ship-of-Opportunity Programme (SOOP) and its Implementation Panel (SOOPIP) is an operational programme under the intergovernmental governance of the Joint WMO-IOC Technical Commission for Oceanography and Marine Meteorology (JCOMM). The primary goal of SOOP is to satisfy upper-ocean data requirements which have been established by GOOS and GCOS, and which can be met at present by measurements from ships of opportunity (SOO).

SOOP operates a global network of Expendable Bathythermograph (XBT) and ThermoSalinoGraphs (TSG) systems on board of merchant ships, from which data are transmitted in real time and made available to the oceanographic and meteorological communities for operational use in ocean models and for other scientific purposes. Around 14,000 XBT probes are launched every year and more than 30,000 TSG observations are collected annually. Other types of measurements are also made. The following devices are commonly used:

- (a) *XBT (Expendable BathyThermograph)* is an expendable (disposable) temperature- and depth-profiling system;

- (b) *TSG (ThermoSalinoGraph)* is an automated sea-surface temperature and salinity measurement system for making continuous underway measurements from the ship's water intake;
- (c) *CTD* is an electronic set of instruments to make precise conductivity, temperature, and depth measurements. The instrument is connected to the ship by a conducting cable; Accuracies better than 0.005 mS/cm are usually achieved for conductivity, better than 0.002° C for temperature, and better than 0.1 per cent of full-scale range for depth;
- (d) *XCTD* is an expendable (disposable) conductivity, temperature and depth profiling system.
- (e) *ADCP (Acoustic Doppler Current Profiler)*. A beam of sound of known frequency is reflected from small particles moving with the water. Adequate sampling of this backscattering beam allows current measurements by the Doppler effect at different depths. ADCPs can, for example, be installed on the hull of the ship "looking downwards" or lowered from a ship to different depths to measure a wider range of current profiles. An accurate GPS positioning system can then be used on a moving ship to subtract the ship's speed from the measured current vector;
- (f) *pCO₂*. Measurements of the "partial pressure of CO₂" (pCO₂) on the ocean surface indicate whether the local ocean is acting as a source or a sink of CO₂. Measurements use a standardized infrared analyzer or a gas chromatograph to determine the concentration of CO₂. The probe is installed in the hull of a ship, and measurements can be made while the ship is under way. Partial pressure of CO₂ in the air can also be measured. Accuracies in the order of 0.2 parts per million can be achieved.

4.2.4 Hydrography

The direct sampling of ocean water by lowering bottles from a ship and bringing water samples up on board ship for analysis remains one of the fundamental tools of ocean observations. A CTD rosette, equipped with Niskin bottles, is lowered to its deepest point and then as it is winched up to the ship the bottles are closed, one at a time, capturing a CTD profile of the water column along the way. The water can be sampled for CO₂, chlorophyll, microorganisms, biogeochemistry, and a wide variety of other uses. The International Ocean Carbon Coordinating Programme and the CLIVAR Programme organize and coordinate major hydrography cruises and maintain databases of tens of thousands of hydrography profiles taken throughout the world's ocean. These programmes provide essential data streams for GOOS, as they provide precise and accurate *in situ* measurements that benchmark observations measuring the penetration of heat in the ocean or the changes in alkalinity, monitoring the ocean's uptake of CO₂ that is changing the ocean acidity levels.

4.2.5 Surface drifting buoys

The Global Drifter Programme manages the deployment of surface drifting buoys around the world. These simple buoys take measurements of seawater-surface

temperature, salinity and marine meteorological variables that are telemetered in real time through the WMO's Global Telecommunications System (GTS) to support global meteorological services, climate research and monitoring. The surface drifters are a flexible component of GOOS and can be deployed quickly for such tasks as monitoring an approaching typhoon. The global array is designed to use 1,250 buoys to cover the oceans at a resolution of one per 5° x 5° of latitude and longitude. This array provides over 630,000 sea-surface observations per year. The surface temperature data are used to calibrate satellite temperature imagery, bringing bias errors down from 0.7° Celsius to less than 0.3° C, allowing accurate climate-change monitoring. Along with the Argo profilers, the surface drifter programme has contributed to the success of a real-time monitoring system of the oceans, enabling much more accurate weather and climate forecasts.

4.2.6 Continuous Plankton Recorder

Launched over the side of a research vessel, merchant ship, or other vessel of opportunity, the Continuous Plankton Recorder (CPR) captures plankton from the near-surface waters as the ship tows the instrument during its normal sailing. Since 1946, the CPR has been regularly deployed in the North Atlantic and North Sea on several routes. The CPR is a critical component of GOOS and monitors the near-surface plankton in the North Atlantic and North Sea on a monthly basis from a network of shipping routes. Many other tracks around the world are now covered by the CPR programme. The amounts and types of phytoplankton and zooplankton captured by the CPR are analyzed in a laboratory. After analysis, the counts are checked and added to the CPR database, which contains details of the plankton found in over 170,000 samples taken since 1946 in the North Sea and North Atlantic Ocean, and increasingly elsewhere.

4.2.7 Global Sea Level Observing System (GLOSS)

The Global Sea Level Observing System (GLOSS) is an international programme conducted under the auspices of the JCOMM of the WMO and the IOC. It coordinates a network of sea-level monitoring gauges installed along the coasts of over 70 countries. The main component of GLOSS is the "Global Core Network" (GCN) of 290 sea-level stations around the world for long-term climate-change and oceanographic sea-level monitoring. Each station is capable of accurately monitoring sea-level changes with high accuracy, and many are able to transmit information in real time via satellite links. The GLOSS sub-network that transmits in real time is part of the global tsunami warning systems.

Real-time measurements of water-level changes can provide tsunami warnings for locations surrounding the affected sea basins. Sea-level observations are also useful for local navigation and continual refinement of tide-table predictions. Tide gauges measure rising water levels from storms and extreme tides, which can be responsible for billions of United States dollars in damage and lost productivity every year.

4.3 Ocean Biological Data

As a result of the ten-year-long effort by the Census of Marine Life, a significant

increase in biological data took place. This new data was integrated to pre-existing data into the Ocean Biodiversity Information System (OBIS <http://www.coml.org/global-marine-life-database-obis>). Several of these new data streams are associated to the tagging and tracking of live animals, for example the Tagging of Pacific Pelagics (TOPP) programme in Western North America and the Australian Animal Tracking and Monitoring System (AATAMS). The tagging of marine animals, fish, birds, turtles, sharks, mammals, with electronic sensors is increasingly being undertaken by scientists worldwide to track their movements. Electronic tags such as archival, pop-up archival and satellite positioning tags are revealing when, where and how marine animals travel, and how these movements relate to the ocean environment. (<http://www.scor-int.org/observations.htm>). An Ocean Tracking Network is being developed. The network will track thousands of marine animals around the world using acoustic tags safely attached to the animals. At the same time, the network will be building a record of data relevant to climate change, through observation of changes in the animals' patterns of movement.

5. Socioeconomic aspects of marine scientific research

Three major points emerge from the foregoing analyses and the material in other chapters on the results of marine scientific research in the fields they cover.

First, the success of the management of human activities that affect the marine environment is conditional upon having reliable information about that environment. If adequate information is not being collected, then management decisions will be less than optimal. Parts of the world that do not have adequate infrastructure for an adequate collection of information about their local marine environment are disadvantaged. Although research based in other parts of the world may provide a good understanding of how the marine ecosystems operate, and of the pressures to which they are subject, such a general understanding must be supplemented by adequate local information. Such collection of local information is always likely to be more efficient, effective and economical.

Second, as the world's marine environment is very much interconnected, sub-optimal management in one part of the world is likely to affect the quality of the marine environment in other parts of the world. This is the case of land-based point-sources of pollution that, depending on circulation, can broadcast their negative impacts across maritime borders; or if stocks of marine living resources are not well managed in one part of the world, diminishing the landings of a certain target-species, this may increase fishing pressure on the same or similar species in other parts of the world.

Third, even though universities and other educational establishments produce good-quality marine experts throughout the world, graduates will experience pressure to move to those parts of the world where they can hope to have access to the best equipment for their further research. It is only in that way that they can hope to develop their careers most successfully. Such a "brain drain" will undermine efforts to establish adequate marine research in all parts of the world until appropriate local

conditions for the development of scientific research exist.

6. Environmental impacts of marine scientific research

Any observation of a natural system has the risk that it will disturb that system. Proper design of marine scientific research can reduce, or even eliminate, this risk. It is particularly important that efforts that aim at improving the understanding of marine ecosystems should not damage those ecosystems.

The IOC has an important role in establishing safeguards for marine research projects that risk adversely affecting the marine environment. Efforts have been increasingly made to address this task. The International Ship Operators forum, answering to concerns of the impact of both ship operations and marine scientific research operations, developed a Code of Conduct for Marine Scientific Research Vessels that was approved at the 21st International Ship Operators Meeting (ISUM) in Qingdao, China. The code calls for *“the utilisation of environmentally responsible practices”* (...) and to *“adopt the precautionary approach as the basis for the proposed mitigation measures”*. *“Every vessel conducting marine science should develop a marine environmental management plan”* which *“should be designed to employ the most appropriate tool(s) to collect the scientific information while minimizing the environmental impact.”* Among the activities addressed by the code are: dredging, grab & core sampling, lander operations, trawling, mooring deployments, remotely operated vehicle (ROV) sampling, jetting system operations for cable burial, high intensity lighting for camera operations.

Other example can be taken from the Argo floats programme. Every year, about 1 per cent of floats are beached or trapped in fishing nets. These are recovered, secured and redeployed when possible, or recycled through a procedure coordinated by JCOMMOPS. All other floats finish their mission at depth, which is the best compromise found to date to limit the impact on the environment: (1) to avoid energy consumption to recover the instruments at sea by the use of motor vessels, and (2) to avoid having floats drifting at the surface for a long time (after a set of predefined cycles) and becoming a potential issue for navigation. The total mass of float hardware reaching the sea floor every year (less than 30 tons), and more precisely the small fraction of polluting material inside, can be more than fairly compared to old metro trains sunk to provide structure for artificial reefs, merchant ships, fishing vessels, off-shore stations, lost containers and decommissioned offshore oil platforms, that sink to or stay on the sea floor.

Technological improvement now allows the use of a bi-directional telecommunication system, which can “control” the behaviour of the platform by sending new configuration parameters and receiving data. About 30per cent of the Argo array is now equipped with this system. A float can then be asked to stay at surface to await its imminent retrieval. This is already being done today in pilot projects, and is used in particular to recover biogeochemical floats, which are equipped with expensive sensors and require some post-calibration. The involvement of civil society (for example, the yachting community, non-

governmental organizations and foundations) and industry in offering deployment opportunities to cover large ocean areas can be also a way to improve retrieval capacity. This requires a large networking capacity and is encouraged by IOC through its operational Centre JCOMMOPS. The manufacturers of floats are also encouraged, with rest of the world industry, to use environmentally friendly materials, whenever possible. As Argo is the main pillar of the ocean climate warning system, the ratio between advantages and disadvantages for the environment is judged to be more than satisfactory by the marine scientific research community, and at the same time that community continues to develop strategies to mitigate its impact.

Another example of the development of precautions against damage to the marine environment from marine scientific research concerns hydrothermal vents. In the 1990s, an international organization called Interridge was established and is today supported by China, France, Germany, Japan, the United Kingdom and the United States of America, together with Canada, India, Norway, Portugal and the Republic of Korea as associates, to pool resources for the investigation of oceanic ridges. Within this framework, recommendations have been developed on how to protect hydrothermal vents during research (Interridge, 2001). This provides a helpful model for developing protocols to ensure that marine scientific research does not harm the very objects that it wants to study.

7. Conclusions and capacity-building and information gaps

Major disparities exist in the capacities around the world to undertake the marine scientific research necessary for proper management of human activities that can affect the marine environment. The other chapters of this Assessment demonstrate how these disparities constrain the tasks of managing these human impacts. Capacities to undertake marine scientific research exist in most parts of the world.

Although a full assessment of all the existing programmes of capacity development is beyond the scope of this chapter, several long-standing international programmes have addressed these disparities. For example, the Train-Sea-Coast Programme, established in 1993 by the United Nations Division for Ocean Affairs and the Law of the Sea (DOALOS) with initial funding from the United Nations Development Programme and then by the Global Environment Facility, although now closed, aimed to build capabilities to enhance national/regional capabilities on key trans-boundary topics/problems in coastal and ocean-related matters. Topics addressed were quite wide, and ranged from coastal zone management, marine pollution control to marine protected areas and responsible fisheries. On geophysics, the IOC/UNESCO has maintained an annual Training Through Research ocean-going programme for young students to acquire hands-on experience in the operation, use and interpretation of data from current equipment used in marine geology and geophysics. In the area of living marine resources, the Food and Agriculture Organization of the United Nations (FAO) and Norway have developed for the last 40 years the ocean-going Nansen Programme funded by the Norwegian Agency for Development Cooperation (Norad) and executed in a partnership between the

Norwegian Institute of Marine Research (IMR) and FAO. The first R/V *Dr Fridtjof Nansen* was commissioned in October 1974. The third version of the R/V is currently being built and expected to be commissioned in 2016. The International Seabed Authority (ISA) has three active training streams, the *Endowment Fund* supporting the participation of qualified researchers from developing countries in cooperative research on the seabed; the *ISA/Contractors Training programme* aimed at training developing countries' scientists and managers and the *ISA Internship Programme* that, in a twofold approach, receives young scientists and managers from developing countries at ISA headquarters to learn about the goals and functions of ISA, but also receives young, highly qualified personnel to reside and contribute for short periods to ISA activities.

Many other international training initiatives on marine sciences, bi-lateral or multilateral, do exist, especially in the academic/education domain, but no comprehensive global reporting or cataloguing of these important efforts exists to date.

Gaps remain in the abilities to integrate the results of scientific research into the development of policy: capacity-building gaps thus exist in creating an effective science/policy interface first and foremost at the national level, but also at the regional and global levels.

Furthermore, efforts to fill the capacity-building and information gaps identified in other chapters will be much less productive if they are not made against a background of developing a global coverage of systems that can provide adequate integrated management information to global, regional and national authorities. This will be both more efficient and more economical, because a coherent body of scientific information will ensure that unexpected results of human activities and efforts to manage them will not go undetected, and will avoid duplication and overlap.

As this chapter has suggested, systematic information and knowledge about the progress of marine science is lacking. This therefore strengthens the case for supporting within the UN System the IOC's efforts to develop a World Ocean Science Report (see Decision EC-XLVII/6.2) that would eventually complement the existing World Science Report of UNESCO.

Chapter 31. Conclusions on Other Human Activities

Contributor: Alan Simcock (Lead member)

1. The nature and magnitude of the human activities

1.1 *Communications and transport*

The network of shipping routes covers the whole ocean. There are particular choke points, where large numbers of ships pass through relatively limited areas, with consequent increases in the risks of both disasters and chronic pollution problems. The impending opening of the Panama Canal to larger ships will tend to modify the pattern of ship movements. Global warming is likely to lead to more use of the routes between the Atlantic and Pacific Oceans through Arctic waters, with increased risks to ecosystems that have slow recovery times, and where infrastructure for response to disasters does not currently exist. Shipping traffic grows in relation to world trade, and considerable further growth is therefore likely. Cargo ships have been steadily increasing in size, but limits are probably being reached because of the draught limitations of some of the world's choke points. More emphasis is being placed in many areas on coastwise movement of goods by ship to reduce pressures on roads. Passenger shipping is largely divided into cruise ships and ferries. The cruise-ship market is growing steadily and is also moving to larger vessels. Ferries are most important around the Baltic Sea, the North Sea and the Mediterranean Sea (where there are large international cargo movements over relatively short crossings) and in States with a large scatter of islands (such as Greece, Indonesia and the Philippines).

Ports form the nodes of the network of shipping routes. General cargo ports have changed completely over the past 50 years with the introduction of containerization. A hierarchy of these ports is developing, with transshipment as cargoes are cascaded to the ports nearest to their final destinations. Specialized oil and gas ports are naturally located near the sources of supply and the major centres of demand. This pattern is likely to change as a result of changes in the oil and gas markets. Other bulk terminals respond to the same drivers. In some cases, there are challenges because of the location of sources of supply or established delivery centres near important sites for marine ecosystems and biodiversity.

Submarine cables likewise cross nearly all ocean basins. The development of fibre-optic cables in the 1980s permitted the parallel development of the internet. Submarine pipelines linking land-terminals are relatively limited in their coverage, being mainly found in the Mediterranean Sea, the Baltic Sea and the waters around the United Kingdom. The environmental challenges that they present are the same as those for pipelines linked to offshore oil and gas operations.

1.2 *Waste*

All parts of the ocean are affected by waste materials arriving by a variety of routes. Waste can take the form of discharges of liquid waste from land and emissions to the air, of dumping solid waste and other matter at sea, and of marine debris resulting from poor management of waste on land, discharges of garbage by ships and loss of fishing gear. Areas of particular concern are large conurbations, where large amounts of human bodily waste have to be disposed of, and areas of heavy industrial concentrations. Sewage from areas of high human population does not inevitably cause problems, since it can be treated to remove the potential to cause problems. However, in many parts of the world, particularly in developing countries, there is a lack of adequate sewage collection and treatment systems, and large amounts of untreated sewage are discharged to the sea. Much progress is being made in some places (particularly South America), but there is still a vast amount of further installation needed. Likewise, methods exist to avoid discharges of hazardous substances from industries, or to control them to acceptable levels, but these are not being applied everywhere. In this context, the massive growth of chemical industries in East Asia over the past decade-and-a-half presents particular difficulties. High levels of use of agricultural fertilizers and pesticides are also leading to discharges and emissions of nutrients and hazardous substances. Recent studies suggest that windborne transport of all these kinds of emissions is causing problems in the open ocean.

1.3 *Extractive industries*

Offshore oil and gas exploration and development is focussed in specific geographic areas where important oil fields have been discovered. Notable offshore fields are found: in the Gulf of Mexico; in the North Sea; off the coast of California (in the Santa Barbara basin), United States; in the Campos and Santos Basins off the coast of Brazil; off the coast of Newfoundland, Canada; off West Africa, mainly west of Nigeria and Angola; in the Gulf of Thailand; off Sakhalin Island on the Russian Pacific coast; in the Persian Gulf, on the Australian North West Shelf and off the west coast of New Zealand.

Offshore mining is a localised activity and is currently limited to relatively close to the shore. The activity on the largest scale is sand and gravel dredging, which takes place in Canada, Denmark, Japan, the Netherlands, the United Kingdom, and the United States. Other minerals extracted from the seabed include tin, titanium ores and diamonds. Countries where such activities are currently active include Australia, Brazil, India, Indonesia, Malaysia, Myanmar, Namibia, New Zealand, South Africa and Thailand. Other minerals currently being considered for extraction include gold (Alaska, United States) and iron (New Zealand – where currently a permit has been refused by the Environmental Protection Authority). The impacts are largely in the form of smothering the seabed. As regards deep-sea mining in the Area (the seabed and ocean floor and their subsoil beyond national jurisdiction) no actual extraction has yet started. Without careful management of such activities, there is a risk that the biodiversity of areas affected could be destroyed before it is properly understood.

1.4 Coastal zone

All around the world, there is a constant interaction between sea and land. On rocky coasts, changes usually take place over geological time. On softer coasts, the changes can happen within a human lifetime. The changes happen both by the sea eroding land and by sedimentation creating new land. In many places, humans assist these processes, either by undertaking works to protect the land against erosion, or by reclaiming land from the sea. Significant areas of land reclamation have occurred in Europe (about 15,000 km²) and in Asia (about 12,000 km²) over the past century. This has led to losses of much coastal habitat (especially of mangroves, salt marshes and coastal flood plains) and to significant adverse effects from changes in the form of the coast (in particular, the creation of “armoured”, artificial coastlines). In comparison, about 15 km² is eroded from the coast of Europe every year. An important driver in reclamation processes is the increasing proportion of the human population who live in coastal areas.

Tourism and recreation is a major use of the coastal zone. It is also a significant element of many national economies, and (especially in the case of many small island States) it may be the main support of the local economy. In most cases, the attractions of a coastal tourist resort will lie in beaches, dramatic scenery or interesting flora and fauna (either on land or in the sea), or some combination of these. But the natural attractions have to be linked to the provision of adequate facilities for the tourists. In many cases, therefore, there is an inherent tension between conserving the natural attractions and developing the necessary facilities.

1.5 Other activities

The other activities discussed in Part V have very distinct profiles. Desalinization is crucial for the States on the southern shore of the Persian Gulf: without it, the present populations of that area could not be supported. The same applies to some island States, such as Malta and Singapore. Elsewhere, it is more of a fall-back for situations when natural water resources are insufficient, but may have an important role in avoiding constraints on urban development and in facilitating mining in desert areas. Renewable energy production from the sea (through offshore wind-farms and from wave and tidal power) is still in its infancy in much of the world, but clearly has great potential for growth. The use of marine genetic resources is also in its infancy. Finally, marine scientific research is fundamental for improving the management of all other human activities that affect the ocean. Without adequate coverage of all parts of the ocean, it will be difficult to make progress.

2. Socioeconomic aspects of the human activities

2.1 Communications and transport

Shipping is fundamental to the world economy, both for the supply of raw materials to those who will process them as well as for the delivery of agricultural and industrial products to consumers. The lead time for the delivery of new ships and the fluctuations in the world economy mean that there are substantial variations in the demand and supply sides of shipping, with consequential effects on the profitability of the industry. Ship-building has become concentrated in East Asia, and ship-breaking in South Asia. The personnel of the industry are drawn mainly from North America, Europe and South and East Asia, with Africa and South America being under-represented. At present supply and demand for qualified officers and crew are more or less in balance, but there is a risk of a lack of qualified officers and crew if and when the world economy expands rapidly. Women form only about two per cent of those employed in shipping, and are mainly on cruise ships and ferries. There is a lack of information about deaths and injuries to seafarers.

The move in general cargo shipping to containerization has revolutionized ports: investment in machinery that requires skilled operators has ended the need for large numbers of dockworkers capable of handling heavy loads by hand. The efficiency of port operations is very important for ship-operators. Increasingly, the ports in a region are in competition with each other, and the charges are affected by the extent to which port charges are expected to cover the costs of construction and maintenance of ports and their road links to the hinterland. The quality of port infrastructure and operations varies widely, although many developing countries achieve the highest standards in both.

The provision of submarine cables is driven by demand for internet bandwidth. This shows no signs of slowing its growth. Submarine cables to carry the traffic are mainly provided by consortiums of telecommunications companies, internet service providers and private-sector investors. The market appears to be working smoothly.

2.2 Waste

The socioeconomic aspects of waste reaching the sea have both direct and indirect features. Waterborne pathogens are commonly carried with sewage. These can seriously affect human health, both through bathing in contaminated water, and through eating fish and seafood contaminated with them. Other wastes have socioeconomic implications by affecting food quality and through their effects on fish and other species used for food by, for example, adverse effects on reproduction. More indirectly, effects of waste on water quality can damage tourism and reduce the aesthetic, cultural, religious and spiritual ecosystem services that humans get from the sea.

2.3 *Extractive industries*

The offshore oil and gas industries are significant for the economies of the countries that have started them: the industry accounts for about 21 per cent of Norway's gross domestic product (GDP), 35 per cent of Nigeria's GDP, 3.5 per cent of the United Kingdom's GDP and 1.5 per cent of United States GDP. The number of people employed is relatively small: estimated at 200,000 worldwide.

Compared with land-based mining, the extraction of minerals from the seabed is a very small-scale activity. The United Kingdom industry for extracting sand and gravel seems to be the largest, with 400 employees.

2.4 *Coastal zone*

Since a high proportion of humans live in the coastal zone, there is a preoccupation with making sure that: (1) land used for housing, industry or agriculture is not lost or flooded, (2) the demand for land suitable for urban development and ports (and in some cases agriculture) is met, and (3) existing homes and infrastructure are not destroyed. This leads to a readiness to invest substantial amounts in both coastal protection and land reclamation. The long-term effectiveness of hard engineering approaches to these tasks has been called into question, and in many parts of the world the approach tends more towards adjusting the natural process of erosion and sedimentation to achieve the desired ends.

As has been said, in many parts of the world, tourism and recreation is a major economic activity in the coastal zone. It requires a relatively high proportion of labour in preparing and serving food and in cleaning and maintaining accommodations, providing jobs that in many regions are strongly seasonal. A high proportion of these jobs are filled by women.

2.5 *Other activities*

Desalinization is essential for the continued existence of many States. It may likewise be important for avoiding constraints on future economic development in other places. Renewable energy from maritime sources, which is beginning to be implemented in some parts of the world, has a significant potential role to play in mitigating climate change,. The use of marine genetic resources offers possibilities of finding and applying new marine ecosystem services. Marine scientific research is an essential underpinning of managing the sustainable use of the ocean.

3. Pathways from the human activity to its environmental impacts

3.1 *Communications and transport*

There are three main pathways by which shipping impacts on the environment: loss of ships, chronic discharges and emissions, and noise.

Ports also impact on the environment in three main ways: the demand for coastal land (which often leads to reclamation of the necessary land from the sea), changes in the form of the coast (with hard coastlines replacing softer ones) and dredging to maintain navigation channels (and the consequent need to dispose of the dredged material). Ports also inevitably lead to concentrations of shipping, and therefore represent areas where the impacts of shipping are equally concentrated.

Submarine cables have very limited environmental impacts, since they are very slim (typically 25 – 40 millimetres wide in the deep sea), and since their routes are usually chosen to avoid, where possible, areas that may cause problems from bottom trawling and ships' anchors. In soft substrates on continental shelves the cables are usually buried by ploughing, but again the zone affected is narrow.

3.2 *Waste*

Waste products reach and affect the marine environment through a variety of routes. Liquid discharges may reach the sea either through discharges to rivers or directly through pipelines. Waste emissions to air can be carried to the sea directly, or through run-off from the land on which they are originally deposited. Substances applied to land may volatilize and be re-deposited, either directly to the sea, or through successive re-volatilizations and re-depositions. Solid waste and other matter may be deliberately dumped into the sea, or may reach it from badly-managed waste disposal on land.

3.3 *Extractive industries*

The offshore oil and gas industries affect the marine environment through six main pathways: the effects of seismic exploration during the exploration phase; the drill cuttings (and the drilling muds used to lubricate the drills which are mixed with them) that are discarded on the seabed; the chemicals that are used and discharged during operation; the produced water (and its admixture of oil) that is discharged during production, and which increases in quantity as the wells age; the gas that may be flared off during production; and the oil spills that may occur. In addition, there is the question of the disposal of offshore production platforms when they are decommissioned at the end of the field's life.

Since offshore mining is currently based on dredging, the impacts on the marine environment come from disturbance of the seabed and (except with sand and gravel extraction) the discharge of the dredged material that is rejected as not containing the minerals that are sought. Disturbance of the bed of the deep sea by future mining has considerable potential to harm benthic biodiversity, about which there is as yet limited knowledge.

3.4 *Coastal zone*

There are two main ways in which anthropogenic change to the natural processes of erosion and sedimentation along the coast affects ecosystems. First, wherever and

however the anthropogenic change happens, there are likely to be consequential changes in the processes elsewhere in the general neighbourhood. Secondly, such change usually involves moving from soft shore forms (gravel, sand or mud) to hard shore forms (stone or concrete). In addition to these two processes, changes in land affecting river regimes (for example, through the building of dams) tend to reduce the flow of sediment from land to sea, weakening beach replenishment, as well as weakening the force of rivers, which can lead to the extension of sand bars at their mouths.

Significant provision of tourist and recreational facilities usually leads to major changes in the shore environment. Hard shorelines can replace soft ones. Urban development can destroy the natural hinterland of the shore. Night-time lighting can significantly affect habitats. Increased discharges of sewage (especially if not properly treated) can produce the problems associated with excessive nutrient discharges. Regular cleaning of beaches removes the natural detritus which is important for many shore-living birds and animals.

3.5 Other human activities

The pathways by which desalinization can affect the marine environment are mainly through its intakes of seawater and discharges of brine. The energy required for desalinization can also have important implications when it is provided by the burning of fossil fuels. Most forms of renewable energy generation make substantial demands for ocean space which cannot be used for other purposes. The structures required for wind-farms may have effects on migrating birds, but with proper planning these seem to be limited. Although potential pathways for environmental effects exist for other forms of human activity, they are currently judged to be minimal. Provided collection of specimens is done with care, there is no reason why the development of the use of marine genetic resources should adversely affect the marine environment. Marine scientific research has to be involved with all forms of marine biota and habitats, but provided proper protocols are followed, no significant adverse effects should result.

4. Major ecosystem impacts

4.1 Communications and transport

Steady progress has been made in reducing the numbers of ships lost at sea, thus damage to the environment from shipping disasters has dropped significantly, particularly in respect of the amounts of oil spilled in such disasters. Regimes have been established to control chronic discharges from ships, in particular in the form of oil, sewage, garbage and air pollutants. Measures have also been taken to deal with invasive species carried in ballast water and with wrecks. The challenge now is to improve enforcement of these regimes. Noise from ships may well be a source of significant human impact on marine life. Losses of containers overboard are low.

Ports have an important role to play in enforcing the control regime over ships. Since they are often in competition with other ports in the region, the regional memorandums of understanding on port state control have an important function. The quality of port reception facilities for waste oil, sewage and garbage is also important in reducing environmental impacts of ports and their users. The disposal of dredged material needs proper management. Even where the material is harmless, it can damage bottom-living plants and animals by smothering them. Where the material contains contaminants (usually from historic industrial activities), disposal at sea risks remobilizing them and again requires proper management.

Submarine cables have always been at risk of breaks from submarine landslides, mainly at the edge of the continental shelf. As the pattern of cyclones, hurricanes and typhoons changes, submarine areas that have so far been stable may become less so, and thus produce submarine landslides and consequent cable breaks. With the increasing dependence of world trade on the internet, such breaks (in addition to breaks from other causes, such as ships' anchors and bottom-trawling) could delay or interrupt communications vital to that trade.

4.2 *Waste*

Waste material introduced into the ocean can cause problems for the marine environment in a variety of ways. Hazardous substances (heavy metals, persistent organic pollutants, polycyclic aromatic hydrocarbons (PAHs), pesticides and endocrine disruptors) can be toxic to marine biota, reduce their reproductive success or weaken their immune systems so that they succumb more easily to disease. Excessive discharges and emissions of nutrients (particularly nitrogen compounds) from human bodily wastes, animal excreta, food-processing plants, agricultural fertilizers and traffic can produce hypoxic (low oxygen) dead zones in the sea, which can kill bottom-living plants and animals and reduce fish stocks. They can also cause algal blooms which can smother beaches and which can consist of algae species that generate toxins harmful both to humans and marine life. Pathogens in human and animal waste can cause illness from contact with the water into which they are discharged and from food from the sea that they contaminate. All these impacts undermine human health and ecosystems and make them much less resilient to other pressures.

4.3 *Extractive industries*

It is possible to regulate all the pathways by which the offshore oil and gas industries affect the marine environment to keep the impacts at an acceptable level. The success of such regulation depends on the regulatory methods chosen and the degree to which they are enforced. The impact of noise disturbance from seismic exploration depends very much on the overlap of the area to be explored with the habitats of marine life that is sensitive to noise. These animals often have seasonal patterns of migration, and seismic exploration can be timed so that overlaps do not happen. Information on the impact is limited. The impact of drill cuttings is mainly

from the drilling muds with which they are mixed, although some release of metals can occur from the rock cuttings themselves. Regulation of the drilling muds used can control this problem. The same approach can be used to control the chemicals used on, and discharged from, offshore installation. Produced water, because of its quantity, has to be discharged to the sea. The problem which it poses is the oil content. This oil content can be largely removed by centrifuges, and an acceptable level (usually 30 parts per million or less) can be achieved. In the North Sea, steps have been taken to tighten limits as the amount of produced water increases. Spills from offshore installations or breaks in pipelines occur. The main safeguard against such spills is the proper environmental management of the whole operation. In at least one region, steps have been taken to encourage high standards of such management. There are two main approaches to the removal of decommissioned installations. Under 1989 IMO Guidelines, installations should be removed so that there are 55 metres of clear water over any remains. In the North Sea, removal of the rest of the installation is the norm, although exceptions can be made. In the Gulf of Mexico, it is much more usual to allow installations to be placed to form artificial reefs.

For current offshore mining, the main issue are the turbidity created by the dredging and the management of the disposal of unwanted dredged material. In most cases, both are likely to mean that the area mined will be effectively cleared of marine biota. Recovery and the scale and speed of re-colonization after mining has ceased in an area will very much depend on local circumstances.

4.4 Coastal zone

The form of consequential changes resulting from anthropogenic changes to the land/sea boundary will depend entirely on local circumstances: it may take the form of promoting erosion that would not otherwise have happened, because the longshore water movements are re-focused, or it may take the form of causing siltation where it has not previously happened, or it may be a mixture of these in different places. Only very careful modelling during the planning process can hope to identify the consequences, and even then the best models can prove not to have been adequate. Where soft shorelines are replaced with hard shorelines, the local biota will be affected. It will become more difficult for animals to move from sea to land and back, which may disturb their foraging or breeding patterns. It may also affect local plant communities. Such changes are likely to make the shoreline less resilient. Finally, it will offer a new hard substrate to biota that arrive, which is likely to change the local fish and shellfish communities. The natural consequence of beach erosion is the landward retreat of coastal habitats, but this natural process is hindered by coastal development, which causes so-called "coastal squeeze"; there is no space for the habitats to retreat. Coastal squeeze results in the fragmentation and removal of some habitats and the species they support. Finally, in areas where sediment loads have increased above natural levels, impacts include burial of habitat, reduced light levels caused by turbidity, changes to substrate (e.g., mud draping over once rocky habitat), and smothering of coral reefs and other sessile fauna.

Tourism and recreational development is likely to produce all the problems of coastal development described above. In addition, it is likely to lead to large numbers of people walking on the shore (and thus compacting sand and disturbing breeding sites) and using the water (and thus disturbing larger animals and fish (not least with noisy motorized devices), creating oil films on the water surface from sun-tan preparations and leaving litter that becomes marine debris).

4.5 *Other activities*

Any effects of desalinization intakes and discharges are very local – a matter of tens of metres – and even these can be reduced by proper design. The remaining other activities should not create major environmental impacts, but the use of autonomous floats in marine scientific research needs – and is receiving – care over their eventual fate.

5. Integration of environmental and socioeconomic trends

5.1 *Communications and transport*

The levels of activities in shipping and in the ports that it uses, and the demand for submarine cables, all respond fairly directly to the world economic situation. The growth of industry in the Pacific basin, especially in the west, means that the pressures from all forms of communications and transport will particularly increase there. Growth in communications and transport activity means that, even if all ships, ports and cables achieve the best currently practicable level of environmental protection, the pressures from them will nevertheless continue to increase. Since the environment is finite, it will only be possible to limit the pressure on the environment to no more than current levels, if improved performance in safeguarding the marine environment against those pressures is achieved.

5.2 *Waste*

Waste generation has tended to increase at least in step with economic growth. In some ways, economic growth has generated additional forms of waste, particularly through the development of packaging to protect agricultural and industrial products. It is only relatively recently that efforts have been devoted to waste minimization. Population and industrial growth means that, even if the best currently practicable levels of waste reduction and control are generally achieved, there will be increasing pressure on the finite marine environment. As with shipping, this implies that continuous improvement in environmental protection is needed.

5.3 *Extractive industries*

The creation of an extractive enterprise is the result of a decision balancing the economic benefits to be gained against the environmental and other impacts. It is

therefore important that, when a decision is initially taken, there should be a clear view of what measures will be required to protect the marine environment. There is now widespread understanding of what is required in most environments. Problems arise, however, when the circumstances of a new development are very different from past experience. This is particularly the case in Arctic conditions, where natural processes to break down contamination will be slower because of the cold.

5.4 Coastal zone

Socioeconomic pressures are likely to be strongly in favour of intervention to reclaim land and prevent erosion. With economic growth, there will be pressure for ports to improve their capacities, which is likely to require more land. Short of complete relocation of the port, reclamation of land from the sea may be the only option. Equally, where erosion or flooding is threatened, there will always be pressure to safeguard existing investments in housing, industrial buildings and infrastructure.

Because of the economic importance of tourism and recreation in so many places, there is usually pressure to extend tourist facilities. The problem is that too great an extension is likely to lead to devaluing the attractions that enabled a tourist industry to develop in the first place, and thus to undermine the justification for any extension. Without integrated coastal zone management to balance economic gain against environmental change, there is a risk that the basis of the economic gain can be eroded.

5.5 Other activities

Pressures to increase the amount of desalination that is carried out will result from pressures to expand populations in water-poor locations. The economic and social drivers of such developments are outside the scope of this Assessment. The need for mitigation of climate change is undeniable, and the economics of expanding the amount of energy produced from marine renewable sources will depend on judgments about how far this form of mitigation is good value. Much of the genetic diversity in our seas and oceans remains unknown and relatively unexplored. Without marine scientific research, it will be difficult (if not impossible) to achieve and maintain sustainable management of all human activities affecting the sea.

6. Environmental, economic and social influences

6.1 Communications and transport

The global shipping industry has recognized the need for improvement of its environmental performance. States have thus adopted, through the International Maritime Organization (IMO), a range of measures to try to improve the industry's performance. Enforcement of these measures is crucial. The IMO has now started a collective process to improve the performance of its members in this enforcement.

For submarine cables, the International Cable Protection Committee brings together cable owners, maintenance authorities, cable system manufacturers, cable ship operators, cable route survey companies and governments to consider all aspects of ensuring the safety of submarine cables and reducing their impact on the environment.

6.2 *Waste*

Global systems have been put in place to control persistent organic pollutants and mercury. These offer the possibility that the impacts of some forms of hazardous substances on the marine environment will be brought under control. In some regions (for example, the European Union), more general systems have been set up for controlling present and future chemicals that are placed on the market. There is general recognition in most international investment programmes of the need to improve sewage collection and treatment in many developing countries. The Global Programme of Action to Protect the Marine Environment from Land-Based Activities provides a framework within which States can consider their overall approach to these problems. The challenge is to make all these various steps operational.

6.3 *Extractive industries*

Offshore oil and gas extraction is usually significantly more expensive than extraction on land by normal drilling processes. Placer mining from the coastal seabed, however, may well not be much more expensive than winning the same minerals on land. Commitment to offshore developments will therefore depend on judgements about future demand, costs and prices. The hydrocarbon market is currently changing significantly with the emergence of new sources such as “fracking” and the Athabasca oil sands. The global market in hydrocarbons, and the other minerals mined from the seabed, will therefore determine the pressures to develop marine extractive industries further. However, in the longer term, the increasing difficulties of sourcing minerals on land are likely to increase the interest in mining the bed of the deep sea. The International Seabed Authority is charged with regulating such activity in the Area.

6.4 *Coastal zone*

In the absence of integrated coastal zone management, with its capacity to bring together in one decision-making process all the various factors that can affect the sustainability of a coastal zone, there are bound to be problems in balancing the different factors involved in the land/sea interface and in maintaining a successful tourist industry.

6.5 *Other activities*

The factors that will affect developments in the other human activities discussed in Part V are those sketched out above.

7. Capacity building gaps

The capacity-building gaps identified in this Part are summarised in Chapter 32 (Capacity-building in relation to human activities affecting the marine environment).

Chapter 32. Capacity-Building in Relation to Human Activities Affecting the Marine Environment

Group of Experts: Renison Ruwa, Sean Green, Amanuel Ajawin, Osman Keh Kamara, Alan Simcock and Lorna Innis

1. Introduction

The oceans provide various ecosystem services or what are also referred to as the "benefits that people desire from ecosystems" (Millennium Ecosystem Assessment, 2005). It is therefore necessary to know the types or nature of services that humans receive from the oceans and the scale or level of human activities that can be exerted without causing imbalances that could affect sustainability. Achieving sustainability requires strong public understanding of the importance of the ocean. This therefore calls for enhanced outreach and communication efforts through the development of mechanisms and partnerships to build capacity for outreach and awareness programmes. The major types of ecosystem services are described in Chapter 3. For sustainability the following are needed: scientific understanding of the services; assessment of the level of food production which results from various ecological processes, in order to address food security and safety; assessment of aesthetic uses of the ocean environment; and the level and type of capacity for studying and managing human activities and their impacts arising from exploitation of the ecosystem services. The level of capacity-building reflects, among other things, the efforts at identifying knowledge gaps in science, technological advances, human skills development and infrastructure.

To fulfil the overall objective of the Regular Process, all States need to address the overall objectives of the Regular Process as set out in the reports of the Ad Hoc Working Group of the Whole (AHWG) to the United Nations General Assembly (UNGA) (A/64/347, 65/358), and the United Nations Secretary-General's Report (A/65/69/Add.1) (UNGA 2010, UNGA/AHWG 2009 and 2010). This outcome can only be achieved with significant efforts at capacity-building. The Regular Process itself therefore promotes, facilitates, and, within its capabilities, ensures that capacity-building and technology transfer are undertaken through promoting technical cooperation, including South-South cooperation amongst developing countries and taking gender and equitable geographical distribution into account. Over the long-term (i.e., beyond this first Assessment), the Regular Process will support and promote capacity-building through identifying opportunities and facilitate linkages for international cooperation that includes technical cooperation and technology transfer with regard to developing countries (in particular the least developed countries, African coastal States and Small Island Developing States), in order to improve the capacity in these geographical areas

to undertake integrated assessments. Substantial capacity-building efforts are being undertaken by United Nations agencies through technical cooperation programmes. It is also important that gaps are identified and priorities shared so that a coherent programme to support capacity-building in marine monitoring and assessment, including socioeconomic aspects, is achieved. The approach for this first baseline Assessment was to conduct integrated assessments using the "Driver Pressure State Impact Response" (DPSIR) methodology commonly used to represent human-environmental /economic interactions, including scaling up assessments (national, sub-regional, regional and global). The workshops were also used as fora to explain the processes for conducting integrated assessments. The workshops were participatory and helped to promote ownership of the Regular Process outcomes at various scales. Furthermore, the workshops not only added further value in creating and promoting awareness of the Regular Process, but also promoted institutional capacity linkages. Various regional and international reviews of capacity-building have been conducted by various agencies. These also provide sources of information for a critical analysis of this subject, in particular for identification of gaps; therefore this chapter also includes an overview of these regional and international initiatives as per the chapters authored in this section.

This first Assessment has two chapters on capacity-building: one each in Parts V and VI. Part V deals with "Assessment of other human activities affecting the marine environment" and includes this chapter on "Capacity-building in relation to human activities affecting the marine environment." Part VI, entitled: "Assessment of marine biological diversity and habitats", includes Chapter 53 on "Capacity-building needs in relation to the status of species and habitats". The topics addressed in the chapters are based on the DPSIR Methodology as approved by the AHWGW. Furthermore, pursuant to the guidance of the AHWGW, the regional workshops will also contribute to identification of capacity-building strategies to address the approved themes in the two chapters on capacity-building for regional needs.

2. Outcomes based on regional workshops on capacity-building needs

The analysis showed that for most regions the main capacity needs were cross-cutting issues among the regions; these are summarized as follows: (i) Data accessibility and data sharing; (ii) The provisions for mentoring and training opportunities for less experienced scientists and practitioners; (iii) Data collection and marine habitat mapping to inform management of ecosystems, biodiversity and fisheries; (iv) Need to improve professional capacities to assess socioeconomic issues; and (v) Capacity to conduct integrated and ecosystem-services assessments.

The regional workshops were undertaken in the following regions: south-west Pacific region (UNGA 2013a), Wider Caribbean region (UNGA 2013b), eastern and southeastern Asian Seas (UNGA 2012a), South-East Pacific region (UNGA 2011), the joint North

Atlantic, Baltic Sea, Mediterranean and the Black Sea region (UNGA 2012b), the Western Indian Ocean (UNGA 2013c), South Atlantic Ocean (UNGA 2013d) and Northern Indian Ocean (UNGA 2014). The regional outcomes in terms of knowledge gaps and capacity needs were as follows:

2.1 Capacity needs for marine assessments in the south-west Pacific Region

This workshop was held in Brisbane, Australia, 25-27 February 2013 (UNGA 2013a). The focus was on linkages and upscaling from national to regional and global scales to promote synergies for building capacity which will include mentoring, learning and cooperation in communication, data and information transfer, as follows:

- The production of global marine assessments should be linked to ongoing efforts to support regional (led by the Secretariat of the Pacific Regional Environment Programme) and national state-of-the-environment reporting and streamlining of reporting arrangements (led by the Pacific Islands Forum Secretariat/Secretariat of the Pacific Regional Environment Programme). By providing capacity development and other support to these initiatives, the region will be better placed to contribute to and benefit from the Regular Process. The production of global marine assessments should be done in a way that provides mentoring and learning opportunities for less experienced scientists and practitioners.
- Active facilitation of involvement of practitioners from Pacific Island countries and territories in producing global marine assessments, including improved communication efforts to ensure awareness of the opportunity to be involved, assistance in registering for the Pool of Experts and resourcing support for and formal recognition of work done will all contribute to capacity-building in those countries.
- A large quantity of data and information exists, but it is often not readily identifiable or accessible. Enhanced regional and national capacities to store, access, share and interrogate data and information would assist the production of global marine assessments and facilitate the meeting of regional and national objectives.
- Resourcing is a substantial constraint on the capacity of the region to contribute to the production of global marine assessments. This can in part be addressed by the nature, scope and process for the development of assessments that more deliberately support national and regional objectives, as well as the objective of producing a global report. For example, the global marine assessment could provide region-specific information and access to the underlying data and information.
- Because of the limited capacity of the region to engage in the drafting of this Assessment, the review stage might be an efficient point for the region to ensure that regional information and perspectives are appropriately reflected therein. A second workshop or network among involved practitioners may provide

mechanisms for doing this. Similarly, providing support to an appropriate Pacific regional organization to facilitate and coordinate ongoing regional engagement may be useful.

2.2 *Capacity needs for marine assessments in the Wider Caribbean Region*

This workshop was held in Miami, United States of America, 13-15 November 2012 (UNGA 2013b). The emphasis was placed on: needs for projects to include capacity-building and have specialized research institutions and research vessels offer opportunities for training, including the use of ships of opportunity; specialized research institutions to offer learning and mentoring opportunities, especially data and information analysis and synthesis; building collaboration and networks across experts, institutions and a variety of stakeholders, and promoting a culture of manpower retention for sustaining research in institutions. Other points included:

- Previous or ongoing regional marine assessments, specifically the Caribbean Coastal Marine Productivity Programme, the Caribbean Planning for Adaptation to Climate Change Project and the Caribbean Large Marine Ecosystem Project, were highlighted as successful cases of capacity-building.
- In some disciplines, such as physical oceanography and remote sensing of the ocean environment, capacity is highly concentrated in a few institutions. In other disciplines, such as social sciences, it is highly dispersed.
- Access to research vessels (e.g., NOAA ships) and ships of opportunity (e.g., those used in relation to the Living Oceans Foundation) offer opportunities and synergies on a wider scale with advanced technology for enhanced marine assessments.
- Data are often abundant, including data collected by ships of opportunity; the limitation is in the capacity to manage the data, including how to organize, store, synthesize and analyse them. Participants discussed the need for nationals to study at institutions where data are already being used and then to bring the expertise home.
- Building collaboration among scientists, resource managers and other stakeholders is central to capacity-building, especially as it includes building a willingness to share and communicate. With this in mind, capacity-building in the region would benefit from establishing and promoting networks of practitioners, experts, institutions and countries and promoting regional programmes.
- A fundamental shortfall exists in capacity to integrate the key insights of existing research into policy and management agendas, and this is a core area where capacity-building would yield benefits.
- There would be great costs in capacity from failure to retain the knowledge that is invested in training employees and management leadership. Such retention requires fiscal incentives to retain individuals in positions. The constant cycle of promotion at all levels results in an export of knowledge out of the field. Often,

the bulk of expert individuals will be lost from policy and management to narrow academic research fields.

2.3 *Capacity-building needs for the eastern and south-eastern Asian Seas*

This workshop was held in Sanya, China, 21-23 February 2012 (UNGA 2012a). The focus was on building skills in integrated assessments, methodologies and quality assurance of data through effective creation of synergies and communication for data and information sharing. Creating awareness of the Regular Process within the scientific community of the region was emphasized. A successful WOA would require the ability to understand the implications of what we know about the status of biodiversity and link this with the state of the environment, as well as with ecosystem-based fisheries assessments in order to produce accurate fisheries status reports. In addition to assessing capture fisheries correctly, there is insufficient capacity for assessing impacts of aquaculture on the surrounding marine ecosystems and more generally for assessing environmental impacts that are anthropogenic, and/or due to climate change and invasion of alien species, as well as for socioeconomic assessments of human well-being. All these are candidates for capacity-building that would improve capacity to conduct integrated assessments. Other points included the following.

1. At the highest level, the workshop participants identified as the first priority the need for improved skills in and knowledge on the conduct of integrated assessments (i.e., including environmental, economic and social aspects). Such experience/skills were lacking throughout the region and training in methodologies for conducting integrated assessments would be of direct benefit to the Regular Process.
2. Additional short-term capacity-building needs (i.e., that could deliver results within the next 18 months) identified by the workshop included the following:
 - (a) Building awareness of the need for interoperability between States and regions regarding several areas, including: an international classification standard for marine economic activities; quality assurance/quality control for data collection and analysis; enhancing comparability and compatibility of data from different sources; and biological information management, including taxonomy;
 - (b) Improved international networking and resource sharing, including a network to facilitate international communication and cooperative platform-building related to marine environmental, social and economic data;
 - (c) Following the kind offer from UNEP, IOC-UNESCO and the Asia-Pacific Network for Global Change Research (APN), the organization of a regional workshop focusing on capacity-building and the technical and scientific aspects of the Regular Process would aim to share information about available assessments, data and knowledge of methodologies to be used

in compiling and developing the first global integrated marine assessment.

3. This regional workshop would aim at gathering scientists and relevant national authorities to raise awareness of the Regular Process within the scientific community of the region. The workshop would also aim at facilitating the appointment by States of individual scientists from the region to the pool of experts. The workshop would be co-organized by UNEP, IOC-UNESCO, GRID-Arendal, the North-West Pacific Action Plan (NOWPAP) and the Coordinating Body on the Seas of East Asia (COBSEA), with the support of APN.
4. Long-term capacity-building needs (i.e., that should be started quickly but which would only deliver results in the next three to five years) identified by the workshop included the following:
 - (a) Conduct of marine habitat mapping to inform management of ecosystems, biodiversity and fisheries. This included the development of skills in areas such as collection and analysis of remote sensing data, acoustic seafloor mapping, underwater video analysis and statistical analysis of biophysical environmental data;
 - (b) Long-term and well-planned biodiversity assessments were needed on both commercial and non-commercial marine species, including using genetic information to trace and determine stocks and species;
 - (c) Ecosystem-based fisheries assessment for capture fisheries and forecasting the status of fish and shellfish stocks;
 - (d) Assessing impacts of capture fisheries on the marine ecosystem;
 - (e) Assessing impacts of aquaculture on the surrounding marine ecosystem;
 - (f) Assessing impacts of habitat degradation (e.g., using ecological modelling and forecasting) on projected fish and shellfish stocks and aquaculture;
 - (g) Monitoring anthropogenic contamination of water, sediment and biota, to ensure maintenance of food security;
 - (h) Assessing impacts of climate change on marine biota and ecosystems, including the effects of ocean temperature change, ocean acidification, changes in coastal sediment and water discharge, changes in tidal and other currents, swell and wave patterns and coastal habitat changes due to sea-level rise;
 - (i) Assessing impacts of alien species;
 - (j) Assessing socioeconomic aspects.

2.4 Capacity needs for marine assessments in the south-east Pacific Region

This workshop was held in Santiago, Chile, 13-15 September 2011 (UNGA 2011). The focus was on addressing institutional and individual capacity-building, especially with regard to technical support and joint development and implementation of partnership projects. It called attention to the insufficient capacity to monitor harmful and alien

species using remote sensing capabilities, as well as creating capacity to organize databases using standardized tools and formats. It was also important to build capacity to assess the effects on biodiversity of human activities and to address biophysical and socioeconomic issues for human well-being. Other needs included:

2.4.1 Information

- Information on this vast ocean region of the South Pacific is scattered and has not been summarized and collated, although it exists in the form of reports of scientific expeditions, historical records of fishing activities (fishing fleets) and a large number of scientific publications. The large increase in databases on biodiversity from 5 million entries in 2005 to over 32 million geo-referenced records in 2011 was noted;
- The South-East Pacific Group of Experts considered it essential in the short term to strengthen the capacities of the competent technical bodies with regard to integrated assessment methods. The DPSIR methodology adopted by the UNGA as the conceptual basis for carrying out this first integrated assessment of the marine environment, although known in the region and widely used in the terrestrial environment, has thus far not been regularly used in marine environmental assessments. The fruitful exchange of information between experts from the west coast of the Americas, from Mexico to Chile is noted;
- Incorporate geo-referencing information systems for ecosystem-focused analysis;
- Improve information and monitoring systems;
- Compile base-line data, which is difficult and costly;
- Improve information systems that can be shared.

2.4.2 Capacity-building

- The South-East Pacific Group of Experts acknowledges the shortfall in ability to generate capacity to analyse the ocean environment in areas beyond national jurisdiction;
- More experts able to conduct research on climate change with reference to oceans;
- Capacity to organize databases using standardized formats and tools for access by the public;
- Strengthen methodology for economic assessment;
- Pilot project in Chile to harmonize economic assessment methodologies.

2.4.3 Knowledge gaps

- Technical support for the maintenance of equipment and sensors;
- Development of projects and research capacity on palaeoclimatology at the regional level, including effects on marine coastal areas (corals, sediments, ice cores, etc.);
- Monitoring of harmful algal blooms by remote sensing;

- Assessment of wide-scale processes at the level of the entire South Pacific Basin is of great importance in understanding and predicting the behaviour of living marine resources, particularly those exhibiting migratory behaviour (birds, turtles, mammals and pelagic fish species) in the south-east Pacific region;

2.5 Capacity needs for marine assessments in the North Atlantic, the Baltic Sea, the Mediterranean Sea and the Black Sea

This workshop was held in Brussels, Belgium, 27-29 June 2012 (UNGA 2012b). The meeting determined that transfers of skills within the region were needed and that the region can provide a source of knowledge and skills for other regions through creation of partnerships. It is necessary to address food security, marine biodiversity and habitats and information on anthropogenic impacts on the marine environment. Other points included:

- It was agreed that capacity shortfalls did exist within the area covered by the workshop, and that the region could serve as a source of knowledge for other regions. Transfers of skills within the region were needed both from north to south (particularly within the Mediterranean) and from west to east.
- Knowledge gaps at national and regional scales were identified in the report entitled “Analysis of the existing marine assessment in Europe”, prepared in June 2012, including information on:
 - a. Food security;
 - b. Marine biological diversity and habitats;
 - c. Human activity affecting the marine environment.

2.6 Capacity needs for marine assessments in the western Indian Ocean

This workshop was held in Maputo, Mozambique, 6-7 December 2012 (UNGA 2013c). The focus was on capacity needs to address biophysical issues, which are important for alteration of biodiversity, and socioeconomic impacts due to anthropogenic impacts which consequently influence human well-being. Further emphasis was placed on building institutional and individual capacity to address biodiversity, fisheries, tourism, aquaculture, information and data, mining, and economic valuation of natural resources and the environment for human well-being.

The experts assembled at this workshop clearly endorsed the Regular Process; however, capacity-building needs were not highlighted in the December 2012 workshop report. In the assessment workshop of August 2012 the following capacity needs and gaps were identified:

- Information on environmental flows for major rivers;

- Information on ocean acidification: degree and extent of ocean acidification resulting from human activities (including coral bleaching) and socioeconomic implications;
- Regional perspective on ocean-source carbonate production;
- Information on pollution determination from aquaculture use and modification of habitats;
- Environmental flow assessments of coastal, riverine and atmospheric inputs from land;
- Lack of capacity for assessing offshore hydrocarbon industries;
- Lack of capacity to assess offshore mining industries;
- Carrying-capacity studies need for tourism and recreation;
- Economic valuation of resources/environment.

2.7 *Capacity needs for the marine assessments of the South Atlantic Ocean*

This workshop was held in Grand-Bassam, Ivory Coast, 28 to 30 October 2013 (UNGA 2013d). The focus was on identifying knowledge gaps with regard to the biophysical, food security and safety, socioeconomic, and biodiversity aspects, based on which the capacity needs were identified.

2.7.1 *Biophysical aspects*

The principal gaps identified by the experts are: (i) Absence of continuous long time-series on sea-level rise and its impact on the coastal and marine environment; (ii) Absence of information on the knock-on effect of El Niño in the sub-region, especially in West Africa; (iii) Poor links between meteorological and oceanographic institutes; (iv) Lack of continuous, long time-series on acidification, especially *in situ* measurements at tropical latitudes; (v) Scarcity of studies on the factors influencing surface-layer and *species variation, notably studies based on in situ measurements of surface layers and plankton.*

2.7.2 *Food security and safety aspects*

In the South Atlantic region, many national institutions and regional organizations conduct assessments of the status of fish and shellfish stocks and fisheries. Although fisheries statistics are available, continuous time series are lacking in many areas. In fact, many assessments are project-related, so when financing stops, the data collection is discontinued. This happens in all countries; the only exceptions are Argentina and Uruguay, where fairly complete time series are available for the most economically important fish stocks. Vessel availability for independent fishery surveys is a constraint for the whole region.

2.7.3 Socioeconomic aspects related to fishing

The principal gaps identified by the experts in the economic evaluation of fishing activities are: (i) Scarcity of evaluations of economic consequences (risk assessment) of disasters and impact of other activities on fisheries and the living standards of fishers; (ii) Scarcity of studies on the impacts of the global economy on fisheries; (iii) Lack of data on post-fishing losses (during processing, marketing, etc.); (iv) Absence of studies on the impact of harmful algal blooms on fisheries in West Africa; (v) Lack of information on the contribution of artisanal fisheries.

The principal gaps identified by the experts on fishing practices and health and safety are: (i) Stock assessments of species caught by both the industrial and artisanal sectors (they are frequently pooled together, although some countries have good reporting systems); (ii) Scarcity of information on illegal, unreported and unregulated (IUU) fisheries, although the Food and Agriculture Organization of the United Nations (FAO) evaluates the implementation of the Code of Conduct for Responsible Fisheries country by country; (iii) Scarcity of assessments of incidental catches of marine mammals, turtles and birds, especially in the African countries; (iv) Scarcity of information on the number of people employed by the sector; (v) Ineffective implementation of health and safety control systems (poor reporting mechanisms).

2.7.4 Socioeconomic aspects related to environment

The principal gaps identified by the experts on environmental pollution affecting human health and their socioeconomic impacts are: (i) Poor reporting mechanisms and/or difficulty in accessing existing documentation (reports) on oil leakages and spills; (ii) Lack of information on the types and amounts of oil dumped into the sea and trends for the next decade; (iii) Poor capacity in the region to assess the disposal of solid waste in the ocean; (iv) Impacts of exploration and exploitation activities and the lack of regulation of offshore oil and gas exploration and exploitation as well as of sand and gravel mining; (v) Scarcity of studies on land reclamation and habitat modification; (vi) Lack of socioeconomic data and technological skills; (vii) Scarcity of studies on the tourism industry and poor capacity to assess tourism and all associated (i.e., economic, environmental and social) aspects.

2.7.5 Biodiversity aspects

The principal gaps identified by the experts regarding coastal areas, continental shelf and deep sea habitats are: (i) Scarcity of information on deep sea and continental shelf habitats; (ii) Lack of information on the current status of the mangrove species (in this regard, surveys and geographic information system (GIS) mapping projects need to be conducted); (iii) Scarcity of seagrass mapping programmes; (iv) Lack of research on vulnerability and adaptation in response to climate change; (v) Scarcity of close monitoring programmes of cetaceans, especially in West Africa; (vi) Absence of monitoring programmes for certain estuarine areas, especially in West Africa; and (vii) Scarcity of knowledge with regard to deep-water corals and plankton.

2.7.6 *Capacity needs*

A major capacity shortage facing many countries in the South Atlantic region is the ability to conduct assessments of the state of the marine environment at national to regional spatial scales. This need is mainly due to the lack of funding, but also due to the lack of resources and capability to conduct such studies, especially at the local and national levels. It is important to note, however, that capacity needs are unevenly distributed and that South-South cooperation also represents an opportunity to fill existing gaps. The experts therefore suggested that more capacity-building activities be organized under the umbrella of the Regular Process.

Another important gap concerns the geographical discontinuity of information in the South Atlantic region, and in particular the scarcity of studies on biophysical and socioeconomic dynamics in the region. This was deemed to be an important gap that hinders the development of an integrated regional assessment. Optimizing the coordination of marine environmental data-collection activities within countries and within the region should contribute to the production of an integrated regional assessment.

2.8 *Capacity needs for marine assessments in the northern Indian Ocean*

This workshop was held in Chennai, India, 27-29 January 2014 (UNGA 2014). The meeting focused on identifying short-term and long-term capacity-building needs that were determined through gap analyses. The capacity-building should concentrate on developing methodologies for integrated assessments and standardization of data and information generation for national, sub-regional, regional and global assessments. It is also a priority to create regional partnerships for undertaking joint research and to mobilize funds for capacity-building. Capacity-building to address biodiversity, critical habitats, microbial assessments, shipping, and environmental monitoring using satellite technology is also highlighted as a priority. Other points included:

- (1) The immediate action plan recommendation includes identification of the needs for capacity-building (including the acquisition of necessary technology) for marine monitoring and assessment (including integrated assessments). The capacity-building activities need to concentrate on the following issues:
 - (a) methodologies to obtain the information from various sources on a regular basis;
 - (b) standardization of the information content for assessments at various levels;
 - (c) developing common methodologies to carry out the assessment and to train data collectors: this is very important for uniform data collection. The procedure, data collection, formatting and preparation of reports should be standardized for all the member countries.

- (d) developing methodologies for scaling up national, sub-regional, regional and global assessments; and
 - (e) developing reporting forms to assist the integration process, with the aim of securing coherence, consistency and comparability as far as possible.
- (2) Development of a short-term capacity-building plan to mobilize the information and knowledge that is known to exist but has not yet been systematically organized in a way that would allow its use for the Regular Process. However, for this purpose, it may be necessary to identify the gap areas, and make efforts in capacity-building for those areas. India can help other States in capacity-building at various levels.
 - (3) To identify and fill gaps like microbial assessment, seagrass mapping, etc. Satellite-based techniques can be used to identify mangroves, seagrasses, etc., and create an ecosystem report card.
 - (4) Undertake assessments on the open ocean and activities related to shipping.
 - (5) To enhance cooperation between member States of the region, a template / matrix will be developed for circulation to neighbouring countries to complete; the questionnaire will include information for identifying gaps and capacity needs.
 - (6) It is stressed that improving communication among the countries of the region is the most important first step.
 - (7) Shortfalls in continuous monitoring of the environment using satellite technology.
 - (8) Insufficient involvement of regional organizations, undertaking joint research programmes, and securing funds for capacity-building activities.

3. Outcomes based on chapters focussing on knowledge gaps to inform capacity-building needs

3.1 Assessment of major ecosystem services from the marine environment (other than provisioning services)

This section deals with three types of ecosystem services: regulating, cultural and supporting services (Chapters 3-9). The identified gaps and capacity-building needs to address them are as follows:

3.1.1 Ecosystem services other than provisioning services

- Data availability and resolution at different scales and geographical ranges: the developing world especially has massive gaps.
- Capacity to undertake heuristic/participatory processes at regional and global levels: this should involve training and empowering local

stakeholders to enable them to understand the impact of ecosystem services on their well-being.

- Human capacity and infrastructure (research laboratories and institutes, observatories and oceanographic fleets) should be developed on a continual basis.

3.1.2 *Oceans and the hydrological cycle*

- Skills to quantify potential impacts on society and natural environment due to flooding and sea-level rise: the latter are acknowledged as being among the most serious issues confronting humankind.
- Capacity is inadequate to determine local sea-level changes which are also influenced by several natural factors, such as regional variability in the ocean and atmospheric circulation, subsidence, isostatic adjustment, and coastal erosion. It is necessary to study the latter too.
- Regional capacity is not sufficient to study changes in the rates of freshwater exchange between the ocean, atmosphere and continents because of their significant impacts. There is also inadequate ability to determine spatial variations in the distribution of evaporation and precipitation that create gradients in salinity and heat that in turn help drive ocean circulation.
- Capacity is insufficient to utilize traditional knowledge as an additional resource to address adaptation in given impact settings; this knowledge should be carefully evaluated within adaptation planning.
- Capacity is insufficient for standardizing methodologies to address regional differences which are due to differing data sources, temporal periods of analysis, and analysis methodologies.
- Capacity is insufficient for disaster preparedness to address high-intensity cyclones, because the scientific consensus shows that global warming will lead to fewer but more intense tropical cyclones globally. This will certainly affect coastal areas that have not been exposed previously to the dangers caused by tropical cyclones.

3.1.3 *Sea-air interface*

- Regional capacity is not adequate to determine levels of rising carbon dioxide (CO₂) in the atmosphere and increased absorption of CO₂ by the oceans, which has created an unprecedented ocean acidification (OA) phenomenon that is altering pH levels and threatening a number of marine ecosystems. It is necessary to map OA hotspots, which have now become a global problem.
- Capacity is insufficient to study the impact of shellfish farming due to acidification and to establish indicators for OA to facilitate determination of OA hot spots.

3.1.4 *Plankton productivity and nutrients*

- There are important shortfalls in regional capacity in terms of both infrastructure and human skills to enable measurement of primary production *in situ* and through remote sensing. The infrastructure includes multiplatform infrastructure, e.g., laboratories, oceanographic ships, moorings, drifters, gliders, aircraft, and satellites that can enable continuous measurements for both short-term and long-term monitoring.
- Various regions lack long-term measurements of primary production and therefore lack long-term data to construct predictive models to estimate trends.
- Phytoplankton can play a significant role in climate regulation to undertake continuous regional measurements of phytoplankton production through carbon sequestration, which is an order magnitude higher than that provided by grasslands and forest vegetation, and also form a basis for prediction of fisheries production to address food security. For both reasons it is important to undertake continuous regional measurements of phytoplankton production, and these measurements will require improved capacity for plankton monitoring.
- There is insufficient ability to identify which species of phytoplankton are most suitable for development of bio-fuels and pharmaceuticals.
- There is insufficient ability to identify which species of phytoplankton engage in nutrient recycling or nutrient stripping from seawater, culture them and use them for management of water quality in aquaculture.

3.1.5 *Ocean-sourced carbonate production*

- There is a shortfall in capacity to deal with the impacts of global warming and sea-level rise.
- There are gaps in our knowledge of the impacts of future rises in sea level on individual atolls; determining shoreline changes has rarely been undertaken, and long-term studies are especially lacking.
- Drastic effects from loss of sand dunes to beach mining and interruption of sediment pathways, especially as caused by coastal protection works.
- There is shortfall in capacity to deal with the impacts of acidification, which inhibit organisms from secreting carbonate shells or skeletons. Furthermore, reduction in sand-carbonate production leads to a decrease in supply to sand beaches. Relatively few studies exist of rates of carbonate production and transport of marine sand and gravel to contribute to coastal ecosystems.

3.1.6 Aesthetic, cultural, religious and spiritual ecosystem services derived from the marine environment

- It is necessary to identify the priority concerns in terms of the nature of the aesthetic, cultural, religious and spiritual ecosystem services derived from the marine environment in relation to the various geographical areas, developed and developing countries, and find out how humans have adapted for their own well-being.

3.2 Assessment of the cross-cutting issues: Food security and food safety

Food security and food safety are important activities which play a crucial role in human well-being in the provisioning services category of the ecosystem services panoply. The major activities covered are capture fisheries and aquaculture, as well as scientific and socioeconomic aspects. From the gap analyses, the capacity-building needs to address are as follows:

3.2.1 Oceans and seas as sources of food

- Covering 71 per cent of the earth's surface, the oceans offer a variety of habitats for various fisheries species which are used for various competing needs: these are both consumptive and non-consumptive but of varying socioeconomic value. To maximize benefits, to address these competing needs would require multidisciplinary research teams. Fisheries must address food security as well as recreational, cultural and spiritual aspects.
- To enhance the traditional subsistence type of fishing commonly practised in the developing world will require addressing fishing in terms of commerce and profit and thereby creating employment and supporting livelihoods. Advanced capacity-building for appropriate skills will be required to be able to use advanced technologies to create wealth from capture fisheries and mariculture in a sustainable way.

3.2.2 Capture fisheries

- Efforts have been made to create awareness to reduce post-harvest losses, especially in small-scale fisheries, as a means of increasing production. However, little is known to what extent this is implemented and to what extent it has increased production, although this would greatly improve the socioeconomic benefits to small-scale fishers. Enhanced capacity-building for appropriate research and innovative technology and its transfer would address these issues.
- Efforts have been made to reduce by-catch and increase awareness of this problem, including efforts to make by-catch excluder devices. Globally it is still poorly known whether this has been successfully achieved in terms of the relative ratio of the target catch landed and the by-catch caught and either landed or discarded. To address these issues would require building capacity to monitor and ensure compliance and promote observer programmes effectively.

- To improve the ecosystem approach to fisheries management to address not only ecological issues and governance but also socioeconomic issues for human well-being will require increased efforts to promote ecosystem-based management.
- To avoid fisheries depletion requires controlling fishing effort for stocks. For most important fisheries, historical fishing trends are unknown and their recovery rates are also poorly known, but their fisheries continue to expand into new areas. These issues can only be addressed with increased efforts to build enough capacity with appropriate technological and scientific skills to provide adequate information and data to facilitate regional and global management.
- There is insufficient capacity to address fish diseases from capture fisheries and illnesses caused by ingestion of toxic fish. Globally the phytosanitary issues are not well known, especially in developing countries.

3.2.3 *Aquaculture*

- To obtain a clear understanding of the trends and contribution of mariculture globally in terms of aquatic farming will require building capacity to address the relative ratio of freshwater aquaculture production and mariculture. Mariculture includes marine plant cultivation, which mostly consists of seaweeds.
- There is insufficient knowledge of mariculture diseases and how to combat them because they are poorly known, especially in the developing world. Filling this knowledge gap would require greater capacity in fish health in mariculture contexts.
- There is insufficient capacity to categorize mariculture for addressing food security, ornamental and decorative uses and clearly document their socioeconomic benefits.
- There is insufficient capacity to map cultivated species, where they are farmed regionally and globally, and share information and data to facilitate world production.
- To promote sustainability of mariculture will require building capacity to improve mariculture technologies that are environmentally friendly.
- There is insufficient capacity for improving industrial production of fish feed using low-value or trash fish, including by-catch that would otherwise be discarded. However, this should not compete with fish for direct human consumption or deliberate fishing that would be undesirable for biodiversity conservation.

3.2.4 *Fish stock propagation*

- There is insufficient capacity in aquaculture technologies which will promote efficient and effective stock propagation; this includes culture techniques under controlled conditions, provision of artificial habitat, feeding, fertilization, predator control and subsequent release of the aquatic organisms into the sea.
- Improved sustainability of fish stock propagation requires applying a comprehensive integrated ecosystem-based fisheries-management approach and therefore it is necessary to build capacity in terms of individuals, infrastructure and institutions that can deliver effective stock propagation.

3.2.5 *Seaweeds and other benthic food*

- Seaweed farming and aquaculture are seriously affected by disease and there is insufficient capacity to research seaweed diseases and build techniques for combating the diseases.
- To harness their wide variety of nutrients, medicinal and food values would require undertaking and building capacity for biochemical research on seaweed extracts from various species.

3.2.6 *Social and economic aspects of fisheries and other marine food*

- Certain issues, particularly at the micro level, demand additional research and therefore need capacity-building to address them. The state of small-scale fisheries throughout the world, and gender issues in fisheries, are particularly prominent and are poorly studied. A further issue that has been seriously under-researched is the relationship between capture fisheries and aquaculture.

3.3 *Assessment of other human activities and the marine environment*

The activities addressed in this section are basically centred on *in situ* use of the ocean, e.g., in shipping, ports, tourism, waste disposal and extractive uses, e.g., mining, desalination, etc. The gaps and the needed capacity-building are as follows:

3.3.1 *Shipping*

Knowledge gaps

- The IMO has emphasized the need for better information on the health and well-being of ships' crews. The death rate is unacceptably high, and little is known about causes of death, injuries and illnesses, with the result that it is difficult to formulate policies to address the problems.
- The potential development of Arctic shipping routes between the Atlantic and the Pacific highlights the inadequacy of charts of these waters: some date back to surveys in the mid-19th century. Similar shortcomings exist in Antarctic waters.
- As new anti-fouling systems for ships are developed, the resolution of the parties to the IMO Convention on the Control of Harmful Anti-fouling Systems on Ships

calling for the harmonization of test methods and performance standards for anti-fouling systems containing biocides presents a necessity to investigate and evaluate such methods and standards.

Capacity-building

- Potential shortages exist in adequately trained ships' officers and crew, and both Africa and South America are proportionally under-represented in the global pool of such officers and crew. Capacity-building to develop training institutions of high quality and to use such institutions to meet the demand is therefore desirable.
- Increased navigation in the Arctic Ocean and (in spite of the emergency response plans of the International Association of Antarctic Tour Operators) the presence of large passenger cruise ships in the Southern Ocean mean that there are gaps in adequate emergency response systems in both areas.
- In coastal areas where large numbers of very small vessels (especially with wooden hulls) operate, to ensure that the operators of such vessels have the knowledge and equipment to make them safe would require capacity-building. This could include capacity-building to ensure that maritime administrations can apply regional safety codes where they exist, or develop them where they have not yet been prepared.
- Improved port-state control is very important for ensuring the safety of shipping and the protection of the marine environment from accidents and unacceptable practices involving ships. There are gaps in the technical skills and equipment in some States for implementing effective port-state control.

3.3.2 Ports

- Because the operation of a port can significantly affect both the successful operation of ships and the economic performance of the countries it serves, some ports need capacity-building in the operational skills needed for successful port operation.
- The delivery to shore of garbage from ships is an important element of combating marine debris. Building capacity in this field for ports which do not have adequate and easily used port waste-reception facilities would improve their ability to combat marine debris.
- Many ports that need dredging to maintain or improve navigation adjoin bays, rivers or estuaries with a history of industrial discharges. Decisions on whether such material can safely be re-deposited in the sea, guided by international standards, requires the capacity to examine the dredged material relative to such standards.

3.3.3 Submarine cables and pipelines

- If coastal States wish to safely locate submarine cables and pipelines that cross areas of potential geological change and disruption, or (at least) to negotiate

successfully with commercial undertakings planning to install cables in such locations, they need access to the skills in marine geology needed.

- In taking decisions on submarine cables and pipelines, States need to have the capacities to address possible competing uses of the seabed on which the cables and pipeline are laid.

3.3.4 Coastal, riverine and atmospheric inputs from land

Shortfalls were found the skills and capacities for several important disciplines, including:

- Skills and infrastructure to monitor wastes and waste water (municipal, cruise ships and degree of treatment, industrial discharges, agricultural runoff, atmospheric emissions).
- Skills and infrastructure to treat waste and wastewater.
- Gaps in capacity to assess the environmental, social and economic aspects related to coastal, riverine and atmospheric inputs from land.
- Capacity to identify hazardous substances, which also includes ability to establish: thresholds of toxicity, persistence and bio-accumulation, a substance database with experimental data, monitoring and assessment programmes.
- Ability to monitor and assess atmospheric circulation and detect airborne inputs.

3.3.5 Offshore hydrocarbon industries

- A major capacity gap is the ability to manage environmental impact assessments and monitor compliance, mainly within (but not confined to) developing countries.

3.3.6 Other marine energy-oriented industries

The other sources of marine energy production industries are: offshore wind, waves, tides, ocean currents, marine biomass and energy from ocean thermal differences between different water layers. The capacity gaps to assess the environmental, social and economic aspects of offshore renewable energy deployment/generation are:

- Lack of information and data for full evaluation of Environmental Impact Assessments (EIAs). Data gaps are very common due to remoteness, or the level of technology not being available for long-term data and information gathering (especially for developing countries).
- Capacity in terms of enabling infrastructure to exploit these sources of energy.
- Skills or knowledge capacity lacking in most developing countries.
- High organizational capacity to foster relationships and linkages among ocean users, stakeholders and resource managers required to enable proper planning for use of these sources with minimal conflict and environmental impact.

More awareness campaigns would enhance appreciation of the fact that these renewable sources of energy, given their immense potential, can reduce use of the fossil-fuel carbon-based energy sources and reduce CO₂ emissions.

3.3.7 *Offshore mining industries*

- As in oil and gas, the major gap for this activity is the ability to undertake EIAs and monitor compliance, especially because of their remoteness; this is mainly so in developing countries.
- The offshore mining technology and management are still nascent and in mostly shallow water (<50m depth). Where such mining affects various stakeholder activities, social and economic conflicts can arise. Enhanced capacity for meaningful engagement with stakeholders will contribute to avoiding and resolving such conflicts.

3.3.8 *Solid waste disposal*

Information gaps

- Serious information gaps exist on the nature and volume of dumping. These gaps exist with regard to waters under the jurisdiction or control of both parties and non-parties to the London Convention and Protocol. The understanding of the potential effect of the dumping of solid waste on the marine environment is directly affected by these gaps.
- In areas where the possibility exists that explosives or containers of harmful substances, such as chemical weapons, have been dumped in the past, especially in areas where fishing vessels operate or where it is planned to locate submarine cables or pipelines, information on the location of such dumping must be available to the authorities, fishers, and others involved in activities in those areas.

Capacity-building

- Where States are still authorizing the dumping of solid waste, they need access to the skills and equipment needed to analyze the chemical constituents of potential hazardous waste to see whether it may be acceptable to be dumped in the sea.

3.3.9 *Marine debris*

- One of the major barriers to addressing marine debris is the absence of adequate scientific research, assessment, and monitoring. Scientific research is needed to better understand the sources, fates, and impacts of marine debris.
- Research is inadequate to qualify and evaluate the effects of plastic polymer masses that cause irritation in the stomach tissue and abdominal discomfort, and stimulate the organism to feel full and cease eating.
- Scientific evidence is insufficient to test for direct links between the chemical characteristics of marine debris and adverse effects on marine life.
- In spite of the growing number of studies documenting the distribution and abundance of marine debris, the ecological impacts, including effects on habitats, are not well documented.

- Research is insufficient to qualify and evaluate the presence of floating debris which can similarly undermine the quality of pelagic habitats; as is information on the impacts of marine debris in benthic habitats which are comparatively well studied.
- Scientific evidence and assessment efforts have not been adequate to evaluate the impacts of microplastics in the water column of the ocean.
- To date, the introduction of an alien species via marine debris has yet to be documented and there are important shortfalls in the scientific evidence of the role of marine debris in introducing alien species, especially in developing countries.
- Research, assessment, and monitoring are not sufficient to evaluate impacts of marine debris on coastal and marine species, habitats, economic health, human health and safety, and social values. Research and monitoring are insufficient to understand and in many parts of the sea, to qualify, the status and trends of marine debris. Development of new technologies and methods for detecting and removing accumulations of marine debris will also require additional research.
- The capacity to raise awareness about the problems posed by marine debris needs to be strengthened, especially in developing countries.

3.3.9 Land/sea physical alteration

- Capacity for data acquisition, especially in developing countries which suffer data-poor conditions.
- Capacity to undertake integrated assessments by multidisciplinary teams in the framework of ecosystem-based management in order to assess and understand the impacts on coastal and shoreline changes caused by a multiplicity of factors which include both anthropogenic and natural causes; capacity for modelling coastal processes, and to collect quality data based on defined standard techniques for use in developing such models.
- Due to the transboundary nature of large coastal water flows and sediment dispersal, undertaking to meet identified research needs can only be done with an improved regional capacity of individuals from various disciplines and a network of institutions.

3.3.10 Tourism and recreation

- Information is inadequate in many parts of the world on the extent of coastal tourism and its contribution to the local economy.
- Authorities concerned with the management of coastal areas where tourism is or could be occurring as an important activity need access to the skills necessary for integrated coastal management.

3.3.11 Desalinization

- Many areas suffering from shortages of freshwater could be helped by the creation of installations for desalinization and the skills needed to maintain and manage them. This is likely to become increasingly important with changes in rainfall as a result of climate change.

3.3.12 Use of marine genetic resources

- Marine biodiversity is best known in areas within national jurisdiction, and it is least known in the vast offshore oceanic areas beyond national jurisdiction.
- Biotechnology of marine biodiversity for commercial products is similarly at its infancy at the global level, and it is almost non-existent in developing countries.
- If marine genetic resources are to be explored and where appropriate developed, there are currently insufficient analytical technologies, especially for developing countries.
- There is current insufficient knowledge and skills to ensure application of environmentally friendly harvesting techniques in poorly known habitats and vulnerable marine ecosystems, such as cold water coral and sponge systems or hydrothermal vents; any exploitation in such areas requires a precautionary approach.
- There is inadequate capacity to study and collect marine genetic resources: this will require suitable vessels, both for deep sea and shallower waters, and appropriate research laboratories; the absence of this spectrum of needed resources is usually an important constraint in developing countries.

Part VI

Assessment of Marine Biological Diversity and Habitats

Chapter 33. Introduction

Group of Experts: Jake Rice, Alan Simcock

The biodiversity of the world's oceans directly supports many of the services and industries reviewed in Parts III, IV, and V, and may be affected by how the various social and economic benefits are used. To ensure the ongoing availability of those benefits to current and future generations, and to maintain healthy oceans, it is essential that the uses made of the ocean are sustainable, both individually and in the aggregate. In Part VI we examine ocean biodiversity from several perspectives, and when trends are apparent, link those trends to their main drivers. From this multi-perspective investigation of biodiversity trends, we obtain the third part of the information to be integrated in this first Assessment. This information may contribute importantly to improving global ocean literacy worldwide, and informing policies and selection of management measures from local to global scales.

The Convention on Biological Diversity¹ (CBD 1992) emphasizes that “biodiversity” exists on many scales: from genetic diversity within populations, through diversity of populations of the same species, the diversity of species in ecosystems, to the diversity of habitats within geographic areas. The diversity at all of these scales reveals patterns and structures that are crucial to the functioning of ecosystem processes and the delivery of ecosystem functions. However, in-depth analyses of patterns and trends, linking them to all drivers that underlie them and their ecological, social, and economic consequences are not feasible for the entire ocean, at even one of these scales.

Therefore Part VI presents overviews of these biodiversity features first spatially, and then followed by more focused examinations of key species groups and habitats. From these overviews, it is possible to present an analysis that integrates how global ocean biodiversity is changing as a result of the impacts of humanity's uses of the ocean, with the ability of the ocean to sustain itself, and humanity's uses of it into the future.

Chapters 34 and 35 present the main global patterns of diversity of populations, species, and habitats. Chapter 34 summarizes what has been learned about the nature and scales of those global patterns of diversity in species, and the dominant natural

¹ United Nations, *Treaty Series*, vol. 1760, No. 30619.

gradients that underlie those patterns, including features of the seabed such as depth, topography and types of substrate, of the water column such as temperature, salinity, nutrients and currents, and planet-scale features such as latitude, seasonality, and proximity to coasts. These patterns and their natural drivers underlie natural variation in biodiversity and provide the foundation for evaluating the potential for supporting human uses and sustaining perturbations from those uses. The ocean is vast and complex, hence these patterns in global biodiversity are incompletely quantified and their natural drivers are not fully understood. Chapter 35 summarizes the degree to which the biodiversity of the world's oceans has been sampled at even a descriptive level, and the subset of places and taxa for which sufficient sampling exists to quantify trends in biodiversity components in space and time, and to provide strong evidence linking those trends to specific natural and anthropogenic drivers.

Two contrasting messages emerge:

(a) An immense amount remains to be learned about the ocean's biodiversity. Sampling has been insufficient to fully quantify patterns and relationships with potential drivers in most of the ocean, and even to describe the biodiversity present in many parts of the ocean. This presents major challenges to fulfilling a core task of this Assessment – setting baselines against which to measure future changes.

(b) Nevertheless, with the current levels of sampling, much can be concluded about how the ocean has changed in the past decades and centuries and trends that may continue into the future. These past changes and current trends provide information about the sustainability of human interactions with marine biodiversity, whether those interactions take the form of direct use or indirect impacts. Although relationships between biodiversity variation and its drivers need to be better quantified almost in all parts of the world, we have sufficient knowledge to indicate which outcomes are likely to be more sustainable or less sustainable, and thus inform our choices. Nevertheless, we must acknowledge that uncertainties will remain and surprises will be encountered.

Chapter 36 comprises the largest part of Part VI. That chapter presents the major temporal trends in biodiversity from the primary and secondary producers (phytoplankton and zooplankton), through the benthos and fish to the top predators. To the extent that they are known in each case, it also links the major trends to their key natural and anthropogenic drivers. Where important changes in trends are documented, the knowledge of the degree to which the changes are due to natural causes to impacts of human uses or to responses to efforts to mitigate past impacts, is summarized. This provides the raw material for integration of biodiversity trends with sustainability of human uses of marine biodiversity. Chapter 36 is subdivided into eight divisions, presenting similar assessments of trends in biodiversity for the northern and southern sub-basins of the Atlantic and the Pacific Oceans, for the Indian Ocean, the

Arctic Ocean and the Southern Ocean, and for the open-ocean and deep-sea areas of all the oceans together.

For all but the open-ocean division, the trends are generally reported separately for coastal and offshore/shelf areas, because the species and habitats, and the main drivers of trends, often differ in the near-shore and the offshore/shelf areas. Even at this level of subdivision, only major trends in biodiversity can be reported, and often it is necessary to report the patterns and trends at finer geographic scales, because these sub-basins and oceans contain many partially independent marine ecosystems, with differing species and habitats, different temporal trends, and possibly different drivers of trends.

None of these regional assessments can be exhaustive of all trends in biodiversity at the regional scale. They focus on trends that are well documented, and likely to be representative of what is happening to biodiversity at those regional scales. Illustrative examples of the trends and their relationships to drivers are presented consistently, and some chapters are supported by technical annexes with additional data and references to enable more in-depth documentation of the conclusions in the sub-chapters. Although several divisions of Chapter 36 have made some use of traditional knowledge in assessing patterns and drivers, in all divisions, institutional assessments and scientific publications were the predominant source of information on patterns, trends, and drivers. That creates an unavoidable (but unintentional) bias towards more extensive assessment of biodiversity trends and drivers in the parts of the world with larger investments in scientific research and monitoring, and where such investments have occurred over longer periods. If the divisions of Chapter 36 report fewer trends in biodiversity in parts of the world with less research and monitoring, this reflects the mandate of this Assessment to use only published sources. Hence at least some of the differences among the regional assessments arise from differences in the quantity of information that informs this Assessment, and not necessarily differences in what is happening to marine biodiversity at these large regional scales. When strong trends are present consistently in regional assessments where appropriate data are available, it would be precautionary and sound scientific practice to consider them as relevant information for less data-rich areas as well.

Regional assessments are only one perspective for documenting, and to the extent possible explaining, trends in biodiversity. Other perspectives are legitimate, and for some aspects of biodiversity the regional assessments may not be the most powerful assessment approach, for two reasons. First, some species groups include wide-spread and highly migratory species; hence no one region captures the trends in the populations, and some habitat types important to biodiversity often are found in relatively small individual occurrences (as well as, rarely, larger ones) but in many of the regions, and a piecemeal regional approach may be inefficient. Second, some groups of species and certain types of habitats are considered particularly vulnerable to natural and anthropogenic drivers. Hence assessments of trends and drivers are most powerful

when all the relevant information is viewed together, regardless of the specific regions from which the parts of the whole story were documented.

Therefore Part VI concludes with short chapters on five key species groups with the above characteristics: marine mammals, seabirds, marine reptiles, elasmobranchs (sharks, rays, and their relatives), and tuna and billfish. Chapters then follow on a number of key habitats. Many are near coastal habitats of known high biodiversity value and subject to multiple human pressures, such as estuaries, kelp forests, and similar habitats. Several are offshore or deep-sea habitats known often to be biodiversity hotspots, and to be attracting increasing pressure from direct or indirect human uses. Examples include seamounts, tropical and sub-tropical corals, cold-water corals, cold seeps and hydrothermal vents. These shorter and more focused assessments of species groups and habitats that are both highly valued economically, culturally, or both, and highly vulnerable to impacts from unsustainable use, provide flagship cases to integrate ecological, social, and economic aspects of marine biodiversity and its contributions to human well-being.

Collectively, across Part VI, this Assessment evaluates the patterns of occurrence of marine biodiversity (Chapter 34) and the extent to which it is known (Chapter 35), the major trends in coastal, offshore, and deep-sea biodiversity, usually at regional scales and sometimes sub-regional scales, as well as the main known drivers of those trends (Chapter 36A-36H), and examines issues of particular concern for species (Chapters 37-41) and habitats (Chapters 42-51). This provides the third main pillar of this Assessment, for integration with Parts II-V in Part VII (Overall Assessment).

Chapter 34. Global Patterns in Marine Biodiversity

Contributors: Paul Snelgrove (Convenor), Edward Vanden Berghe, Patricia Miloslavich, Phil Archambault, Nicolas Bailly, Angelika Brandt, Ann Bucklin, Malcolm Clark, Farid Dahdouh-Guebas, Pat Halpin, Russell Hopcroft, Kristin Kaschner, Ben Lascelles, Lisa A. Levin, Susanne Menden-Deuer, Anna Metaxas, David Obura, Randall R. Reeves, Tatiana Rynearson, Karen Stocks, Marguerite Tarzia, Derek Tittensor, Verena Tunnicliffe, Bryan Wallace, Ross Wanless, Tom Webb, Patricio Bernal (Co-Lead member), Jake Rice (Co-Lead member), Andrew Rosenberg (Co-Lead member)¹

1. Introduction

Marine environments encompass some of the most diverse ecosystems on Earth. For example, marine habitats harbour 28 animal phyla and 13 of these are endemic to marine systems. In contrast, terrestrial environments contain 11 animal phyla, of which only one is endemic. The relative strength and importance of drivers of broad-scale diversity patterns vary among taxa and habitats, though in the upper ocean the temperature appears to be consistently linked to biodiversity across taxa (Tittensor et al. 2010). These drivers of pattern have inspired efforts to describe biogeographical provinces (e.g. the recent effort by Spalding et al., 2013)) that divide the ocean into distinct regions characterized by distinct biogeochemical and physical combinations). Biogeographers such as Briggs (1974) examined broad-scale pattern in marine environments in historical treatises and although many of the patterns described therein hold true today, the volume and diversity of data available to address the question have increased substantially in recent decades. We therefore focus our chapter on more recent analyses that build on those early perspectives. The International Census of Marine Life programme that ran from 2000-2010 provided significant new data and analyses of such patterns that continue to emerge today (McIntyre, 2011; Snelgrove, 2010). Indeed, many of our co-authors were part of that initiative and that influence is evident in the summary below. In the few years since that programme ended, some new perspectives have emerged which we include where space permits, noting that we cannot be exhaustive in coverage and also that the large data sets necessary to infer broad-scale patterns do not accumulate quickly.

Not surprisingly, the different scales, at which many organisms live, from ambits of microns for microbes to ocean basins for migratory fishes and marine mammals, along with variation in the drivers and patterns of diversity, render a single analysis impossible. In order to assess gradients in marine biodiversity we use a taxonomic framework for some groups of organisms and a habitat framework for others.

¹ The writing team thanks Roberto Danovaro, Esteban Frere, Ron O'Dor, Mayumi Sato and Chih-Lin Wei for their valuable contributions to this chapter.

Comparatively well-sampled groups taxonomically (primarily pelagic (water column) vertebrates and cephalopods) could be treated at a phylum or class level globally, whereas for taxa in which taxonomic or geographic knowledge is highly uneven, we followed a habitat framework, noting that a group by group treatment of benthic invertebrates would encompass more than 30 phyla and would render the chapter unwieldy. We therefore organized the chapter into an Introduction, a series of summaries on biodiversity patterns in pelagic taxa, and then summaries of knowledge on biodiversity in contrasting benthic ecosystems. Although this strategy is imperfect (e.g. many fishes occupy primarily benthic environments), it nonetheless creates a framework in which to evaluate current knowledge of biodiversity patterns within a relatively short chapter. Space limitations also preclude comprehensive coverage of all habitats and taxa, and we therefore present a broad but incomplete summary that omits kelps, seagrasses, and salt marshes, for example. We therefore encourage readers to also review the more detailed chapters within the World Ocean Assessment that focus on the biology and status of specific taxa and ecosystems. Our goal in this chapter is to identify the key environmental drivers of global diversity patterns based on current knowledge, while acknowledging many data gaps that will necessitate revising these patterns as new data become available. Specifically, we address how depth, latitude, productivity, temperature and substrate influence broad-scale distributions and diversity patterns, and identify the knowledge gaps (taxonomic, geographic) that constrain our ability to assess such patterns. Below we summarize knowledge on biodiversity gradients with a few key references, but we also include a more extensive reading list for those seeking more detailed information (Appendix).

2. Pelagic ecosystems

2.1 Marine Mammals

Marine mammals include cetaceans (baleen whales and toothed whales, dolphins and porpoises), pinnipeds (seals, sea lions, walrus), sirenians (manatees and dugongs), the marine otter (*Lontra felina*), and sea otters (*Enhydra lutris* and subspecies) and the polar bear. Excluding the seven extant freshwater species, about 120 wholly or partly marine species are currently recognized (www.marinemammalscience.org). However, ongoing taxonomic revision will keep this number in flux. Marine mammal species occupy almost all marine habitats: from fast ice to the tropics, on shorelines where pinnipeds haul out during their moulting, mating or pupping season, in shallow coastal waters where some dolphins and baleen whales spend much of their time, and in the open ocean where many pelagic pinnipeds, baleen whales, and toothed cetaceans occur. However, other than sperm whales and perhaps some of the beaked whales capable of diving beyond 2,000 m, air-breathing limits marine mammals to bathypelagic depths at most. In contrast to highly restricted distributions in some smaller cetaceans and pinnipeds, many species exhibit circumglobal or circumpolar distributions, with some (baleen whales in particular) undertaking long annual migrations.

Many marine mammals spend most of their time offshore, but sirenians, marine and sea otters, and some small cetaceans and pinnipeds, as well as benthic feeders such as walrus and grey whales, rarely venture beyond the continental shelf except when migrating. Global marine mammal species richness peaks at mid-latitude (around 60°) in both hemispheres (Kaschner et al., 2011; Figure 1a)². Pinnipeds mostly drive the peaks, which despite some highly endemic species in the subtropics, largely concentrate in polar to temperate waters (Figure 1b). Thick blubber or fur layers insulate marine mammals; hence they occupy all climate zones, although temperature nevertheless influences distributions (Tittensor et al., 2010), often through feeding and breeding constraints. As with other marine predators, food availability drives patterns in many marine mammals, but so does availability of breeding habitat for many species. Dugongs, as highly specialized herbivores, associate with sea grass beds in warm, shallow coastal waters and estuaries. Baleen whales, which feed at low trophic levels, require dense prey aggregations to sustain their metabolic needs, forcing most species to migrate to high latitudes during peak feeding seasons to utilize high summer productivity (except for some resident tropical populations associated with productive upwelling waters). Some species concentrate at specific breeding or calving grounds in winter. Toothed cetaceans generally feed at higher trophic levels and are not linked, as are some baleen whales, to zooplankton aggregations along the polar ice edges, and this helps drive higher species diversity at mid-latitudes (Figure 1a) (Kaschner et al., 2011). Nevertheless, the finer-scale distribution of most species links with ocean features that aggregate prey such as eddies, fronts or upwelling areas, or with specific breeding grounds. Many pinniped distributions correlate with prey aggregations; however, availability of suitable haul-out sites, on either land or sea ice, for moulting, breeding and pupping, limits most pinniped species, as does maximum length of foraging trips, as well as temperature (Tittensor et al., 2010).

Despite their often impressive body size, new discoveries of whale species still occur by re-evaluation of molecular and morphological evidence. Despite well-established broad-scale distributions of most small cetaceans, pinnipeds, sirenians and otters (Reeves et al., 2002), range maps or predictions of environmental suitability for the beaked whales (ziphiids) largely represent guesswork; their actual distributions potentially span entire ocean basins (Kaschner et al., 2011). Similarly, even after centuries of intense whaling in all oceans, the breeding grounds and migration patterns of some of the large baleen whales, such as North Pacific right whales, are still not well known.

Relatively low densities with often very large ranges, low detectability, and inconspicuous behaviour of many species limit studies on marine mammal distributions. To date, most dedicated sampling has centred on Northern hemisphere continental shelves and slopes (Halpin et al., 2009). Large knowledge gaps remain on species occurrence throughout much of the tropics and Southern hemisphere temperate waters north of 60° (Kaschner et al., 2011). Although range maps and opportunistic sightings

² All figures and tables can be found at the end of this chapter.

document species presence in an area and facilitate larger-scale biodiversity inventories, extending these types of sources to estimate density or abundance or to assess relative ecological importance often proves problematic. Dedicated sighting surveys of cetaceans conducted annually in offshore areas of the North Pacific under sponsorship of the International Whaling Commission (IWC) (IWC-POWER: IWC) can help address these gaps and evaluate North Pacific whale recovery trajectories (Halpin et al., 2009)

2.2 *Seabirds*

“Seabirds” denotes species that rely on the marine environment for at least part of the year, and include many spectacularly mobile species that travel thousands of kilometres, returning to land only to breed. Seabirds as a group occur in all seas and oceans worldwide, exploiting surface waters in all habitats from the intertidal zone to the open ocean. Globally, seabird density, diversity and endemism are highest in the highly productive temperate latitudes and in upwelling areas (Croxall et al., 2012; Chown et al., 1998).

Seabirds are central-place foragers (foragers that return to a particular place to consume food) during the breeding season, with many adapted to exploit highly clumped prey. Therefore largest aggregations occur where food availability is high within a restricted foraging range from a suitable nesting habitat (Lascelles et al., 2012). Foraging ranges vary from a few kilometres from shore (e.g., seaduck and small terns) to several thousand (e.g., larger albatross). Seabirds adopt a range of behaviours to capture prey, from surface-seizing to plunge or pursuit diving. Feeding generally occurs at or immediately below the water’s surface, although the Emperor Penguin reaches depths over 500 m.

Seabirds can be roughly subdivided into three groups. “Pelagic seabirds”, such as porcellariiformes, pelecaniformes, alcids and penguins, often travel far from land, primarily use oceanic pelagic water (seas above the open ocean, typically >200 m in depth). In contrast, “coastal seabirds (year-round)”, including most larids, are those that primarily use coastal inshore water (seas along coasts, typically <8 km from the shoreline) throughout the year. “Coastal seabirds (nonbreeding season)”, such as seaduck, grebes and divers, are those that primarily use coastal inshore water during the non-breeding season.

For much of the year coastal species tend to be relatively static, often tied to particular habitats or topographic features. Pelagic species distributions, however, often link to dynamic processes and variables and require complex analyses to define. BirdLife International recognizes around 350 species as seabirds (i.e., 3.5 per cent of all bird species), of which over 280 meet a stricter definition (excluding ducks, loons, etc.) used in some earlier reviews. However, ongoing taxonomic revision will keep this number in flux. In recent years new species have been found, as well as rediscovery of some thought to be extinct. Re-evaluation of molecular and morphological evidence has split some taxa, adding an additional eight species since 2000 with a further 15-20 under

review in the coming years. Knowledge of the at-sea distribution of species remains patchy. Many species are relatively well studied at specific sites, but at-sea movements across entire ranges are known for only a few species, as are areas used during non-breeding periods and those areas visited by juvenile birds. The at-sea distributions for many tropical species, particularly in the Central and South Pacific and South East Asia are also under-studied.

Seabird distribution may vary depending on their breeding site (e.g., tropical vs. temperate zones), age, sex, whether it is day or night and the time of year (Lascelles et al., 2012). In addition, many species, particularly procellariiforms, alternate between “long” and “short” foraging trips during the breeding season. Areas most important for their survival have rarely been defined in any systematic way, although recent studies, such as the BirdLife Marine Important Bird Area Atlas, have helped fill this gap and show distribution patterns at multiple scales.

2.3 Turtles

Marine turtles have inhabited the world’s oceans for more than 100 million years, having survived the dinosaurs and numerous major global shifts in climate. Today there are seven recognized marine turtle species, six belonging to Cheloniidae, green turtles *Chelonia mydas*, hawksbills *Eretmochelys imbricata*, loggerheads *Caretta caretta*, olive ridleys *Lepidochelys olivacea*, Kemp’s ridleys *Lepidochelys kempii*, and flatbacks *Natator depressus*, and one extant member of Dermochelyidae, the leatherback *Dermochelys coriacea*. Despite few species, marine turtles occur circumglobally, inhabit nearly all oceans, occupy unique ecological niches, and exhibit variations in abundance and trends, as well as reproduction and morphology among populations of the same species (Wallace et al., 2010).

Marine turtles have evolved several adaptations to marine habitats (e.g., maintaining water balance in saltwater, hydrodynamic body shape and swimming efficiency) that are unique compared to other turtle species, but because they are reptiles, temperature fundamentally constrains their distributions and life history (Spotila, 2004). For example, the development, and survival of marine turtle embryos means successful hatchling production requires the consistently warm temperature (28-33°C) of sandy beach environments. Because these habitats are limited to the tropics and subtropics, most major marine turtle nesting sites occur between the equator and 30° latitude (Wallace et al., 2010) (see Figure 1, chapter 39).

Temperate also limits marine distributions, as most population ranges only reach 45° latitude (see Figure 1, chapter 39), extending only seasonally into northern and southern extremes of their ranges (Spotila, 2004). Leatherbacks defy this pattern, with core migratory and foraging habitats into temperate and even sub-arctic regions and average water temperatures between 10-20°C (Eckert et al., 2012).

Within ocean basin-scale distributions, adult marine turtles generally migrate hundreds to thousands of kilometres from nesting beaches for foraging, often showing high site fidelity to both breeding and feeding areas. Immature turtles also show site fidelity to areas used for foraging and growth. For some species, primary habitat types, e.g., coral reefs for hawksbills, seagrass beds for green turtles, constrain foraging to tropical regions (Spotila, 2004).

Many marine turtle populations demonstrate ontogenetic variation in habitat use that is related to geography and oceanography (Bolten, 2003). In several places around the world, hatchlings disperse from nesting beaches and orient toward persistent, offshore current systems (e.g., Gulf Stream in the Atlantic Ocean), where they associate with ephemeral habitats in convergence zones, such as *Sargassum* communities. After spending the first few years of life in these oceanic areas and growing to larger body sizes, juvenile turtles tend to recruit to neritic habitats where they remain—for the most part—until reaching sexual maturity. Although this description provides a useful heuristic for understanding sea turtle life history distribution patterns, significant within-population variation exists in timing and duration of recruitment by individuals from one life stage—and habitat type—to another; these variations have implications for overall population dynamics and management (Bolten, 2003).

The wide distributions of marine turtles can vary greatly among populations, which are subject to multiple threats that operate on different spatial and temporal scales. Effectively prioritizing limited management resources requires understanding which threats will most strongly influence distribution patterns in space and time (Wallace et al., 2011).

2.4 Fishes

In English, ‘fish’ designates any aquatic multicellular animal (jellyfish, cuttlefish, starfish, etc.). The term ‘finfish’ designates those with a central spine comprised of vertebrae (Chordata/Vertebrata – vertebrates), whether or not present in adults, ossified, or with paired and/or impair fins supported by rays. Although no longer recognized as a valid taxonomic group, ‘finfish’ (hereafter “fish”) offers a practical descriptor of a group exclusive to aquatic life that constrains many adaptations and defines a similar body plan, while acknowledging diverse body forms.

By the end of 2013, more than 33,000 valid species of extant species were described (Eschmeyer, 2014), constituting more than half of all vertebrates; ca. 17,500 occur in marine environments for at least part of their life cycle. Surprisingly, species descriptions have accelerated since World War II: between 1999 and 2013 (15 years), a new fish species was described every day, a rate that is still increasing (Figure 2). This increase comes in spite of decreasing fish taxonomists around the world, and cannot be attributed to recent molecular advances, given the low proportion of species discovered by genetics methods. Different editions of *Fishes of the World* (e.g., Nelson, 2006) report new discoveries (Table 1), and although the deep seas were expected to deliver

many new species, given the assumed high rate of exploration of continental shelves <200 m, species richness per surface area in shallow waters remains much higher, noting that waters below 2,000 m deep remain largely unexplored. Coral reefs still deliver most newly described marine fishes each year, especially for cryptic species such as gobies and small labrids. Coral reefs are not the only source of new species: for instance, populations of many fish species previously thought to be distributed widely in the Indo-Pacific region are now recognized as different species between the Indian and the Pacific Ocean, and even more recently between the Red Sea and the Indian Ocean.

Fishes are ubiquitous throughout the world ocean, in locations as small as tidal pools that may dry up daily, and from the poles down to the base of the Marianas Trench in the West Central Pacific (11,782 m). They live in caves, on the shoreline, sometimes out of the water for some periods in mangroves or intertidal areas, over, on or in soft or hard bottoms, in crevices in rocky or coral reefs, and a few are even found in poorly oxygenated water. As in many groups, species richness (as well as species per family or genus, and number of genera) generally increases from high to low latitudes (Figure 3), more so than the number of families, but local climate, oceanography or phylogenetic history may alter this pattern (Tables 2 and 3). Shallow coral reefs with a high diversity of habitats and high biomass productivity support the most species; deep-sea corals are less species-rich. Several studies show highest species richness in the Coral Triangle (Indonesia, Philippines, Papua New Guinea region), thought to be the centre of tropical marine diversity. More than 300 widespread species (2 per cent) occur in 10 or more FAO areas (from over 19 possible areas), and 8,000 (47 per cent) occur in just one area (12,000 – 65 per cent in 1 or 2). Geographic and/or hydrological conditions restrict the majority of species distributions. Amphitropical distributions occur only in large pelagic species.

Although fishes occupy all depths, species diversity drops dramatically below the continental shelves. Depth ranges are incomplete for many species, but about 6,800 (58 per cent) of the 11,000+ species with recorded ranges in FishBase (www.fishbase.org; Froese & Pauly, 2014) are restricted to the upper 200 m, with only ca. 620 spp. (4 per cent) below 2,000 m. Lack of data on deep-sea species, except for a few targeted around submarine seamounts in the high seas by non-sustainable fisheries, illustrates a serious sampling bias that demands cautious interpretation.

Only a few species of shark and rays have been caught below 3,000 m and none below 4,000 m. Gobies that constitute the most speciose family in marine life zones in tropical and temperate waters in general, are barely present in the North Pacific above 40° N. The life cycles of more than 700 hundred species (including salmonids, eels), alternate between marine and fresh waters (amphidromy, diadromy, catadromy, anadromy).

Few herbivorous species occupy high latitudes as compared to tropical areas. Although anti-freeze blood proteins prevent ice formation in the blood of some cold water fishes, digesting plants requires a higher metabolic activity than most cold water fishes can maintain. Based on recorded information for about 6,400 species in Fishbase, about 1,000 species are top predators and carnivores, 4,400 are predators or omnivores, and

1,000 are herbivores or omnivores. The commercial large species that are most studied predominantly occupy the upper trophic levels.

The high diversity of forms, behaviour, ecology and biology based on one body plan enables great success in the marine environment. However, the populations of many exploited species are threatened by fisheries that now access stocks in almost the entire water volume between 0 and 1,500 m depth. Despite some local extirpations, no marine fishes are reported to be globally extinct; however, large species with few offspring, such as some sharks and manta rays, are endangered, often because of threats along migration pathways. Populations of some shark species targeted for their fins have decreased by 90 per cent, but although the populations are no longer economically exploitable, no sign of extirpation has been noted so far (Ferretti et al., 2010).

2.5 *Cephalopods*

Shell-less coleoid cephalopods occur from pole to pole, and from the ocean's surface to depths of many thousands of metres; many can even fly above the ocean's surface. They range from surface-dwelling tropical forms with adults the size of a grain of rice to 30-m giants in the deep oceans.

Squid compete with fishes in nearly all marine niches, although there are only one tenth as many species, perhaps reflecting their relatively recent radiation since the disappearance of the dinosaurs. The same event killed all of the Ammonites, a highly diverse group of cephalopods that lived near the sea surface. The deep ocean remains sparsely sampled for cephalopods, raising questions about their total biomass and global patterns. For those areas that have been sampled, recent evidence suggests that primarily oceanic squid peak in diversity in the northern hemisphere at temperate latitudes, a pattern reflected by (primarily coastal) non-squid cephalopods in the Pacific Ocean at least; temperature strongly drives these patterns (Tittensor et al., 2010).

More information on the biology, biogeography and diversity of cephalopods is available from CephBase (cephbase.eol.org), which is now available through the pages of the Encyclopedia of Life.

2.6 *Marine Microbes*

Marine microbes, defined as single-celled or chain forming microorganisms, span a very broad size range, from microscopic cells that are $<1/50^{\text{th}}$ the diameter of a human hair to forms visible to the naked eye. They are found throughout all the oceans, from the tropics to the poles and from the surface to the deepest depths. These single-celled organisms divide asexually, up to several times per day, leading to high biomass that fuels nearly all marine productivity, including all important fisheries around the globe, and drives global biogeochemical cycles, including carbon, oxygen, and many others. Marine microbes also represent the most phylogenetically diverse organisms on Earth. A single litre of seawater can contain representatives of all major branches of the tree of

life: Archaea, Bacteria and all major kingdoms of Eukaryotes. Microbial diversity within the plankton far exceeds that in terrestrial habitats. For example, planktonic photoautotrophs represent deep phylogenetic diversity, including 20 diverse clades. In contrast, autotrophic diversity in terrestrial environments is dominated by just one clade (Falkowski et al., 2004). Planktonic heterotrophs are equally diverse.

Eukaryotic plankton includes purely autotrophic species (phytoplankton) that convert inorganic to organic carbon, fuelled by light energy through photosynthesis. Primary production supplied by phytoplankton forms the basis of the food web and ultimately feeds all marine organisms, up to the largest whales. Eukaryotic plankton also includes heterotrophic microbes that ingest organic carbon through a myriad of feeding strategies, and so-called mixotrophic species, which include species either simultaneously or sequentially alternating between phototrophic and heterotrophic modes. Feeding by heterotrophic and mixotrophic plankton is the single largest factor in reducing primary production; it can control the abundance and biogeochemical activity of phytoplankton, and it is essential for the transfer of matter and energy to higher levels in the food web, and for the recycling of nutrients (Sherr et al., 2007). Bacteria are also essential for recycling and remineralizing organic matter and contribute substantially to primary production.

Latitude, proximity to land, and season primarily delimit global large-scale distribution patterns of plankton. Abundance declines from high nutrient coastal areas to the vast areas of the generally low-nutrient (oligotrophic) waters of the open ocean. But exceptions exist. For example, Charles Darwin on his '*Beagle*' voyage noted that nitrogen-fixing phytoplankton can become very abundant in the open ocean and form surface mats and filaments. Latitude interacts with season in forcing plankton abundance patterns. In lower latitudes, seasonal variations in irradiance and temperature, including ice cover, result in highly variable plankton abundances seasonally, with spring and fall peaks. Organism physiology, nutrient availability, susceptibility to grazing, and viral attack, as well as the fluid flow regime, further define distributions.

2.7 Zooplankton

Zooplankton occur from pole to pole, and from tide-pools to the deepest trenches in the ocean. They span the size range from single cells and multicellular organisms that are smaller than 0.05 mm, to gelatinous colonies that are longer than the largest whales. In the vast scale of the oceans, they are united by their inability to control their movement in the horizontal scale, but many perform vertical migration of hundreds of metres per day.

As an assemblage, the ~7,000 described species of multicellular zooplankton (Wiebe et al., 2010) encompass species from every major animal phylum, and the majority of the minor phyla; some of these 15 phyla are almost exclusively planktonic (Bucklin et al., 2010). Many additional phyla are classically considered as non-planktonic, but they do in

fact live within the plankton for their earliest life stages, and are referred to as meroplankton, in contrast to the holozooplankton generally considered. This means that the zooplankton encompass an exceedingly wide range of body plans, and modes of life, ranging from relatively passive herbivorous species, to blindingly fast attack carnivores. It also includes some of the world's most passive predators that literally rely on prey blundering into them. Finally, some zooplankton taxa have developed symbiosis with internally housed algae so successfully that they no longer rely on other organisms as prey.

The majority of zooplankters range from <1 mm to 1 cm in length. With ~2,000 described planktonic species typically representing 80-90 per cent of total zooplankton abundance and living biomass in most marine ecosystems, copepods represent the most successful body plan. These small, robust crustaceans are easily collected with simple nets and manipulated for experimental purposes, making them the central focus of ecological research on plankton for the past century. Different species of copepods play almost every imaginable ecological role: the majority are suspension-feeding grazers on smaller single-celled plankton, some are scavengers and detrital feeders, and others range from active attack to passive ambush predators. Several other diverse crustacean groups illustrate a wide range of feeding strategies: ostracods (detritivores), euphausiids (filter-feeders), amphipods (predators, or commensalists), mysids (scavengers) and decapods (predators); note that the latter two groups may be considered either planktonic or benthic, given their tight association with the seafloor.

Lacking the arthropod skeleton, most other planktonic groups are considered "gelatinous" zooplankton, which are generally not well collected in nets because of their fragility and often lower abundances. With the exception of the nearly 140 species of pelagic tunicates (larvaceans, pyrosomes, doliolids and salps) and about 80 species of shelled pteropods, all other groups are clearly predatory. Two of the three classes of medusae or "jellyfish" within the phylum Cnidaria (hydrozoans and scyphozoans), are clearly the most speciose gelatinous groups, followed by the phylum Mollusca with its three functional groups (shell-less pteropods, heteropods, and cephalopods – although the latter are considered by many as nekton, as are the fishes). Once grouped with the cnidarians, the Ctenophora, or comb-jellies, are probably the most seriously underestimated group in terms of their biodiversity: their extremely fragile body construction confounds specimen collection. Of the extant worm-like groups, only Chaetognatha (arrow worms) occur in plankton samples in high abundance; primarily benthic polychaetes and nemertines usually occur in the plankton in modest diversity and abundance.

The >100-year quest to find patterns in zooplankton distribution shows that each species has its own environmental preferences and tolerances, with some species confined to specific regional habitats and others that are relatively wide-spread. Over time, several broad patterns have emerged for zooplankton that exhibit consistency across multiple taxa (Dolan et al., 2007). Diversity in offshore habitats exceeds that in coastal regions, although coastal abundance and biomass may be higher. Diversity increases from the poles to the tropics, often with an equatorial dip (Boltovskoy, 1999)

(again in contrast with abundance and biomass). Diversity increases with increasing depth in polar systems (Kosobokova et al., 2011), has a mid-depth peak in temperate/subarctic systems, but may peak in surface waters of tropical oceans. Although these trends hold for the overall zooplankton community, they vary among every taxonomic group within the assemblage.

Zooplankton experts seek to create global maps for every major taxonomic grouping, or even for entire communities or ecosystems, particularly using observational data, in conjunction with environmental data, to predict biodiversity distribution (e.g., Rombouts et al., 2009). Obtaining sufficient data for all taxa under consideration, across the full spectrum of habitats, remains a primary hurdle. One of the greatest accomplishments of the Census of Marine Life (CoML) was to build the Ocean Biogeographic Information System (OBIS), a system that can address such questions by pulling together the disparate datasets to allow such synthetic tasks to be undertaken (e.g., Tittensor et al., 2010; Vanden Berghe et al., 2010).

New insights derived from DNA-based approaches represent the biggest current challenges in understanding zooplankton biodiversity. Initially, these tools offered great promise in tackling simple issues, such as phenotypic variation or rates of hybridization. In practice they are revealing numerous cryptic species not previously recognized based on morphology alone, that force rethinking on what represents a species, and the geographic/environmental boundaries between them. Many species believed to span several ocean basins may in fact represent species assemblages, suggesting that current estimates may severely underestimate the overall diversity of marine zooplankton in all groups.

3. Benthic ecosystems

3.1 Rocky Shore Ecosystems

The ease of access and suitability for experimental work of rocky shore habitats have attracted a long history of scientific study and engaged a broad audience. Biodiversity assessments in this habitat typically use quadrat and transect assessment with visual or photographic identification, and do not require ships or complex technology. In many rocky intertidal environments, and particularly in regions with large tidal ranges, aerial exposure at upper tidal levels and predation at low tidal levels create distinct bands of species, or zonation, that represent one of the most striking and well-documented gradients in the ocean (first described by Stephenson and Stephenson 1949). The global distribution of rocky intertidal habitats creates opportunities to compare latitudinal trends and to detect large-scale patterns and changes. Despite fairly well-understood local patterns and processes, large-scale patterns (regional to global) are difficult to discern; however, many drivers, such as temperature and exposure, act on large scales, as do human influences, such as invasive species and pollution. Examples from around the world (e.g. Thompson et al., 2002) demonstrate the past and current effects on

rocky shores of pollution (e.g. oil, eutrophication), overfishing, introduced exotic species, modification of coastal processes (e.g. coastal defences, sedimentation) and global change (e.g. temperature, sea level). The relative magnitudes of some anthropogenic pressures differ among industrialized countries and developing countries.

Very few long-term studies have addressed temporal trends in rocky shore biodiversity and most focus locally and regionally. Barry et al. (1995) and Sagarin et al. (1999) observed changes in the abundance of macroinvertebrate species in a rocky intertidal community in California between surveys in 1931-33 and 1993-96. These changes are consistent with recent climate warming that shifts species northward. Eight of nine southern species increased in abundance and five of eight northern species decreased; however, cosmopolitan species displayed no trend. Blanchette et al. (2008) described the spatial pattern of distribution of species abundance for rocky intertidal communities along the Pacific coast of North America from Alaska to Mexico (more than 4000 km).

This biogeographic study represents one on the larger-scale analyses of this habitat, and reported strong spatial structure in the rocky intertidal communities of the north-east Pacific. Breaks in similarity among clusters generally linked with known biogeographical and oceanographic discontinuities. Sea surface temperature and species similarity both correlated strongly, coinciding with long-term temporal trends along the California coast that point to both geography and oceanographic conditions as primary determinants of patterns of intertidal community structure.

Recent efforts through the NaGISA project of the Census of Marine Life (e.g., Iken et al., 2010) and others demonstrate large-scale patterns. The NaGISA project gathered information on rocky shore systems globally, and compared diversity and abundance of key benthic groups from intertidal and shallow subtidal rocky shore sites in order to identify latitudinal trends and their environmental drivers. Global analyses were constrained by differences in sampling efforts (numbers, years, and strata sampled), timing of sampling, under-sampling of some ecoregions, and unbalanced representation of the northern and southern hemispheres. Results indicate that distribution patterns of diversity and biomass of various taxonomic groups (e.g., macroalgae, gastropods, decapods and echinoderms) are very complex and sometimes defy the expected latitudinal gradient of species decreasing towards the poles. Regional diversity hotspots often complicate any simple broad-scale pattern. Despite differences in sampling effort, timing, and coverage, this effort identified likely drivers of diversity of specific taxa and communities, several of which were tightly linked to human activities. For example, pollution indices correlate significantly with diversity in several phyla (e.g., Iken et al., 2010). Although the natural heterogeneity of these systems complicates unequivocal establishment of cause-consequence relationships, a larger data base for the analysis of global diversity trends and their drivers will provide more substantive evidence for the identification of likely drivers.

However, although much progress has been made recently, our understanding of rocky shore biodiversity patterns remains incomplete, especially beyond local or small

regional scales. Similarly, the complexity of these systems constrains efforts to assign environmental or human-induced drivers to rocky shore diversity, because such drivers can act on different scales (Benedetti-Cecchi et al., 2010), and may act cumulatively, synergistically, or antagonistically. That 40 per cent of the world's population currently lives within 100 km of the coast enhances the urgency of this issue, particularly given that as population density and economic activities increase, so will pressures on rocky shores, as well as other coastal ecosystems from tropical to temperate systems, and even some polar regions.

3.2 *Tropical coral reef ecosystems*

Tropical coral reefs span the Indo-Pacific and Atlantic Oceans, although cool upwelling associated with boundary currents limits distributions along the west coasts of Africa and South/Central America. We refer readers to Chapter 43 for a more detailed discussion on tropical and subtropical coral reef habitats that extends beyond our focus on biodiversity gradients. The diversity and productivity of coral reefs and associated ecosystems (mangroves, seagrasses and pelagic habitats) are among the highest globally, providing essential ecosystem services to tropical countries. The taxonomic richness of corals reefs is second to none, with tropical coral reefs housing 25 per cent of all known marine life on the planet including sea fans, sponges, worms, starfish, brittle stars, sea urchins, crustaceans, and fish. In fact the variety of life supported by coral reefs rivals that of the tropical forests of the Amazon or New Guinea. Temperature and habitat complexity, particularly for stony corals and bony fish, have been shown quantitatively to drive tropical reef diversity on global scales (Tittensor et al., 2010), with other features such as habitat area (rocky substrates within the photic zone), and historical factors (historical speciation/extinction patterns) being secondary drivers of regional to global patterns of coral reef biodiversity.

Tropical coral reefs are restricted to warm waters with average annual temperatures typically above 18 °C though with annual mean temperatures between 20-27 °C, which enable stony corals, via photosynthetically enhanced calcification, to lay down a skeleton fast enough to build up reefs over multiple generations. The symbiosis between stony corals and their intra-cellular symbionts (zooxanthellae) limit coral reefs to sunlit substrates, optimized in the top 10-15 m of the water column but with reef build-up possible down to 30-50 m depth. Thus coral reefs are restricted to island and continental fringes, and shallow oceanic banks that reach the photic zone. Classic coral reef descriptions emphasize oligotrophic low-sediment oceanic conditions being ideal for coral reefs, however vibrant coral and reef growth, with high-diversity communities, can occur in relatively high turbidity and sedimentation conditions in eutrophic waters near highly productive major estuaries (e.g., along the Andaman Sea). This ability for coral reefs to flourish in both sets of conditions is due to tight cycling of carbon and nitrogen between the coral symbionts.

A total of 836 tropical reef-associated coral species have been described globally, with 759 from the Indo-Pacific and just 77 from the Atlantic, with no species in common

across these two ocean systems. The broad swath of equatorial currents that cross the Pacific and Indian Oceans, joined through the 'leaky' Indonesian region, dominates global patterns of coral reef diversity connecting East Africa to French Polynesia - of 4,000 species of tropical fishes, 492 are shared between the Western Indian Ocean and French Polynesia (Randall, 1998). Westwards from here, the large deep-water barrier in the East Pacific isolates the Eastern Tropical Pacific from the broader Indo-Pacific.

At the centre of the Indo-Pacific, the Indo-Australian Arc (IAA) provides optimal temperature conditions and the highest habitat area for corals; within this 'Coral Triangle' (Roberts et al., 2002; Hoeksema, 2007) sub-regions show peaks of over 600 species of hard corals, 550 species of reef fishes and 50 species of stomatopods (Reaka et al., 2008). Diversity declines east and west from here into the Central Indian and Pacific Oceans (<300 coral and fish species, 5-15 stomatopods), though new evidence suggests a second peak of diversity in the Western Indian Ocean/Eastern African region, in both stomatopods (30 species, Reaka et al., 2008) and hard corals (350-400 species, Obura, 2012). The lowest diversity in tropical Indo-Pacific coral reefs is in the Eastern Pacific due to isolation, with <150 coral and fish species, and <5 stomatopod species. Coral reefs harbour high levels of cryptic diversity: for instance, populations of many coral and fish species previously thought to be distributed widely in the Indo-Pacific region are now recognized as different species between the Indian and the Pacific Ocean, and even more recently between the Red Sea and the Indian Ocean.

High levels of endemism are shown in remote island coral reef systems, in low-dispersive groups such as fishes. In Hawaii and the Easter Island group levels of endemism in fish exceed 20 per cent (Randall, 1998), and only 12 shore fish species are shared between the Red Sea, Easter Island, and the Hawaiian Island archipelago. The small size and lower diversity of the tropical Atlantic, with subregions in the Caribbean, Gulf of Mexico and around Brazil, may increase vulnerability to anthropogenic and climate threats compared to the larger, more diverse Indo-Pacific.

Deep-water corals also form reef structures, which we describe briefly in the deep-sea section below; we also refer readers to Chapter 42, which presents a more detailed description of these environments.

3.3 *Mangrove forest ecosystems*

Mangroves are woody plants that grow normally in tropical and subtropical latitudes along the land–sea interface, bays, estuaries, lagoons, and backwaters (Mukherjee et al., 2014). These plants and their associated organisms constitute the 'mangrove forest community' or 'mangal'. Although mangrove ecosystems occur in more than 120 countries world-wide, encompassing just over 80 plant species, subspecies and varieties globally (Massó i Alemán et al., 2010), they are generally species-poor vegetation formations. Nonetheless, they support a complex community of animals and micro-organisms, the numbers of which have never been reliably estimated. Mangrove decapods and, to a lesser extent, insects are better studied than most taxa but the

scientific community is only just beginning to understand how mangrove ecosystems work and what they contribute to ecosystem functions, goods and services, including biodiversity support, storm protection, fisheries production, effects on water quality and providing significant carbon sinks (Dahdouh-Guebas, 2013). Several recent papers document immense carbon sequestration and suggest they may represent the most carbon-rich tropical forests (Donato et al., 2011).

Mangrove tree species may be divided into two distinct floristic groups, an Atlantic-East-Pacific and Indo-West-Pacific, the latter of which represents the mangrove species richness peak between 90 and 135 degrees East. Latitudinal richness peaks globally near the equator (Figure 4). Local species richness links significantly to regional richness (Ellison, 2002), with recent recognition that high variability temperature interacts with aridity in defining upper latitudinal limits of *Avicennia* and *Rhizophora* (Quisthoudt et al., 2012).

The International Union for Conservation of Nature (IUCN) rarely lists mangrove species as threatened because they are often widely distributed, creating conservation challenges. Yet, reports of local extirpations, sometimes hidden as cryptic ecological degradation, may affect local and regional fisheries or other coastal functions (Dahdouh-Guebas et al., 2005). These losses point to an urgent need to re-assess mangrove ecosystems nationally and regionally to identify regions most at risk of losing mangrove ecosystems and associated functions, goods, and services (Mukherjee et al., 2014).

3.4 Coastal sedimentary ecosystems

The coastal zone denotes the relatively narrow transition zone between land and ocean where strong interactions occur with humans. Sediment covers much of the continental shelf from the poles to the equator and supports a wide diversity of invertebrates spanning almost all animal phyla. The shallowest depths along the shoreline support seagrasses, mangroves, and salt marshes, but seabed primary production is otherwise limited to benthic photosynthetic microbes that quickly disappear as light attenuates with depth. Resuspended material and phytoplankton sinking from the photic zone add significantly to benthic production.

For organisms ranging from large megafaunal clams and crabs to meiofaunal nematodes and copepods, temperature primarily defines broad biogeographic provinces, but within regions substrate composition plays a major role in defining composition and diversity of sedimentary fauna. Sand and coarser substrates typically occur in high-energy exposed environments, with muds characterizing quiescent areas. Depth and productivity also strongly influence faunal patterns, with peak diversity at mid-shelf depths and locations with moderate organic input (Renaud et al., 2007). A hump-shaped pattern of maximum diversity linking with productivity has been reported elsewhere, including the Arctic (Witman et al., 2008) and in fossil marine invertebrates (brachiopods) (Lockley, 1983). Intertidal sediments typically exhibit very low diversity,

irrespective of substrate composition; this is likely to be due to the harsh, dynamic nature of that environment.

In a broad sense, evidence suggests high species richness in tropical sediments relative to temperate and polar regions, but because sampling effort is strongly biased towards temperate seafloor environments, this complicates broad-scale comparisons. For example, total species number for sedimentary invertebrates in the Canadian Arctic compares favourably with the Canadian Pacific and Atlantic (Archambault et al., 2010) and on the eastern and western coasts of the United States, gastropod molluscs increase in species richness from the Arctic towards the equator, but peak in the subtropics (Roy et al., 1998). Multiple studies testing latitudinal gradients over varying scales find few consistent patterns, and suggest that complex differences in local environments play a much greater role than latitude in defining diversity and composition; indeed, landscape heterogeneity may obliterate a simple broad-scale pattern, except where broad physical drivers dominate. The strong influence of the Gulf Stream on coastal European waters produces high species richness in high latitude sediments (Ellingsen and Gray, 2002). Algal genera generally exhibit an inverse latitudinal gradient, with biodiversity hotspots in temperate regions, but bryopsidalean algae peak in diversity in the tropical Indo-Pacific region (Kerswell, 2006).

Key data gaps in species richness data for coastal sediments of Africa, South America, the western tropical Pacific and polar regions (Costello et al., 2010) constrain latitudinal comparisons, but we do know that Australian coastal sediments support very high species richness (Butler et al., 2010), and that Antarctica diversity (Griffiths, 2010) only modestly exceeds Arctic diversity (Piepenburg et al., 2011).

However, it is recognized that even with less attention than European waters, the Indo-Pacific area is the most diverse area of our oceans. Molluscs have the largest diversity of all phyla in the marine environment (Bouchet, 2006), and mollusc diversity is exceedingly high in the tropical waters of the Indo-Pacific, particularly in coral reef environments (Crame, 2000). How this pattern translates to sedimentary fauna remains unknown and leads us to conclude that we need far more studies in many regions to draw firm conclusions about general patterns of marine biodiversity in the coastal zone.

Very few studies compare sedimentary fauna across sharply contrasting sediments because differences in sampling gear complicate such comparisons. Sampling cobbles and gravel, which support a wide diversity of encrusting epifauna and flora, requires very different tools than sampling muds or even coarse sand. Nonetheless, a qualitative comparison of species lists indicates strongly different faunas within these substrata, linking to a wide range of variables spanning physical disturbance, larval supply, and food quality, to name just a few.

3.5 *Deep-sea benthic ecosystems*

The deep sea spans depths from 200 m to almost 11,000 m, encompassing more than 90 percent of the global ocean area, and representing the largest ecosystem on Earth (Watling et al., 2013). However, less than 5 percent of its area has been explored, and less than 0.001 per cent, the equivalent of a few football fields, has been sampled quantitatively, making it among the least known environments on Earth. Decades ago researchers projected 1 to 10 million total species in the deep sea (Grassle and Maciolek, 1992). More recently, Mora et al. (2011) predicted that 91 per cent of marine species remain unknown, largely due to undersampling of the deep sea (other works downsize that estimate – see Appendix). For example, 585 of 674 isopods species collected in recent expeditions to the deep Weddell Sea were new to science (Brandt et al., 2007). Sampling is uneven, with very limited understanding of hard substrate biota outside of chemosynthetic ecosystems, and under-sampling of metazoan meiofauna and protozoa.

Deep-sea sediments cover much of the deep-sea floor, with little variation in temperature and salinity. The absence of photosynthesis below ~200 m means that most deep-sea life depends exclusively on sinking food from surface waters. These sediments support a highly diverse fauna spanning most phyla; the first comprehensive sampling covered just 21 m² of seafloor, yielding 1,597 species from 13 different phyla of invertebrates (Grassle and Maciolek, 1992). The best known broad-scale diversity patterns for deep-sea invertebrates and fishes are the unimodal diversity-depth relationship, bathymetric zonation, and a general decline in species richness towards the poles. Macrofauna in total and as individual taxa provide the strongest evidence for unimodal diversity-depth relationships (Rex and Etter, 2010) in which, despite some contradictory patterns in some locations, highest diversity occurs at depths of ~1,500-2,000 m. Significant unimodal diversity-depth relationships have also been reported for nematodes, ostracods, and foraminifers in the Arctic Ocean, and for megafaunal invertebrates and fishes in the western North Atlantic. Reduced population densities under extreme food limitation may suppress species diversity in the deep oligotrophic abyss (>3,000-4,000 m depth), whereas elevated carbon fluxes at shallow depths may suppress diversity by driving competitive exclusion or creating physiological stress. On upwelling along continental margins, low oxygen at upper bathyal depths (100-1000 m) suppresses diversity. Declining food supply and thermal energy with depth (and distance from continents) are likely to drive these patterns, which are complicated by regional variation in food availability. Topographic isolation or complexity, boundary effects, sediment characteristics, currents, oxygen concentration, physical disturbance, biological interactions and patch dynamics, as well as evolutionary history, also influence diversity and distribution patterns at regional and local scales (Rex and Etter, 2010).

Many fish and invertebrate taxa occur at a similar depth range in “bands” of distinct assemblages or “zones”. Zonation describes sequences where few changes in species composition occur within a band, but abrupt faunal boundaries occur. However, major oceanographic features, such as oxygen minimum zones, strong bottom currents and

abrupt shifts of water masses, can obscure, alter, or create zonation patterns. Globally, clear faunal differences are observed between upper bathyal depths compared to mid and lower bathyal depths (Rex and Etter, 2010). The preponderance of rare species complicates these analyses, particularly in abyssal environments where many species occur only once in samples (Grassle and Maciolek, 1992).

Multiple biological and physical factors, such as larval dispersal, competition, predation, temperature, oxygen concentration, hydrostatic pressure, and food supply, all potentially drive zonation. Temperature, oxygen, and food supply vary most in the upper bathyal region, where pronounced species turnover occurs, creating a ubiquitous shelf-slope transition zone. In lower bathyal (3,000-4,000 m) and abyssal depths, declining food supply homogenizes fauna and reduces species turnover.

Multiple studies report latitudinal diversity gradients in many deep-sea invertebrate groups, although patterns vary in sparse sampling of limited taxa (Kaiser et al., 2013). For several macrofaunal groups, and for meiofaunal foraminifers, diversity decreases with increasing latitude in the North Atlantic. In the South Atlantic, isopod diversity increases, whereas gastropods and bivalves decline poleward (although there are exceptions to this trend). Strong seasonality and pulses of phytodetritus at high latitudes may depress diversity, much like physical disturbance. Other work suggests increasing diversity in the northern hemisphere for nematodes.

Thousands of topographic features, such as submarine canyons and fjords, incise continental and island margins and increase complexity of bottom topography, modify abundance and diversity by intensifying mixing, amplifying currents, enhancing productivity, sediment and food deposition, and channel cascading shelf waters. Enhanced food deposition drives species aggregations and consequent increased diversity in these habitats compared to adjacent, topographically simpler areas. Steep topography and amplified currents often expose bedrock and boulders within canyons, supporting additional fauna, such as megafaunal and macrofaunal suspension feeders that require hard surfaces for attachment and strong currents for food delivery.

Biogenic reefs (formed mainly by deep-water coral and sponges) occupy hard substrata with high currents, often within basins or along the continental margins. These reefs form from skeletons of dense aggregations of one or a few species. The skeletons create surfaces for colonization, extend higher in the water than the surrounding seafloor (thus reaching faster currents and greater food delivery) and add spaces for protection from predators and other disturbances. These reefs therefore enhance local species diversity, and provide nursery areas for many macro- and megafaunal invertebrates and fishes.

Despite their remoteness, human activities affect deep-sea diversity, resulting in declines in deep-sea fishes, loss of habitat-forming invertebrates (e.g., deep-water corals), and increased contaminants in deep-sea biota. Although these impacts illustrate local to regional effects, the cascading effects of warming surface layers portend substantial changes in the food supply to deep-sea ecosystems. Manifestations of climate change including ocean warming, acidification and deoxygenation, may reduce the bathyal habitats available, with concomitant broad-scale changes in patterns of

species distribution and diversity. Deep-sea biodiversity loss could adversely affect ecosystem functions of the Earth's largest environment.

Hydrothermal vents and cold seeps occur where dissolved chemical compounds emerge at the seafloor at rates and concentrations high enough to sustain chemosynthesis. Chemosynthesis is the process that some microbes use to transform CO₂ into organic molecules. The emerging fluid is often associated with active tectonic features such as spreading centres, subduction zones, and volcanoes, but seeps may also be linked to methane escape via mass wasting, brine pools, turbidity flows, diapirs, and pockmarks, canyons and faults. The resulting habitat distribution tends to be linear, following mid-ocean and back-arc spreading centres, as well as volcanic arcs in the case of vents, and along continental margins in the case of seeps. The fluid emissions at most regions of high carbon accumulation – oil, gas and clathrate-rich deposits – support chemosynthesis. Thus, the microbes form the basis of a food web for a metazoan community that is mostly endemic to these systems. Habitats supporting chemosynthetic production and communities occur in every ocean.

No overall assessment of diversity patterns and drivers exists, although alphadiversity at vents and seeps is often lower than in the surrounding non-chemosynthetic ecosystems. The considerable work on biogeographic patterns includes exploration of faunal relationships and origins. Despite similarity in many taxa at vents and seeps, they usually differ at species or genus levels; however, both habitats harbour many endemic taxa. Some taxa at vents and seeps are new to science at higher taxonomic levels, especially those housing microbial symbionts.

Overall, species diversity at seeps exceeds that at hydrothermal vents, driven by high variability in the geological settings of methane and sulphide release and within-site heterogeneity (Levin and Sibuet, 2012). Depth may describe both the biogeographic similarity of seeps across the Atlantic and, possibly, the decrease of symbiont-hosting species with depth in general at seeps. However, depth may reflect more direct drivers, such as greater production and predation at shallower depths or behaviour of fluid flux sustaining chemosynthesis. Local site longevity and stability of the fluid source will influence any pattern analysis, as will depth; vents in the photosynthetic zone above 200 m differ notably in taxa and structure. These habitats exhibit low diversity within taxa. Habitat and depth drive a variety of patterns in vesicomid clams hosting symbionts, but better systematics are needed. The East Pacific Rise represents a diversity hotspot for the most speciose family, the vent-endemic dirivultid copepods.

Biogeographic patterns at vents are likely to share controlling factors with all ocean fauna: continental barriers, oceanographic barriers, and pressure gradients with depth. However, similarity analyses with growing datasets indicate strong control by the history of spreading ridges from the mid-Mesozoic to the present. Thus, diversity analysis is likely to identify connectivity, geological longevity and ridge stability as important, reflecting the smaller-scale drivers currently known. Recent discovery of vent communities in the Antarctic and Arctic reveal a unique community composition and

suggest that dispersal barriers are also important drivers of diversity (Rogers et al., 2012).

Increasing evidence suggests that the character of the venting fluids fundamentally drives taxonomic composition, overlaid on geographic separation, particularly in the complex settings of the Atlantic and the western Pacific back-arc rifting and volcanism (Desbruyères, 2000); relevant factors may include reduced compound composition, water temperature and metal content. Similarly, the high diversity of animals recently recognized from mud volcanoes relates to the nature of the chemical substrates in emerging fluids and the adaptations of associated microbes and symbiont hosts both across and within sites (Rodrigues et al., 2013). Where geochemical drivers characteristic of vents and seeps come together, an intermediate ecosystem with biodiversity elements from both vents and seeps emerges (Levin et al. 2012). Decay of large organic falls also supports microbial processes and species reliant on chemosynthesis (Smith et al., 2015). Thus vents and seeps also hold many taxa in common with organic remains, such as wood falls and whale carcasses.

Seamounts are undersea mountains historically defined by an elevation of 1 km or more, but more recently by a more ecological definition, that includes knolls and hills with an elevation of 100 m or more. They occur in all oceans of the world, from the tropics to the poles, and cover depth ranges from near the surface to the abyss. The total number remains uncertain because so little of the deep ocean has been surveyed, but estimates range from 14,000-50,000 large seamounts and tens to hundreds of thousands of smaller ones (Stocks, 2010).

Three important characteristics distinguish seamounts from the surrounding deep-sea habitat (Clark, 2009). First, as “islands” of shallower sea floor, they provide a range of depths for different communities. Second, their typical hard and often bare rock surfaces contrast with the fine, unconsolidated sediments that cover the majority of the sea floor. Third, the physical structure of some seamounts alters local hydrography and currents so as to concentrate species and productivity over the seamount, thus increasing their importance as oceanic ecosystems but also attracting commercial exploitation. The very low proportion of seamounts sampled globally limits understanding of their diversity, and the composition, structure, function, and connectivity of seamount ecosystems remain unexplored and unknown except in a few locations (Stocks and Hart, 2007).

Seamount benthic communities are rich and varied; sandy or muddy sediments dominate where currents are slow, with mostly deposit-feeding species of polychaetes, echinoderms, various crustaceans, sipunculids, nemertean worms, molluscs, sponges, and nematodes utilizing sinking particulate matter. Suspension feeders, including corals, crinoids, hydroids, ophiuroids, and sponges, dominate where faster currents expose rocky areas. The large corals and sponges can form extensive and complex reef-like or thicket structures, which add habitat for smaller mobile fauna. Seamount biodiversity research has rapidly increased the number of known species in recent decades. A global

review in 1987 (Wilson and Kaufmann, 1987) recorded 449 species of fish and 596 species of invertebrates from 100 seamounts, but more recent surveys suggest much higher numbers (Stocks, 2010). The Census of Marine Life on Seamounts amalgamated data on over 5,400 taxa (although not all to species) from 258 seamounts into the public database SeamountsOnline (Stocks, 2010), which can currently be accessed through the Ocean Biogeographic Information System portal (www.iobis.org) by selecting the Seamounts Online database. However, gear selectivity and generally few samples per seamount limit biodiversity knowledge for any one seamount.

Depth-related environmental parameters strongly influence seamount species composition, together with seafloor type and character (e.g., substratum, hardness, composition, mobility) (see Clark et al., 2010a). Habitat complexity on seamounts largely determines benthic species occurrence, distribution and diversity. Volcanic activity, lava flows and areas of hydrothermal venting add to habitat diversity on seamounts, creating unique environmental conditions that support specialized species and assemblages (see preceding section). Water column stratification and oceanic flow conditions also add local dynamic responses that can regulate the spatial scale of faunal distributions.

Many early studies suggested high seamount endemism given their geographic isolation, often separated from other seamounts by deep water and considerable distance. Although seamount assemblages can differ in species abundance or frequency, similarity in deep-sea fish assemblages between seamounts and adjacent continental slopes or islands (scales of km), as well as across oceans (1000s of km), contradicts the idea of ecological islands (Clark et al., 2010b). In the latter case, the global-scale circulation of deep-sea water masses presumably influences fish distribution. Regional-scale similarities in faunal composition between seamounts and other habitats in the South Pacific demonstrate that seamounts share a common regional pool of species with non-seamount communities. Schlacher et al. (2014) found high species turnover with depth and distance in seamount assemblages off Hawaii at the scale of individual seamounts, but geographic separation was a poor predictor of ecological separation for the region as a whole. These studies emphasize that the spatial scales over which faunal assemblages of seamounts are structured cannot be generalized. Nevertheless, recent biogeographic classifications for the deep ocean suggest that benthic community composition will vary markedly among basins (e.g., Watling et al., 2013).

Better understanding of global deep-sea biodiversity gradients requires more sampling, but predictive species distribution modelling and use of environmental surrogates can improve our short-term understanding (e.g., Clark et al., 2012) and help inform management options for the deep sea.

3.6 *Cross-taxa integration*

The global ocean houses an enormous variety of life. In total, the oceans support an estimated 2.2 million eukaryotic species (Mora et al., 2011), of which science has

described some 220,000 (WoRMS Editorial Board, 2013). A key question is whether consistent 'rules' constrain the distribution of this life across the variety of different organisms and habitats examined here, and if so, whether they result in consistent large-scale patterns of biodiversity. Global-scale studies to explore this question began long ago and especially in the last decade (e.g., Rutherford et al., 1999; Roberts et al., 2002), but the enormous amounts of data collected and compiled by the Census of Marine Life enable exploration and mapping patterns across more taxonomic groups than ever before (Tittensor et al., 2010) to understand the consistency of diversity patterns.

Perhaps the most common large-scale biodiversity pattern on the planet is the 'latitudinal gradient', typically expressed as a decline in species from the equator to the poles (Figure 5). Adherence to this pattern varies among marine taxa; Chlorophyta and other macroalgae, for example (Figure 5, lower right panel), do not exhibit the same latitudinal gradient, as noted earlier above in this chapter). Although coastal species generally peak in abundance near the equator and decline towards the poles, seals show the opposite pattern; indeed pinnipeds peak at high latitudes (Fig. 1a). Furthermore, strong longitudinal (east-west) gradients, complicate patterns, with 'hotspots' of richness across multiple species groups in the 'Coral Triangle' in the Indo-Pacific and the Caribbean (Figure 6).

Oceanic organisms, such as whales, differ in pattern entirely, with species numbers consistently peaking at mid-latitudes between the equator and poles. This pattern defies the common equator-pole gradient, suggesting that different factors are involved. Different processes may control species richness among oceanic and coastal species (for example, in terms of dispersal, mobility, or habitat structure), but general patterns appear to be reasonably consistent within each group. However, across all groups studied, ocean temperature is consistently related to species diversity (Tittensor et al., 2010), hence the effects of climate change are likely to be observed as a restructuring of marine community diversity (Worm and Lotze, 2009)

Although the above patterns hold for the 11,000 species studied (Tittensor et al., 2010), numerous groups and regions were not represented. For example, global-scale patterns of diversity in the deep ocean remain largely unknown (Rex and Etter, 2010). Our diversity and distribution knowledge is taxonomically biased towards large, charismatic (e.g., whales) or economically valuable (e.g., tunas) species. Our knowledge of patterns in microbial organisms remains particularly limited relative to the enormous diversity therein, and enormous challenges to even measure biodiversity remain. Viruses remain a critical part of the oceanic system for which we lack any global-scale biodiversity knowledge.

Other than species richness, we are just beginning to explore other patterns of global marine biodiversity. Patterns of 'evenness' in reef fishes, which relates to relative proportions of individual species in the community, apparently show an inverse gradient (Stuart-Smith et al., 2013). This pattern, in turn, affects 'functional richness', which relates to the diversity of functions in reef fishes, a potentially important component of

ecosystem productivity, resilience, and goods and services provision. The importance of these patterns depends on their robustness and consistency across different species groups, but opening such new insights into other facets of biodiversity provides additional information with which to manage it, particularly in support of human welfare.

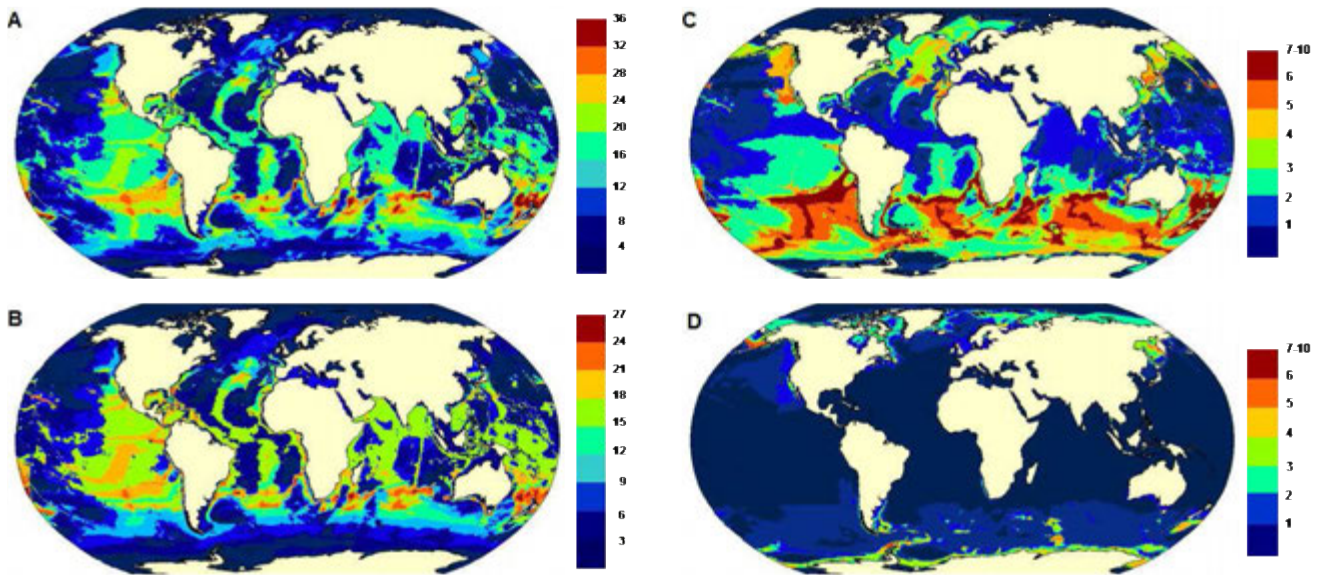

Figure 1a. Global marine mammal species richness peaks between 30 °and 60 ° in both hemispheres. Number of species (as predicted by a relative environmental suitability model, (Kaschner, 2006) was summed over 5° latitudinal bands for all species, mysticetes, small odontocetes, large odontocetes (beaked whales and sperm whales), and pinnipeds (from Kaschner et al., 2011).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1b. Predicted patterns of marine mammal species richness. A. All species included in the analysis (n=115), B. Odontocetes (n=69), C. Mysticetes (n=14), D. Pinnipeds (n=32). Colours indicate the number of species predicted to occur in each 0.5°x0.5° grid cell from a relative environmental suitability (RES) model, using environmental data from 1990-1999, and assuming a presence threshold of RES>0.6. (from Kaschner et al., 2011).

Figure 2. Cumulated number of species described per year between 1758 and 2013. The rate of descriptions accelerates after 1950, mainly due to an increasing number of freshwater species descriptions; the rate of marine species descriptions has been linear since the early 1980s.

Figure 3. Number of species of fish per genus, in each latitudinal band of 1 degree, as calculated from distribution data available in OBIS on 26 September 2011.

Figure 4. Latitudinal species richness of mangrove plant species.

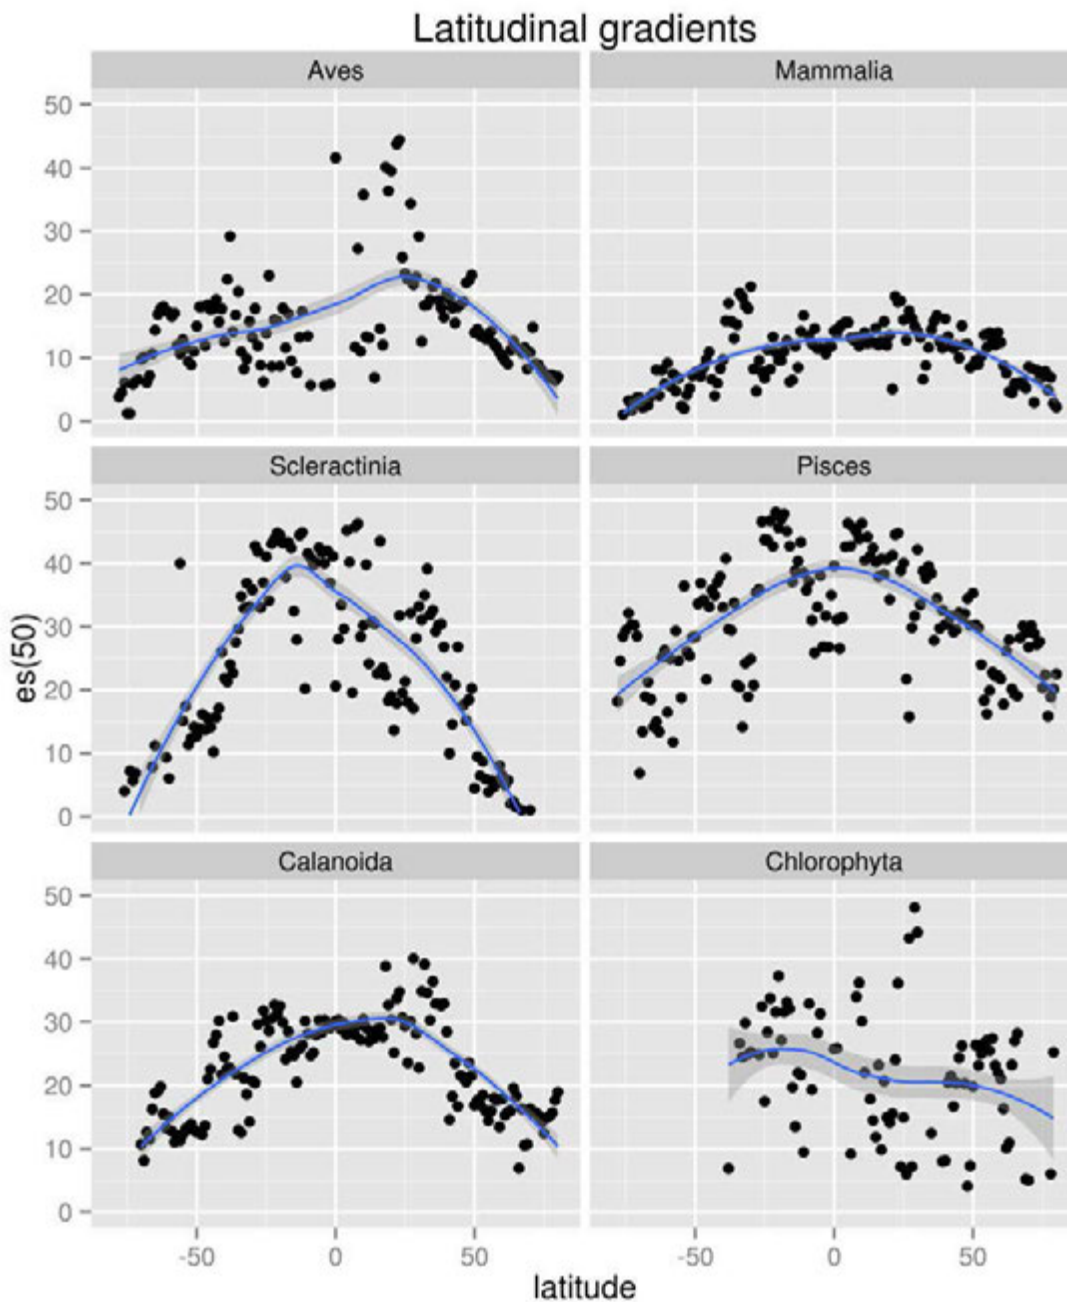

Figure 5. ES(50) calculated for various groups, from the data as available in OBIS as of the end of 2012. ES(50) (or Hurlbert's index) represents the numbers of species expected to be present in a random sample of 50 individuals; this metric measures the diversity (not species richness, as its name might suggest), independent of sample size. Points in the graphs above represent calculation of ES(50) for bands of 1 degree of latitude. The blue line is the LOESS (LOcal regrESSion) prediction/smoothing; the darker grey bands are the 95% confidence intervals around the LOESS estimate. Most groups, but not all (e.g. Chlorophyta) show a clear unimodal pattern. All calculations were made with R (R Development Core Team, 2014), using package ggplot2 for LOESS and plotting (Wickham, 2009).

Figure 6. Coral species richness by province in the Marine Ecosystems of the World Classification, from the IUCN Red List of Threatened Species database (IUCN 2013).

Table 1: Number of species by life zone (Saltwater including diadromous, Freshwater) from the successive editions of Fishes of the World by J.S. Nelson (1976, 1984, 1994, 2006). The last line gives the current counts from the Catalog of Fishes (Eschmeyer, 2014).

Year	Salt Water		Freshwater		Total
Fishes of the World (Nelson) successive editions					
1976	11967	64%	6851	36%	18818
1984	13312	61%	8411	39%	21723
1994	14652	60%	9966	40%	24618
2006	16025	57%	11952	43%	27977
Catalog of Fishes					
2013	17535	53%	15467	47%	33002

Table 2. Number of marine fish species per FAO area.

FAO area	Spp. count
Arctic Ocean	147
Atlantic, Northwest	1129
Atlantic, Northeast	1115
Mediterranean and Black Sea	811
Atlantic, Western Central	2428
Atlantic, Eastern Central	1699
Atlantic, Southwest	1777
Atlantic, Southeast	1779
Atlantic, Antarctic	250
Indian Ocean, Western	4432
Indian Ocean, Eastern	4757
Indian Ocean, Antarctic	250
Pacific, Northwest	5299
Pacific, Northeast	717
Pacific, Western Central	6490
Pacific, Eastern Central	4138
Pacific, Southwest	2249
Pacific, Southeast	1916
Pacific, Antarctic	170

Table 3. Number of marine fish species per Ocean and FAO area. E: East; N: North, S: South; W: West: indicates which part of the ocean. Note: The second eastern central line for Atlantic represents the Mediterranean and Black Seas. The Northwestern Pacific includes some coral reef areas in its southern part which explains the high number of species compared to the Northeastern part.

Ocean	Atlantic				Indian				Pacific			
Latitude												
Arctic	N	147										
North	W	1129	E	1115					W	5299	E	717
Central	W		E	811					W	6490	E	4138
Central	W	2428	E	1699	W	4432	E	4757				
South	W	1779	E	1777					W	1916	E	2249

Tunnell, Jr., Fabio Moretzsohn, Elva Escobar-Briones, Henn Ojaveer, Judith Gobin, Massa Nakaoka, Katsunori Fujikura, Hiroya Yamano, Xinzheng Li, K. Venkataraman, C. Raghunathan, Charles L. Griffiths, Nicholas J. Bax, Alan J. Butler, Angelika Brandt, and Huw J. Griffiths, Jake Rice (Lead member)¹

1. Introduction

This chapter provides a summary of currently assessed marine biodiversity in terms of its coverage for the most conspicuous and well known taxonomic groups, particular ecosystems, and large geographic regions. Assessments will be focused on the evaluation of the state of knowledge of marine biodiversity; however, for some groups, such evaluations are provided indirectly by studies aimed to establish threat and or risk status. The groups that have been summarized globally are the sea mammals (cetaceans and pinnipeds), seabirds, sea turtles, sharks, tunas, billfish, corals, and plankton. The special ecosystems are seamounts, vents, and seeps. Regional summaries of coverage of assessments are provided whenever possible for large basins, such as North Atlantic, South Atlantic, North Pacific, South Pacific, Indian Ocean, Arctic Ocean, and Southern Ocean. However, in some cases, information is compiled by countries (e.g., Canada) when these have more than one basin, or by large continents (e.g., South America) which share a history of surveys and exploration. After each of the sections, a global analysis of the status of knowledge of marine biodiversity is summarized within a few synthesis graphs. About 40 scientists contributed to this effort, each within their area of expertise and specified for each subsection. Supplementary material providing a list of assessments with date, special area, habitat, taxonomic groups, and web information has also been compiled for a few of the regions (Caribbean, Europe, Gulf of Mexico, the Southern Ocean and Sub-Saharan Africa) and States (China, India and Japan), as well as for vents and seeps ecosystems and for turtles (Appendix I). In addition, a complete reference list for further reading for each of the taxonomic groups and regions is provided (Appendix II).

¹ The writing team thanks Esteban Frere, Mayumi Sato and Ross McLeod Wanless for their contributions to this chapter.

2. Groups summarized globally: Cetaceans, pinnipeds, seabirds, sea turtles, sharks, tunas, billfish, corals, seamounts, vents and seeps.

2.1 Marine Mammals

Global assessments of marine mammal distributions are limited by geographic and seasonal biases in data collection, as well as by biases in taxonomic representation due to rarity and detectability. In addition, not all data collected have been published in open-access repositories, thus further constraining our ability to develop comprehensive assessments. Given the financial, logistical and methodological challenges of mounting surveys, especially for animals that spend most of their time underwater, assessments have been most extensive and intensive on the coastal shelves and continental slopes along the coastlines of developed countries (Kaschner et al., 2012 & Figure 1A). Ship-board surveys of large ocean areas have been and continue to be carried out in the Southern Ocean and North Pacific under among others, the auspices of the International Whaling Commission, focusing on those whales previously subject to commercial whaling. Advances in satellite telemetry are helping to fill in some gaps in offshore areas for both cetaceans and pinnipeds (Block et al., 2011).

However, the remaining geographic biases in sampling coverage are very apparent, for example, in the map portal Ocean Biogeographic Information System Spatial Ecological Analysis of Megavertebrate Populations OBIS-SEAMAP (<http://seamap.env.duke.edu>), which is an online data portal compiling occurrence records of higher vertebrates living in the marine environment (Halpin et al., 2009), where the majority of species observation records fall within the coastal shelves and continental slopes of the Northern Hemisphere. Around 95 per cent of the marine mammal observations published on the portal are from inside the 200-nautical-mile (nm) exclusive economic zone (EEZ), while ~5 per cent are in areas beyond national jurisdiction (ABNJ). A recent analysis of global coverage of cetacean visual line-transect survey coverage showed that only ~ 25 per cent of the world's ocean area had been covered by systematic surveys by the year 2006, and only 6 per cent had been covered frequently enough to be able to detect population trends (Kaschner et al., 2012). Pinniped and cetacean populations are monitored fairly frequently in the United States of America, European and Southern Ocean waters; more than half of the total global line-transect effort from 1978 – 2006 was in areas within the national jurisdiction of the United States (Kaschner et al., 2012) and ~35 per cent of all marine mammal observations held in OBIS-SEAMAP are from within the 200-nm EEZ of the United States.

Geographically, the largest gaps in sampling coverage are in the Indian Ocean and the temperate South Atlantic and South Pacific, where comparatively few dedicated surveys have been conducted. In the Southern Hemisphere, surveys have been carried out mostly in the EEZs of Australia, New Zealand, Chile, Argentina, and South Africa where more than 50 per cent of the world's species are found, and endemism is relatively high. Seasonally, most data collection using standard visual monitoring methods is concentrated in the summer as poor weather conditions seriously lower detectability,

but again, satellite telemetry and passive acoustic monitoring are helping to fill in some of the temporal gaps. Although passive acoustic monitoring can be very useful in detecting the calls of certain species, and thus help determine their presence in a region, during seasons of poor visibility or low survey effort, such monitoring cannot yet be used routinely for the development of abundance or density estimates.

Sampling effort and reporting is also highly variable for different species. For example, although OBIS-SEAMAP currently contains a total of >560,000 marine mammal occurrence records covering 106 species of the roughly 120 marine mammal species (~88 per cent), the data sets are uneven, with no records available of some uncommon species (~12 per cent) and fewer than 10 records available for others (~14 per cent). Overall, the distributions of some well-known species, such as the humpback whale (*Megaptera novaeangliae*) and the harbour porpoise (*Phocoena phocoena*), have been studied extensively and are well established; they are based on sightings and strandings or analyses of catch data. Relatively large proportions of the known ranges of these species are being monitored frequently, using different survey techniques (Kaschner et al., 2012). Similarly, at-sea movements and occurrence of other species, such as the southern and northern elephant seals (*Mirounga leonina*, *M. angustirostris*), have been investigated in considerable detail, using data loggers and satellite tracking (Block et al., 2011). In contrast, the information on some species is limited and patchy due to their rarity and/or cryptic behaviour. Some have rarely, if ever, been seen alive and are known only from a few stranding records (e.g., Perrin's beaked whale, *Mesoplodon perrini*).

Assessments of marine mammal species distribution and status derived from available data sets must be viewed in comparison to survey effort to control for unsurveyed regions or areas where observation data have not been shared with open-access information systems (Figure 1A). Accumulated data sets and understanding of marine mammal species distributions are improving, but any interpretation of the state of knowledge needs to take account of the significant biases, as noted. In summary, assessment of marine mammals globally is far from comprehensive, with abundance estimation and trend analysis at the population level limited to relatively few species in particular geographic regions, and for some species even such basic information as their actual range of occurrence is still lacking.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1A. Global coverage of visual cetacean line-transect survey effort (Frequency of coverage) (from Kaschner et al., 2012). See also the OBIS SEAMAP data available through <http://seamap.env.duke.edu>.

2.2 Seabirds

BirdLife International is the International Union for the Conservation of Nature (IUCN) Red List authority for birds, and assesses the status, trends and threats of all Critically Endangered seabirds each year, as well as species thought to warrant immediate uplisting. In addition BirdLife International carries out a comprehensive assessment of all 350+ species of seabird every four years. Some seabird populations and/or species lack population monitoring altogether, resulting in unknown population trends for 53 seabird species on the IUCN Red List (Croxall et al., 2012). The International Waterbird Census (IWC) includes certain seabird species. It has run since 1967 and today covers over 25,000 sites in more than 100 countries. Results are reviewed and published in Waterbird Population Estimates, which assess the trends and 1 per cent thresholds for over 800 species and 2,300 biogeographic populations worldwide.

At the global and regional levels many Multilateral Environmental Agreements (MEAs) include priority species lists for which aspects of status, trends and threats are supposed to be assessed. Seabirds are included on some of these lists and are used as indicators for assessing the state of the marine environment. Those currently most actively undertaking work include the Agreement on the Conservation of Albatrosses and Petrels (ACAP) (29 species), the Directive 2009/147/EC of the European Parliament and of the Council of 30 November 2009 on the conservation of wild birds (the European Union (EU) Birds Directive (all seabirds in the EU), the Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR Convention) (9 species), the Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA) (82 species), the Convention for Protection against Pollution in the Mediterranean Sea (Barcelona Convention) (14 species), the Convention on the Conservation of Migratory Species of Wild Animals (CMS) (20 seabird species on Annex I; 50 on Annex II), the Convention on the Conservation of European Wildlife and natural habitats (Bern

Convention) (over 30 species), the Convention on the Protection of the Marine Environment of the Baltic Sea (HELCOM) (11 species), the Convention on the Protection of the Black Sea against Pollution (Bucharest Convention) (2 species), the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) (7 species), the Conservation of Arctic Flora and Fauna (CAFF) (3 species), the North American Agreement on Environmental Cooperation (1 species), and the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES) (6 species). Other MEAs that have this remit but are not yet active include the Nairobi Convention for the Protection, Management and Development of Marine and Coastal and Environment of the Western Indian Ocean Region (the Nairobi Convention) (47 species), the Regional Convention for the Conservation of the Red Sea and Gulf of Aden Environment (Jeddah Convention) (lists not yet provided by contracting parties), Convention for Cooperation in the Protection, Management and Development of the Marine and Coastal Environment of the Atlantic Coast of West, Central and Southern Africa Region (Abidjan Convention) (considering adding a species list), and the Convention for the Protection and Development of the Marine Environment in the Wider Caribbean Region (Cartagena Convention) (5 species). These MEAs (and other processes) have led to the development of individual species management plans, which often outline how (and by whom) monitoring of status, trends and threats can be addressed.

Numerous online databases have pooled seabird data at regional or global scales (as well as national programmes); these include data for:

- Colonies – Sea Around Us Project, BirdLife International World Bird Database and Marine E-atlas, Global Seabird Colony Register, Circumpolar Seabird Data portal, New Zealand National Aquatic Biodiversity Information System (NABIS)
- Productivity - Pacific Seabird Monitoring Database.
- Tracking - Seabirdtracking.org, OBIS-SEAMAP, Movebank, seaturtle.org, Tagging of Pacific Predators (TOPP), British Antarctic Survey, CNRS-Chize
- At-sea surveys - European Seabirds at Sea, North Pacific Seabird Portal, Australia Antarctic Division, Royal Navy Birdwatching Society, OBIS-SEAMAP, Atlas of Seabirds @ Sea, eBird, North Pacific Pelagic Seabird Database, Global Biodiversity Information Facility.
- Threats - the New Zealand Threat Classification System: conservation status of 473 taxa assessed. For seabirds, perhaps the world second largest in terms of number of species assessed (Robertson et al., 2013).

The BirdLife International Marine Important Bird Areas (IBA) e-Atlas provides a site-based information portal for seabird conservation. This first global network of over 3,000 sites covers 6.2 per cent of the world's oceans and was compiled by BirdLife International drawing on work from 1,000 seabird scientists, government ministries and secretariats of conventions. The World Seabird Union (comprised of 22 seabird

organizations) has established the Seabird Information Network aiming to showcase, and link, different global seabird databases.

2.3 Marine Turtles

The primary global assessment framework for marine turtle species is the IUCN Red List of Threatened Species™ (www.iucnredlist.org). The IUCN Marine Turtle Specialist Group (MTSG), one of the IUCN/Species Survival Commission's specialist groups, is responsible for conducting regular Red List assessments of each marine turtle species on a global scale. Currently the Red List identifies the olive ridley (*Lepidochelys olivacea*) as Vulnerable, the loggerhead (*Caretta caretta*) and green (*Chelonia mydas*) turtles as Endangered, the Kemp's ridley (*Lepidochelys kempii*), hawksbill (*Eretmochelys imbricata*), and leatherback (*Dermochelys coriacea*) turtles as Critically Endangered, and the flatback turtle (*Dermochelys coriacea*) as Data Deficient.

To address the critical issue of geographically variable population traits in marine turtle species, the MTSG developed an alternative assessment framework and a new approach to Red List assessments that better characterize variation in status and trends of individual populations (Wallace et al., 2010), which results in official Red List categories for subpopulations in addition to the single global listing.

To address the challenges presented by the mismatched scales of global Red List assessments and regional/population-level variation in status, the IUCN Marine Turtle Specialist Group (MTSG) convened the Burning Issues Working Group of marine turtle experts who developed (1) regional management units (RMUs) (i.e., spatially explicit population segments defined by biogeographical data for marine turtle species) as the framework for defining population segments for assessments (Wallace et al., 2010). These RMUs are functionally equivalent to IUCN subpopulations, thus providing the appropriate demographic unit for Red List assessments. The Group also developed (2) a flexible yet robust framework for assessing population viability and the degree of threats that could be applied to any population in any region, and (3) a "conservation priorities portfolio" for all RMUs, with globally included identification of critical data needs by RMUs, as well as individual population risk and threats criteria, and that reflects the wide variety of conservation objectives held by different stakeholders depending on institutional or regional priorities. South Asia had the highest proportion of RMUs categorized as requiring critical data needs (~40 per cent), followed by the West Indian Ocean (25 per cent) and Australasia (20 per cent). Similarly, population risk and threats scores for RMUs in the Indian Ocean were associated with the lowest availability and quality of data among ocean basins.

Among population risk criteria, insufficient information was available to assess recent and long-term trends for roughly 25-30 per cent of all RMUs. Among threats, climate change was scored "data deficient" in two-thirds of all RMUs, while pollution and pathogens were scored "data deficient" in more than half of all RMUs. These results demonstrate the need to enhance data collection and reporting on population trends,

as well as current and future impacts of climate change and pollution/pathogens on marine turtles.

In addition to the two primary global assessment frameworks described above, several other global status assessments exist for marine turtles. The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) and the Convention on the Conservation of Migratory Species of Wild Animals (CMS, or Bonn Convention) include all marine turtle species in their lists, meaning that international trade in any products of any marine turtle species is prohibited and marine turtles are categorized as being in danger of extinction throughout all or a significant proportion of their range.

National laws to assess and protect endangered species can also result in global assessments. For example, all marine turtle species (except the flatback, *Natator depressus* which does not appear in the United States territorial waters) are listed globally as either Endangered or Threatened under the United States Endangered Species Act. Recently, the United States designated “distinct population segments”—which are similar to the RMUs and IUCN subpopulations described above—for loggerhead turtles (*Caretta caretta*) and listed all populations as either Threatened or Endangered. In addition, global status reviews are performed every five years for all marine turtle species listed under this act in the United States (Wallace, 2010).

Regional assessments offer more detailed views of marine turtle status, significant threats, and data gaps. Three noteworthy examples of regional marine turtle status are highlighted here. First, the Wider Caribbean Sea Turtle Conservation Network (WIDECAST, www.widecast.org) generated an “atlas” of marine turtle nesting sites, legal protection, and other relevant information for more than 40 countries and territories in the Wider Caribbean. Second, regional members of the IUCN Marine Turtle Specialist Group conducted a comprehensive assessment of the distribution, threats, and conservation priorities with regard to marine turtles in the Mediterranean. Third, the Indian Ocean-Southeast Asia Marine Turtle Memorandum of Understanding (IOSEA, www.ioseaturtles.org) has produced status and threats assessments of two species (loggerheads and leatherbacks) across more than 30 countries in the Indian Ocean and Southeast Asia. Assessments of marine turtle status at national and local levels occur around the globe, but a complete review is beyond the scope of this section (see Appendix I – Turtles: Summary of existing assessment frameworks and resources for marine turtles at global and regional scales).

In general, an urgent need remains for enhanced monitoring and reporting of marine turtle population status and trends, as well as of threats to marine turtles globally. Although much information exists in some regions (e.g., Wider Caribbean, Mediterranean, North America), significant data needs are apparent in other regions (e.g., West and East Africa, North Indian Ocean, Southeast Asia). Regional and global efforts to compile all available information in such regions are vital to filling these data gaps. Nonetheless, significant efforts to quantify fundamental marine turtle

demographic rates and processes (NRC, 2010) are still required to improve assessments of marine turtle status at global, regional and local scales (Wallace, 2011).

2.4 *Sharks, Rays, and Chimaeras*

Sharks, rays and chimaeras comprise the Class Chondrichthyes. This group is highly diverse (at least 1,200 valid species) and occur in a broad range of habitats, so a wide range of approaches has been taken to assess the status of individual populations. The most publicly available assessments for chondrichthyans are available from the IUCN Red List. The IUCN Species Survival Commission's Shark Specialist Group (SSG), is a global network of experts in the biology, taxonomy, and conservation of sharks, rays, and chimaeras which continuously conducts global and regional assessments of the Red List Status of chondrichthyans. Established in 1991, the SSG currently has more than 123 members from 33 countries collaborating to assess threat level, collate knowledge, highlight species at risk, and advise decision-makers on effective, science-based policies for sustainable use and long-term conservation (www.iucnssg.org). In 2011, using the 2001 IUCN Red List Categories and Criteria (version 3.1; <http://www.iucnredlist.org/technical-documents/categories-and-criteria>), a total of 1,041 chondrichthyan species had been assessed and their extent of occurrence mapped, highlighting considerable gaps in knowledge (Dulvy et al., 2014). A total of 487 out of the 1,041 species were categorized as Data Deficient, particularly in four regions: (1) Caribbean Sea and Western Central Atlantic Ocean, (2) Eastern Central Atlantic Ocean, (3) Southwest Indian Ocean, and (4) the South and East China Seas (Dulvy et al., 2014), and in 2014, the assessed number of species was raised to 1,088. Since assessments are considered out of date after ten years, a concerted effort has been initiated to reassess all species in support of the 2020 Aichi targets of the Convention on Biological Diversity's Strategic Plan for Biodiversity (e.g. North-East Pacific and Europe regions in 2014; Australia and Oceania planned for 2015).

The Red List Assessments are complemented by data from catch landings, fishery catch rates, fisheries stock assessments, fishery-independent surveys, transect surveys (divers, boats, and aerial), as well as increasing quantities of individual photographic identification data, satellite tracking data and population genetics data, which vary in availability, quality, and geographic and taxonomic coverage. These data collection programmes and research projects are also combined with historical ecological information and traditional knowledge-based assessments of the change in species distributions.

National catch landings data are reported annually to the Food and Agriculture Organization of the United Nations (FAO). From 2000 to 2009, 143 countries/entities reported shark, ray and chimaera catches to FAO. The taxonomic resolution of the global landed catch has improved, but remains poor. By 2010, only a small proportion (29 per cent) of the catch was reported to species level, the remaining bulk of the global catch reported at much coarser taxonomic levels, and around one-third of global catches reported at the taxonomic Class level (i.e. "Sharks, rays, skates, etc"). Among

the top shark fishing nations (Indonesia, India, Spain, Taiwan Province of China, Argentina, Mexico, United States of America, Malaysia, Pakistan, Brazil, Japan, France, New Zealand, Thailand, Portugal, Nigeria, Islamic Republic of Iran, Sri Lanka, Republic of Korea, Yemen), half (11) report 50 per cent or more of their catch at the species and genus level.

The taxonomic and geographic distribution of fisheries assessments of stock biomass and fishing mortality is very sparse. To date, we are aware of 41 stock assessments for 28 chondrichthyan species. The United States and Australia conduct most stock assessments; the majority conducted in the Atlantic Ocean (21), followed by the Indian Ocean (11) and 9 in the Pacific Ocean. Research surveys and shark control programmes are increasingly being used to assess the trajectory and status of shark and ray populations, particularly in the coastal waters of the United States, Europe, South Africa, New Zealand, and Australia. Many of these time series are ongoing and the specific assessment of the status of chondrichthyans is periodic and dependent on research funding.

Emerging technologies, such as satellite tags and acoustic tracking arrays, as well as the widespread availability of digital underwater photography, web-based database capability and photo identification systems, are providing information for better population estimates and refined geographic distributions. The miniaturization and longevity of electronic tags have revealed complex sex-biased migrations, migratory routes and infrequent but biologically important ocean transits connecting populations that were previously thought to be separate. The development of pattern-matching algorithms has transformed collections of photographs into mark-recapture methods for estimating local abundance and spatial dynamics of larger, more charismatic species, such as: White Shark (*Carcharodon carcharias*), Whale Shark (*Rhincodon typus*), and manta rays (*Manta birostris* and *M. alfredi*). Assessment approaches have been complemented by the rapid emergence of worldwide tissue-sampling and population genetics work that has led to an increasing understanding of the variation in gene flow and connectedness of populations within species, and increasingly the degree to which their ecology and life histories shape patterns of genetic relatedness. Genetic information is also increasingly used to assess the scale of the trade in shark fins and other valuable traded items, including the species composition of trade, and occurrences of illegal sale and trade (Abercrombie et al., 2005).

Assessments of long-term changes in distribution and population trajectories are increasingly being compiled from less formal sources of historical ecological information, including newspaper reports, trade records, and sightings. Compilations of museum records, newspaper reports and sightings have been used to reconstruct the former distribution of sawfishes, prompting conservation action. Assessments of historical landings and the traditional ecological knowledge of fishers have revealed a massive reduction in the diversity of chondrichthyans landed in Southeast Asian markets.

Key challenges that remain include continuing ongoing assessment activities, research surveys, and expanding assessments to include other species, not just the larger and

more charismatic species. Assessments would also need to be expanded to include lesser known species, which are often more threatened, particularly the rays and ray-like sharks, and the 90 obligate and euryhaline freshwater species. Geographically, greater attention would need to be paid to Central and South America, Africa, and South East Asia.

2.5 Tuna

As many tunas are commercially important fisheries species, most assessments are based on fisheries-dependent catch data, although these are occasionally augmented by fisheries independent datasets, such as larval trawls, aerial surveys and scientific catch surveys. Fisheries catch data have the potential for bias due to extrinsic factors, such as those that may influence fishing effort (e.g., fuel and fish prices; regulations on fishing times and areas; changes to gear that influences fishing efficiency over time), as well as lack of reporting of catch and/or effort, and changes in the distribution of tuna species that may cause changes in the interaction rates with individual fisheries (Collette et al., 2011). In addition to limitations in data on catch rates, data on basic biological parameters necessary for accurate stock assessments (e.g., growth rates, stock structure, size/age of maturity, natural mortality rates) are often poorly known, thus also affecting the accuracy of the assessments. These limitations have begun to be addressed through advances in scientific methodologies. Electronic and conventional tagging studies have shed light on all these biological parameters, and population genetic and micro-constituent studies have facilitated delineation of stock structure in many tuna species. In addition, traditional sampling methodologies, such as histological sampling of gonads, counting rings on hard parts, such as otoliths and fin spines, and cohort analysis have all provided information on growth rates and reproductive maturity schedules. However, collecting these data costs money, hence data, and therefore the assessments, are usually better for the tuna species that are more economically important.

Most tuna assessments are conducted through regional fisheries management organizations (RFMOs), a collection of national and other fishing parties that jointly manage shared fish stocks (Aranda et al., 2010). Five tuna RFMOs currently exist that regulate fisheries for their member States: the International Commission for the Conservation of Atlantic Tunas (ICCAT), regulates tuna in the Atlantic Ocean, the Inter-American Tropical Tuna Commission (IATTC), regulates tuna in the eastern tropical Pacific, the Western and Central Pacific Fisheries Commission (WCPFC), regulates tuna in the Western and Central Pacific Ocean, the Indian Ocean Tuna Commission (IOTC), regulates tuna in the Indian Ocean and the Commission for the Conservation of Southern Bluefin Tuna (CCSBT), regulates southern Bluefin tuna (*Thunnus maccoyii*) throughout its range. In addition to assessments conducted through RFMOs, other international organizations such as the IUCN, the CITES, national governments and independent scientists also occasionally conduct assessments of various tuna species. Unlike RFMO assessments, which generally seek to assess stock health in relation to optimal fisheries yield, most other organizations conducting assessments on tunas

attempt to estimate extinction risk. As a result, RFMOs' and others' assessments may differ greatly in their evaluations of the health of tuna stocks.

The most commercially important tuna species have been assessed recently, either regionally or throughout their range by the above-mentioned tuna Commissions. The Bluefin tunas (Pacific [*Thunnus orientalis*], Southern [*T. maccoyii*] and Atlantic [*T. thynnus*]) have all had a full stock assessment within the last four years through their respective RFMOs. Likewise, Bigeye tuna (*T. obesus*), Yellowfin tuna (*T. albacares*), Albacore tuna (*T. alalunga*) and Skipjack tuna (*Katsuwonus pelamis*) have all been assessed regionally through the RFMO assessment process, as well as globally through the IUCN. Other species, such as Blackfin tuna (*T. atlanticus*) and Longtail tuna (*T. tonggol*) have not had full assessments conducted through their respective RFMOs, although localized assessments in part of their range may have been undertaken. RFMOs for these are the ICCAT for Blackfin tuna, and the IOTC and WCPFC for Longtail tuna.

Less is known on the stock status of tuna species for which there are only small, directed fisheries or for which most of the catch occurs as by-catch. Slender tuna (*Allothunnus fallai*), frigate tuna (*Auxis thazard*), and bullet tuna (*Auxis rochei*) all range widely, but formal assessments have not been conducted by RFMOs in each ocean basin. Black skipjack (*Euthynnus lineatus*), Kawakawa (*Euthynnus affinis*), and little tunny (*Euthynnus alletteratus*) are all regionally distributed (Eastern Pacific, Western Pacific and tropical Atlantic, respectively), and few data are available on range-wide catches over time; this is necessary for a full population assessment. However, the wide ranges of these six species, coupled with relatively low and localized exploitation, caused these species to be classified under "Least Concern" by the IUCN.

Although formal stock assessments have been completed for almost half of the tuna species (7 out of 15), few standardized data sets exist on catch rates over time for the remainder of the species. Improvements in the collection of fishery-dependent data or initiation of fisheries-independent data collection would be necessary to obtain accurate estimates of stock health. In the meantime, relatively stable catches over time for the unassessed species suggest that there is little immediate threat to the viability of any of these species.

2.6 Billfish

Billfish are epipelagic marine fishes distinguished by elongated spears or swords on their snouts. Most of the species have very large, ocean-wide or cosmopolitan ranges in tropical and subtropical waters and all are tied to the tropics for reproduction. However, the Swordfish extends into temperate waters. All are of commercial or recreational importance; hence our knowledge of their distribution comes largely from fisheries. Three species are restricted to the Indo-West Pacific: *Istiompax indica*, Black Marlin; *Tetrapturus angustirostris*, Shortbill Spearfish; and *Kajikia audax*, Striped Marlin. The

other three species of spearfish and the White Marlin, *Kajikia albida*, are restricted to the Atlantic Ocean.

Most of the species are well known and easily distinguished; fisheries records document their distribution. However, this is not the case for Black versus Blue Marlin or for the spearfish. The Atlantic Longbill Spearfish, *Tetrapturus pfluegeri*, was not described until 1963 and a second species, *T. georgii*, Roundscale Spearfish, although originally described in 1841, was not validated as a species until 2006. This species is easily confused with White Marlin (*Kajikia albida*), hence the exact distributions of these two species are not yet completely clear, but appear to include much of the North and South Atlantic. Due to overfishing, two billfish meet the IUCN Red List criteria for a threatened category, Vulnerable (Collette et al., 2011): *Makaira nigricans*, the Blue Marlin, and *Kajikia albida*, the White Marlin.

The ICCAT, operating since 1969, is the organization responsible for the conservation of tunas and tuna-like species in the Atlantic Ocean and adjacent seas including several species of billfishes including the White Marlin, Blue Marlin, Sailfish (*Istiophorus albicans*) and Longbill Spearfish. Studies carried out by the ICCAT are mostly focused on the effects of fishing on stock abundance and include data on biometry, ecology, and oceanography. In the tropical Atlantic, this responsibility is held by the Inter-American Tropical Tuna Commission (IATTC) operating since 1950.

2.7 Coral and coral reef assessments

Coral reefs are among the most charismatic of tropical marine ecosystems (Knowlton et al., 2010) and have been assessed globally under several frameworks. Interestingly, however, because they occur in complex shallow seas, the application of large scale oceanographic tools and observation systems on major vessels is impossible; at the same time, they are accessible to small-scale, small-vessel direct observation methods. Their visual attractiveness, ecological complexity and the growth of observational science due to the invention of SCUBA technology in the 1960s have made them a focus for direct observational methods by researchers. As a result, even in the most accessible of coral reef systems in the Caribbean, recent synthesis has found diversity of methods and incompatibility of datasets to be the norm (Jackson et al. 2014).

Coral reefs bear among the highest taxonomic diversity of any ecosystem, and at the same time reef science is relatively youthful. This has resulted in high fluidity in the taxonomy of reef species, in particular complex symbiotic organisms, such as corals, though some well-sampled groups such as, bony fish and molluscs have benefited from taxonomic work inherited from other ecosystems. At the same time, molecular techniques, such as barcoding, are showing high levels of un-described diversity in microbial and invertebrate communities, both major components of coral reef biota.

Nevertheless, the broad global patterns in marine biodiversity are well-described through patterns in indicator groups including corals, stomatopods, and fish. The Indo-Malayan region is a clear centre of diversity for coral reef taxonomic groups, resulting from a broad range of biodiversity-generating and -maintaining processes from short to long time scales (Roberts et al. 2002). Diversity assessments in other regions have, however, been less complete, but resulting in emerging evidence of elevated diversity in other regions, such as in Eastern Africa and the South China Sea. The Caribbean or tropical Atlantic region is highly depauperate in terms of species diversity compared to the Indo-Pacific, resulting from isolation mechanisms over tens of millions of years, as well as since the formation of the isthmus of Panama (Veron, 2000). Coral species have been assessed for the IUCN Red List of Threatened Species, resulting in over one-third of species being identified as Threatened, among the highest proportions of all taxonomic groups globally (See also chapter 43).

Most of the global level assessments of coral reefs are ecological in nature, or use higher taxonomic levels, such as genera for recording absolute or relative abundance. The principal variables used in reporting coral reef health include proportional cover for attached benthic taxa (e.g. hard coral cover, in percent), abundance or density per unit area for key mobile taxa (invertebrates and vertebrates) and biomass, particularly for fish. The establishment of the Global Coral Reef Monitoring Network (GCRMN) was in response to the largest global reef impact ever recorded: the 1998 El Niño event. The resulting series of GCRMN reports (Wilkinson 1999, 2000, 2002, 2004 and 2008) exemplify the challenges in continuing such a large effort. At the same time, remote sensing technologies and global threat datasets have been used to prepare global assessments of the health of coral reefs in the Reef at Risk publications of the World Resources Institute (Burke et al. 2011). The most recent reporting under the GCRMN has focused on regional level reporting, with the first major regional assessment focusing on the Caribbean (Jackson et al. 2014). In this regard, it matches the scope of regional assessment frameworks, which have included those for: (1) the Caribbean, such as the Atlantic and Gulf Rapid Reef Assessment (AGGRA), the Caribbean Coastal Marine Productivity (CARICOMP); (2) parts of the Pacific such as the Coral Reef Monitoring Activities in Polynesia Mana Node, Coral Triangle Initiative on Coral Reefs, Fisheries and Food Security (CTI-CFF) and (3) parts of the Indian Ocean such as the Coral Reef Degradation in the Indian Ocean (CORDIO), all building on the governance frameworks that are the product of the United Nations Environment Programme (UNEP) Regional Seas programme established in 1974. Due to the popularity of coral reefs for SCUBA diving, volunteer and participatory monitoring are popular alternatives, with the most comprehensive one being that of Reef Check (Hodgson, 1999). In these, assessments are based on indicator species and estimates of variables such as benthic cover. Though variable in quality and coverage, the resulting data can be invaluable in broad scale scientific assessments of reef status. Coral reef areas with the least investment in assessments are those in poor developing countries with generally low national dependence on the sea (though they may have large sectors of society with high levels of livelihood/subsistence dependence on the sea, e.g. the Indian Ocean) and of

middle/low biodiversity and interest for international science. Coral reef areas with the most investment in assessments are dispersed throughout the Pacific and tropical Atlantic.

Cold-water or deep-water corals are found globally, but have been most extensively mapped in the North Atlantic, due to extension of fishing and exploration for seabed resources in that region, and New Zealand has undertaken significant coral mapping. With greatest development from 200-1,000 m, and on topographic promontories such as seamounts, they can form large reefs of several 100s of m across and 10s of m above the substrate, but are highly vulnerable to damage and changing chemical oceanographic conditions. Further discoveries on the distribution of cold water corals are continuing to be made, such as in the southern Indian Ocean (Cairns, 2007).

Coral reefs are mentioned as a model ecosystem under Aichi Target 10 of the Convention on Biological Diversity (CBD) (to reverse impacts on climate-sensitive ecosystems). The search for “Essential Biodiversity Variables” (EBVs) to support monitoring for such targets and commitments is gaining momentum, and there is recognition that coral reefs may provide one of the ten globally-consistent sources to support this process, and not only with respect to biodiversity - greater recognition of the ecosystem services contributed by coral reefs (to communities, global tourism, and national/global economies and trade) should secure resources for monitoring of the ecosystem processes/indicators that underpin those services and goods, incentivizing monitoring and assessment to manage them for future benefit. In parallel with the CBD, the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystems services (IPBES), and the Sustainable Development Goals may generate increased justification for upscaling coral reef assessments globally.

2.8 *Plankton*

At the global level, the seasonal pattern of Chlorophyll *a* is the best known and most studied phytoplankton-related variable in most marine ecosystems. Long-term studies on seasonal changes in phytoplankton diversity and abundance have been more localized geographically. The Western Channel Observatory (WCO) run by the Plymouth Marine Laboratory and the Marine Biological Association (United Kingdom) holds a marine biodiversity reference dataset for the Western English Channel with some of the longest time-series in the world for zooplankton and phytoplankton. At the Chesapeake Bay, a monthly, continuous 20-year phytoplankton database exists. In the Baltic Sea, historical phytoplankton data on community composition shows long-term changes in comparison to the early 1900s (Hällfors et al., 2013). However, much less is known about how changing diversity affects the productivity and functioning of marine food webs as well as the drivers behind these changes. Some global changes in diversity have been addressed based on the Continuous Plankton Recorder (CPR) data.

Perhaps the longest time-series sets exist for planktonic organisms (zooplankton and fish larvae) from the North-eastern Atlantic (North and Baltic Seas, English Channel and Bay of Biscay). It is important to note that plankton monitoring has extended to practically all the regions of the European coast due to the implementation of relatively recent legislation (e.g., the European Water Framework Directive). In this way, the study of plankton taxonomic composition and dynamics is being conducted in many areas that have been poorly studied or not studied at all. Surveys on micro-, nano-, picoplankton also exist, but these are spatially more restricted and substantially more comprehensive.

Some of the early formal accounts on zoobenthos date back to the famous Michael Sars expedition in the Atlantic in 1910, amended with several major contributions from Census of Marine Life activities (such as “Patterns and processes of the ecosystems of the northern mid-Atlantic”, the Mid-Atlantic Ridge Ecosystem Project (MAR-ECO), and the global project Census of Marine Zooplankton) about a century later and introducing innovative identification techniques involving molecular biology.

2.8.1 The Continuous Plankton Recorder (CPR) survey

The Continuous Plankton Recorder (CPR) survey is recognized as the longest sustained (operating since 1931) and geographically most extensive marine biological survey in the world. The dataset comprises a uniquely large record of marine biodiversity covering ~1,000 taxa over multi-decadal periods. The survey determines the abundance and distribution of microscopic plants (phytoplankton) and animals (zooplankton, including fish larvae) in our oceans and shelf seas. Using ships of opportunity from ~30 different shipping companies, it obtains samples at monthly intervals on ~50 trans-ocean routes. In this way the survey autonomously collects biological and physical data from ships covering ~20,000 km of the ocean per month, ranging from the Arctic to the Southern Ocean. The survey is an internationally funded charity with a wide consortium of stakeholders.

Plankton are collected on a band of silk and subsequently visually identified (~1,000 taxa) by experts from around the world. Additionally, over the last decade the CPRs have been equipped with modern chemical and physical sensors, as well as molecular probes, to provide an array of additional information about our changing oceans. The final stages in the operation of the survey are the archiving of the resulting data and samples and interpreting the results at its central hub in Plymouth, United Kingdom. Strict quality control procedures are maintained for all CPR activities to ensure the integrity and long-term value of the programme. The database and sample archive together provide a resource that can be utilized in a wide range of environmental, ecological and fisheries-related research, e.g., molecular analyses of marine pathogens, modelling for forecasting and data for incorporation in new approaches to ecosystem and fishery management. Since the first tow of a CPR on a “ship of opportunity” in 1931, more than 6 million nautical miles of sea have been sampled and over 100 million data entries have been recorded.

Over the last eight decades the purpose of the survey has also co-evolved, with changing environmental policy, from purely monitoring plankton distributions to addressing and providing indicators for major marine management issues ranging from fisheries, harmful algal blooms, biodiversity, pollution, eutrophication, ocean acidification and climate change. For example, the CPR survey has documented a northerly shift of 1,000 km of marine organisms around Europe associated with climate change over the last four decades, with large ramifications for the European fishing industry. In the Arctic, the CPR survey recently recorded the first modern trans-Arctic migration of a diatom species (*Neodenticula seminae*) related to declining ice coverage (Reid et al., 2007; Edwards et al., 2012).

This diatom species, normally found in the Pacific Ocean, has been absent from the North Atlantic for over 800,000 years; perhaps it signifies the rapidity and unprecedented nature of climate change in the Arctic over recent geological history (Reid et al., 2008). In 2011, the Sir Alister Hardy Foundation for Ocean Science (SAHFOS), along with 12 other research organizations using the CPR from around the world, formed a Global Alliance of CPR surveys (GAC) with the aim of training new surveyors, producing a global ocean status report, capacity-building and developing a global plankton database. This global network of CPR surveys now routinely monitors the North Sea, North Atlantic, Arctic, North Pacific and Southern Ocean.

New surveys are underway in Australian, New Zealand, Japanese and South African waters; a Brazilian and an Indian Ocean survey are under development (Figure 2). These surveys provide coverage of large parts of the world's oceans, but many gaps still exist, particularly in the South Atlantic, Indian and Pacific Oceans. This global network also brings together the expertise of approximately 50 plankton specialists, scientists and technicians from 12 laboratories around the world. Working together, centralizing the database and working in close partnership with the marine shipping industry, this global network of CPR surveys with its low costs and new technologies makes the CPR an ideal tool for an expanded and comprehensive marine biological sampling programme. The database and website can be accessed via www.sahfos.ac.uk (Edwards et al., 2012).

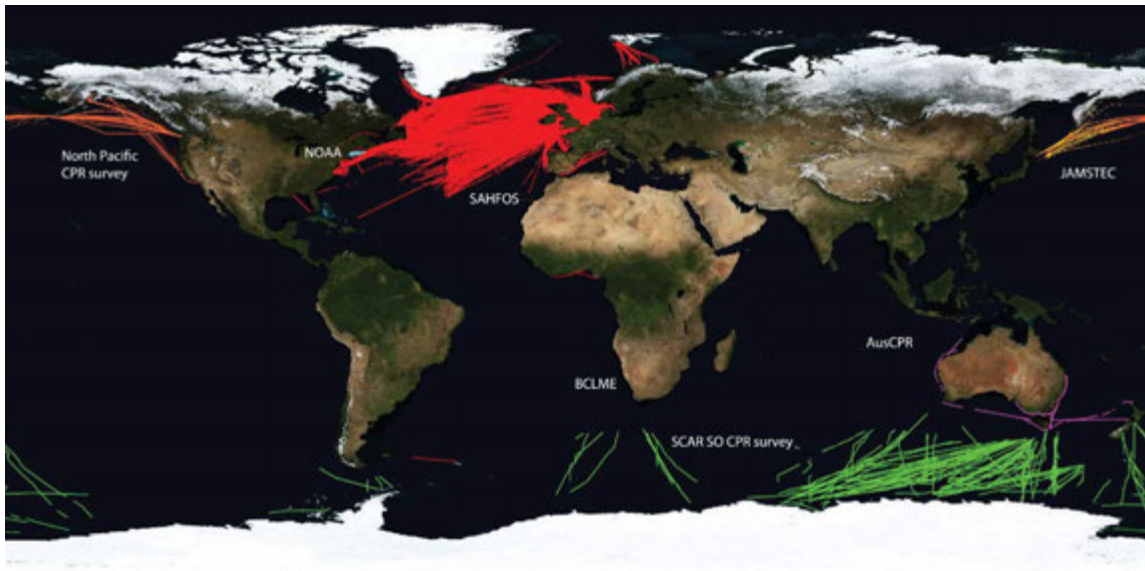

Figure 2. Start of sustained open-ocean biological time series and records (temporally broken and coastal time series are not included) plotted along the global mean SST time series from 1900 (Hadley Centre). Note that the majority of the time series are less than 30 years long. Station P (North Pacific); VICM (Vancouver Island Continental Margin time series); NMFS (National Marine Fisheries Service collection); BATS (Bermuda Atlantic Time Series Study); HOT (Hawaii Ocean Time Series program); Iberian coastal time series (North Coast of Spain); SO CPR survey (Southern Ocean CPR survey); AMT (Atlantic Meridional Transect); AZMP (Atlantic Zone Monitoring Program) (Edwards et al., 2010).

2.9 Seamounts

Several global seamount databases have been compiled, including the Seamount Catalogue (mainly geological), Seamounts Online (SMOL) (biological) and the Seamount Ecosystem Evaluation Framework (SEEF) (ecological) (Kvile et al., 2014). There are also detailed national datasets on seamount location and faunal composition, such as off New Zealand, the Azores, and for the western South Pacific (Allain et al., 2008). These databases and knowledge of seamounts have benefited from increased research on seamounts in the early 2000s by New Zealand, the United Kingdom, the United States, Japan, Australia, Portugal (Azores), among other countries, including the international CenSeam project of the Census of Marine Life (Clark et al., 2010).

A total of 684 seamounts have data recorded in the SEEF and SMOL up to the end of 2012. Their spatial distribution is: 458 in the Pacific Ocean, 164 in the Atlantic Ocean, 22 in the Mediterranean Sea, 12 in the Indian Ocean and 28 in the Southern Ocean. Their distribution is shown in Figure 3.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 3. The distribution of seamounts with geological or biological sample data (sources: SEEF and SMOL).

The seamounts have a mixture of data types: all have geological information, and 54 per cent have had some level of biological investigation (Kvile et al., 2014). Overall, the seamounts in the North Atlantic Ocean and Mediterranean Sea have been the most studied; other oceans are typically patchy. For example, in the Pacific Ocean, over 60 per cent of seamounts in the database had biological data, but extensive sampling was focused on a few areas: on the Nazca and Sala y Gomez chains in the eastern South Pacific, around New Zealand and southern Australia in the southwest Pacific, and off parts of Hawaii, Alaska and the west coast of the United States in the North Pacific.

The last decade has seen a dramatic increase in the number of seamounts being surveyed. This has in part been due to efforts by the fishing industry to find new fish stocks, but also by major national or international (such as the Census of Marine Life project CenSeam) research programmes carrying out biodiversity surveys (see Figure 4, from Kvile et al., 2014). The CenSeam data can be accessed through the OBIS portal (www.iobis.org) by selecting the Seamounts Online database.

Figure 4. The cumulative number of seamounts explored over time (from Kvile et al., 2014).

Biological surveys of seamounts vary considerably in the methods and equipment used. In the North Atlantic, off the west coast of the United States, and in the North Pacific, remotely operated underwater vehicles (ROVs) and manned submersibles have been used to carry out extensive survey work. However, these tools tend to focus sampling on the mega-fauna, the large taxa that are clearly visible to the eye or camera equipment. Fish trawls have been used on many seamounts, and although these sample fish very effectively, they are poor at retaining fragile or small invertebrates. Off New Zealand and Australia, epibenthic sledges have been used on seamounts, which tend to catch a wide size range down to macroinvertebrates. Typically, a combination of sampling gear is necessary to adequately describe the benthic biodiversity on seamounts.

However, globally, a very low proportion of the large number of seamounts have been sampled. Of the nearly 450 seamounts sampled, relatively good data exist only for 300, and few of these are in equatorial latitudes, or deeper than about 2,000 m. Therefore, much about the structure, function and connectivity of seamount ecosystems remains unexplored and unknown. Continual, and potentially increasing, threats to seamount resources from fishing and seabed mining are creating a pressing demand for research to inform conservation and management strategies. To meet this need, intensive scientific effort in the following areas would be needed: (1) Improved physical and biological data; of particular importance is information on seamount location, physical

characteristics (e.g., habitat heterogeneity and complexity), more complete and intensive biodiversity inventories, and increased understanding of seamount connectivity and faunal dispersal; (2) New human impact data; these should encompass better studies on the effects of human activities on seamount ecosystems, as well as monitor long-term changes in seamount assemblages following impacts (e.g., recovery); (3) Global data repositories; there is a pressing need for more comprehensive fisheries catch and effort data, especially on the high seas, and compilation or maintenance of geological and biodiversity databases that underpin regional and global analyses; (4) Application of support tools in a data-poor environment; conservation and management will have to increasingly rely on predictive modelling techniques, critical evaluation of environmental surrogates as faunal “proxies”, and ecological risk assessment.

2.10 Vents and seeps

Since the discovery of hydrothermal vents and continental margin seeps in 1977, many animals found there were recognized as new to science, often at higher taxonomic levels. A recent assessment suggested that about 70 per cent of vent animals and 40 per cent of seep species now known are endemic to these habitats (German et al., 2011). In addition, many animals displayed unusual adaptations to habitats of reduced chemical compounds and physiological stresses. Systematic studies have generated many dispersed publications and some compilations have examined evolutionary patterns in a larger taxonomic group, ecological phenomena within a seep or vent region, and biogeographic pattern analyses. In this Assessment, only the most recent of these compilations are presented.

The InterRidge Vents Database is an important tool for metadata on hydrothermal vent sites that is currently maintained in an open-source content-management system in which updates depend on researcher input (Beaulieu et al., 2013). Over 500 confirmed and inferred referenced locations are listed. In the last decade, vent discoveries in arc and back-arc settings increased the known vent fields within exclusive economic zones. No biological or collection information is listed, hence it is a site for geographic information only. No similar information for seeps and other chemosynthesis-based habitats exists. The most recent map for locations of seeps globally appears to be that of Seuss (2010).

The Census of Marine Life (CoML) sponsored the eight-year project called Chemosynthetic Ecosystem Science (ChEss), with a primary focus to document the distribution of diversity in deep-water chemosynthetic ecosystems. The development of the ChEss database remains ongoing, but it is currently linked to OBIS; however, they are faunal lists and must be manipulated for site or taxonomic comparisons. Assessments emerging from use of the database are underway, but many are specific to faunal groups or regions.

To facilitate work in the field and laboratory, a handbook of vent fauna that assimilated most of the taxonomic papers and locality information related to hydrothermal vent fauna is available. The format of the book is a page for each species with a brief description, drawings or photographs and distribution information; it covers over 500 species in 12 phyla. No overall assessment of diversity is presented, but managers will find useful information on the species in their area of interest.

The ChEss Database has been used to formulate an assessment of the drivers of biogeographic patterns in vent faunas. The assessment focuses on historical relationships and centres of diversity. The approach uses network analysis and is a high-quality assessment of patterns. Another similar analysis for seep faunas of the equatorial Atlantic highlights discoveries on the western African margins and points out regions that still need investigation. Both datasets are available through IFREMER, France.

An overall assessment of vent and seep faunal diversity distribution and major drivers has yet to be executed. Exploration of these habitats is still underway, as biogeographic analysis shows major gaps in knowledge. Because of the close relationship of seeps on continental margins to areas of resource exploration interest (oil and gas, methane hydrates), assessment of the nature of diversity and its role in ecosystem function is important before potential alteration and/or destructions takes place. Similarly, growing interest in the metals associated with hydrothermal vent deposits may drive more work to define diversity patterns at vent habitats, as well as their relationships with other chemosynthesis-based habitats (See Appendix I-Vents and seeps: Major Inventories Available for Vent and Seep Habitats and Faunas). At present, many deep sea research initiatives have teamed up in INDEEP (International Network for Scientific investigation of deep-sea ecosystems) with the goal of providing a framework that will allow coordinated efforts in deep sea research across all its habitats while reaching out scientific results to managers and society.

3. Regional summaries of coverage of assessments: Arctic, North Atlantic, North Pacific, Indian, South Atlantic, South Pacific, and Southern Ocean

The following regional summaries are largely based on the work carried out by the network of National and Regional Committees of the Census of Marine Life (O'Dor et al., 2010; Costello et al., 2010). In this summary, the Caribbean and Mediterranean Seas as well as the Gulf of Mexico are included in the North Atlantic section. There are a few gaps in terms of geographic coverage (e.g. the Pacific coast of the Russian Federation, the Atlantic coast of Africa) due to lack of information or difficulties obtaining the data. However, a complete global analysis including all of the world's oceans was carried out using data from OBIS and presented in part 3 of the chapter.

3.1 *The Arctic*

Despite more than a century of observations on the Arctic's marine life, information on basic species inventories, as well as a quantitative synthesis, has remained fragmented until recently; however, some areas are still poorly known. Renewed interest in marine biodiversity generated by activities, such as those of the CBD, the Census of Marine Life and the International Polar Year, has begun to change this situation, but it is a slow process. At best, we are now armed with relatively complete lists of the species present, and have begun the process of assembling various datasets throughout the Arctic with the ultimate goal of establishing pan-Arctic patterns and trends over time (see Gradinger et al., 2010) for the taxonomic groups. The most comprehensive assessment in the Arctic is the Arctic Biodiversity Assessment (ABA), which includes chapters on marine mammals, birds, fishes, invertebrates, parasites, and ecosystems, contributed and reviewed by more than 100 scientists (Caff, 2013).

There are about 24 species of large unique vertebrates, such as the Polar Bear, Walrus, seals and several species of whales, found in the Arctic. As for seabirds, 64 species are recognized as breeding in the Arctic, and an even greater number of species is known to exploit its productivity seasonally (Archambault et al., 2010). Many of these air-breathing species are displaced southward during the winter's ice cover. As for fishes, nearly 250 species are known from the Arctic. About 30 of these divide their lives between the oceans and freshwater, and the rest are fully marine; the majority of these species are associated with the seafloor rather than living higher in the water column. Invertebrate diversity is higher and, unlike the vertebrates, invertebrates are typically studied in terms of communities rather than by species or higher taxonomic units. From functional and logistical perspectives, these communities are further divided by habitat, as this is how they are targeted during sampling: those associated with the sea ice, those within the water column (plankton) and those living on the seafloor (benthos). Of the functional groups of organisms considered thus far, with the exception of birds and mammals, species discovery continues within them all, especially now with the use of molecular tools for species identification (Gradinger et al., 2010). The Arctic is a mosaic of habitats across all its marine realms, within which information is very unequally collected between regions and over time. Habitat complexity, combined with the logistical challenges of sampling in the Arctic, and the generally limited interest in surveying the perceived low-diversity invertebrate fauna of the Arctic, have greatly impaired our ability to construct precise regional and temporal understanding of marine invertebrate diversity. Although changes have been noted in population size, abundance, growth, condition and behaviour of several marine mammals and fish, few changes for planktonic and benthic systems are documented. No comprehensive monitoring activities are conducted in the Central Arctic Ocean; oceanographic and ecosystem sampling has been occurring largely on an opportunistic basis, as part of national (e.g. Canadian) and international research programmes. Some efforts have been directed at developing directed systematic programmes for data collection, sometimes relying on community-based collaborations, but these are recent

developments and baseline data from the Canadian Arctic Ocean are very limited in their spatial and temporal extent.

Examples of these collaborations are the Arctic Council CBMP (Circumpolar Biodiversity Monitoring Program), the Russian-American Long-term Census of the Arctic (2004-12), which involves a partnership of several United States and Russian Federation institutions to create a baseline dataset in the Pacific gateway area of the Bering Strait and southern Chukchi Sea, and other bi-national collaborations (e.g. United States and Canada, Russian Federation and Norway). Recently, the United States Bureau of Ocean Energy Management (BOEM) initiated programmes in Arctic waters to provide estimates of abundance and species composition of marine fishes and invertebrates, as well as information on the macro- and microzooplankton communities and their oceanographic environment. In 2008, the oil and gas industry began new biological assessment programmes (Chukchi Sea Offshore Monitoring in Drilling Area: Chemical and Benthos) in the Chukchi Sea in response to the sale of leases for new offshore prospect areas (Fautin et al., 2010).

3.2 *Northern Hemisphere: focus on Canada*

Canada borders the Pacific, Arctic, and Atlantic Oceans; and its coastline of 243,791 km (16.2 per cent of the global coastline) exceeds all of Europe combined. At 2,687,667 km², Canada's territorial sea covers 14.3 per cent of the global total. The Census of Marine Life program (Archambault et al., 2010), in collaboration with the Canadian Healthy Oceans Network (CHONe) (Snelgrove et al., 2012), conducted an assessment of the status of knowledge on marine biodiversity in Canada's oceans which included four biogeographical provinces: the Canadian Arctic (including the sub-Arctic Hudson Bay System), Eastern Canada, St. Lawrence estuary and Gulf, and Western Canada (Pacific coast). The taxonomic assessment encompassed the status of knowledge on microbes, phytoplankton, macroalgae, zooplankton, benthic infauna, fishes, and marine mammals resulting in an estimate of between 15,988 and 61,148 taxa (including microbes), a number that is most likely to be an underestimate, as many poorly sampled taxa and regions still exist. This assessment noted that significant data gaps exist, that larger species (e.g., mammals and fishes) are better known than small species (e.g., microbes), and that knowledge of diversity is inversely related to both water depth and geographical remoteness. Thus, even for well-known groups, such as fishes, deep-water and Arctic environments continue to yield new species. The Eastern Canada waters are the best-sampled province of Canada.

The Census of Marine Life was very active in Canada and significantly helped advance knowledge of marine biodiversity. The Barcode of Life developed barcodes for many Canadian species, and the Future of Marine Animal Populations (FMAP) programme provided many new insights on trends in fisheries, global patterns in biodiversity, and movements of animals in the oceans. The Pacific Ocean Shelf Tracking (POST) project provided new insight into movements of Pacific salmon species, sturgeon, and other species along the North Pacific coastline. The Canadian Healthy Oceans Network

(CHONe) (Snelgrove et al., 2012), a five-year national research programme to establish biodiversity baselines in poorly sampled areas, grew out of the Census of Marine Life. Several other Census projects sampled in Canadian waters: include the Arctic Ocean Diversity (ArcOD) project, and the Natural Geography of Inshore Areas (NaGISA), and the Gulf of Maine Area (GoMA) project. The latter project assembled species lists for that region and worked closely with the Canadian scientists of the Ocean Biogeographic Information System (OBIS) program, which assembled extensive datasets produced by Fisheries and Oceans Canada over several decades.

Current monitoring programmes, largely by the Department of Fisheries and Oceans Canada (DFO), the lead agency responsible for monitoring Canada's three oceans (Atlantic, Pacific and Arctic) and freshwater habitats, will further improve knowledge of Canadian oceans. Many of DFO's monitoring activities were initiated to address operational requirements dealing with commercial exploitation of marine and freshwater populations, but over time many have evolved to provide assessments of the state of local ecosystems in the context of a consistent national approach. A general assessment of aquatic monitoring in Canada, conducted in 2005-2006 (Chadwick, 2006), provides an overview of the diversity of activities carried out by DFO and other agencies.

Most programmes that contribute to biodiversity assessments derive data from: (1) broad-scale regional multispecies bottom trawl surveys that provide information on the distribution and abundance of fish and invertebrate species, (2) oceanographic surveys that collect observations of phytoplankton and zooplankton abundance and taxonomic composition, and (3) single-species surveys that can yield knowledge for non-target species caught or observed during data collection. Most surveys are carried out by DFO, but in several instances, most importantly in the Pacific region, partner organizations contribute significantly, such as assessments of coral and sponge diversity distributions aided by academic and by non-governmental organizations (NGO) activities. Coverage varies greatly among aquatic environments.

Monitoring of the Atlantic and Pacific continental shelves and slopes is fairly extensive and generally conducted annually for focus areas. On the Pacific coast, Canada has maintained one of the longest – in duration – datasets that exist on ocean conditions, phytoplankton and zooplankton through the Line P/Station Papa programme. For other species groups, such as marine mammals, groundfish and salmon on the west coast, monitoring remains a DFO focus. Differences in the extent and intensity of survey activities in specific ecosystems within these two ocean areas will affect our ability to detect changes in biodiversity. For example, the coastal sea near Vancouver and the Fraser River salmon runs are the focus of sustained monitoring for many species; however, little information on the biodiversity of the northern west coast fjord exists. Furthermore, protocols for data collection, taxonomic resolution and expertise, and quality assurance vary greatly among survey types and location, which are also likely to significantly affect the estimation of Canadian marine biodiversity, particularly with respect to the occurrence of rare or difficult-to-identify species, including invasive species.

In all of Canada's oceans, information sources on habitat structure, invasive species, food web structure and interactions, species at risk, and any effects of cumulative anthropogenic impacts are limited. There are few systematic efforts to assess ecosystem health, particularly in near-shore and coastal areas, and data pertaining to pelagic species other than plankton are restricted in scope and coverage. Finally, almost all marine observations are collected from ships, yet the number of sea days declined by half between 1995 and 2005, while costs have doubled (Chadwick, 2006).

3.3 *North Atlantic: The East Coast of the United States*

The marine biodiversity of the United States is extensively documented; however, even the most complete taxonomic inventories are based on records scattered in space and time. The best-known taxa are those of commercial importance or large body sizes. Best-known areas are the shore and shallow waters. Measures of biodiversity other than species diversity, such as ecosystem and genetic diversity, are poorly documented. In the North-east Continental Shelf region, scientific sampling of coastal intertidal and shallow subtidal organisms extends back to the mid-1800s. Off-shore, early assessments in the late 1800s and early 1900s include those conducted by the *Fish Hawk*, the *Albatross*, and by Henry Bryant Bigelow.

In the last decade, the Gulf of Maine Area Program of the Census of Marine Life assessed this ecoregion, plus the southern and western Scotian Shelf, the continental slope to 2,000 m, and the western New England Seamounts. In the South-east Continental Shelf region, assessments began during the United States colonial period (seventeenth and eighteenth centuries). Early offshore studies focused on finding exploitable fish populations. In the late 1800s, exploratory surveys were aimed primarily at bottom-living organisms. Since the mid-twentieth century, the United States National Oceanic and Atmospheric Administration (NOAA) and its predecessor agencies (e.g., the Bureau of Commercial Fisheries) have explored habitats and their natural resources off the coast of the south-eastern United States. Beginning in the 1950s, several ships conducted exploratory fishing surveys using trawl nets; they found concentrations of snappers, groupers, and other economically valuable fishes, along with other significant fishery resources (drums, flatfishes, mullets, herrings, shrimps). Additional surveys using dredges, grabs, and other benthic samplers collected invertebrates and new species.

Valuable fish surveys have been carried out by the NOAA Marine Resources Monitoring, Assessment and Prediction (MARMAP) and Southeast Area Monitoring and Assessment Program (SEAMAP) monitoring programmes. Significant regional invertebrate surveys of the South Atlantic Bight (SAB) were conducted under the auspices of the Bureau of Land Management (BLM) and the Minerals Management Service (MMS). From the 1970s until now, surveys of the continental shelf and slope off North Carolina and in the tropical western North Atlantic have been made by the Duke University Marine Laboratory (DUML) and the Rosenstiel School of Marine and Atmospheric Sciences

(RSMAS) of the University of Miami, respectively. The RSMAS collections and archives (Marine Invertebrate Museum: <http://rsmas.miami.edu/divs/mbf/invert-museum.html>) document the biodiversity of the Atlantic and Gulf of Mexico's tropical and deep-sea species and include material from the Straits of Florida and the Florida Keys National Marine Sanctuary. Marine resource agencies of the individual states have also conducted faunal and fishery surveys within state waters, particularly within estuaries (Fautin et al., 2010).

3.4 North Atlantic: The Gulf of Mexico

The most recent survey of the Gulf of Mexico's biodiversity appeared in book form (Felder and Camp, 2009), and as an open-access online database for utilization by anyone, as well as for updating and expansion by taxonomists (see GulfBase at www.gulfbase.org/biogomx; Moretzsohn et al., 2011). Over 15,400 species are listed in the database, with full biological and zoogeographical information for each species.

Historically, environmental studies or assessments on the Gulf of Mexico's biota can be divided into four different periods: (1) Exploratory Period (1850-1939), (2) Local Coastal Study Period (1940-1959), (3) Multidisciplinary Investigation and Synthesis Period (1960-2009/2010), and (4) Ecosystem Focus Period (2009/2010-present). The initial period involved the exploratory work of early oceanographically equipped ships, such as the *Blake* and the *Albatross*, and coastal expeditions from northeastern United States universities and institution. During the second period, over a dozen marine laboratories were established around the shores of the Gulf of Mexico, and scientists at these facilities expanded our biodiversity knowledge in those early locations in the United States, Mexico, and Cuba. Recently, a dedicated issue of the journal *Gulf of Mexico Science* (Volume 28, 2010) mapped the current 35 laboratories around the Gulf and presented a history of 21 of them; many are still instrumental in biodiversity assessments. Important fisheries vessels, such as the *Alaska* and the *Oregon I and II*, also operated in this second period and expanded our knowledge of faunal distributions in the region. In addition, although not comprehensive, the first biotic inventory of species in the Gulf of Mexico was published by Galtsoff (1954).

The third period involved large-scale, multidisciplinary investigations and synthesis projects in selected regions, primarily in the United States and Mexico. In the United States during the early to mid-1960s, the Hourglass Cruises were among the first large-scale projects, focused on the biota of the West Florida Shelf, and funded by the state of Florida. The United States Department of the Interior, Bureau of Land Management, Minerals Management Service, and now the Bureau of Ocean Energy Management, funded decades of environmental studies, including biotic surveys, mainly related to the oil and gas industry and its impact in the northern Gulf of Mexico. These studies first focused on the continental shelves, but as the oil and gas industry began exploring and producing in deeper and deeper water down the continental slope, studies focused on that area and out onto the adjacent abyssal plain. Those reports can be found at: <http://www.data.boem.gov/>.

The fourth period marks its beginning with the publication of the comprehensive inventory of all Gulf of Mexico species (Felder and Camp, 2009; an affiliate Census of Marine Life project) and the Deepwater Horizon blowout and oil spill in 2010, including the establishment of the Gulf of Mexico Research Initiative funded by BP with 500 million United States dollars to study the Gulf and its ecosystems over the next 10 years (at 50 million dollars per year) (See Appendix 1-Gulf of Mexico: selection of the major assessments or surveys - the Gulf of Mexico).

Gaps in knowledge include selected taxa and selected geographic areas or depths within the Gulf of Mexico. Similar to most well-studied areas, the larger taxa are well known, but smaller ones, particularly meiofauna and microbiota (viruses, microbes, fungi, benthic nematodes and harpacticoid copepods, etc.), gelatinous plankton and other soft-bodied invertebrates (that often do not preserve well in non-targeted sampling), as well as parasitic groups, are little known. Biomass, ecology, trophic interactions and diseases are poorly known for most species. Geographically, still not well known are the abyssal plain in the deepest part of the Gulf, and selected areas in the southern Gulf, such as off the northern coast of Tamaulipas and the very southern coast of Veracruz off the San Andres Tuxtla Mountains.

3.5 *North Atlantic: The Caribbean*

Historically, knowledge of marine biodiversity for the Caribbean islands has resulted from inclusions within larger marine surveys and assessments funded by foreign institutions. For example, the Universities of Havana and Harvard (1938 to 1939) carried out a joint marine expedition which was the first such baseline information for the Cuban archipelago. Additionally, some territories have benefited from visiting research vessels (e.g., the 1969 RV *John Elliott Pillsbury* expedition to the Lesser Antilles). More recently, local institutions dedicated to marine research have been established in several islands, such as: The Oceanology Institute (Cuba), the Institute of Marine Affairs (Trinidad) and The Discovery Bay Marine Lab (Jamaica). The Association of Marine Laboratories of the Caribbean (AMLC) (<http://www.amlc-carib.org/>) is an umbrella organization (with over 30 institutions) which has been promoting collaborations in marine sciences since 1968. Other organizations supporting research initiatives in the region are the International Oceanographic Commission-Caribe (IOCARIBE), the Nature Conservancy (TNC), and several universities (e.g., the University of the West Indies island campuses of Mona in Jamaica, Cavehill in Barbados, and St. Augustine in Trinidad and Tobago).

To date not a single comprehensive marine assessment has detailed the Caribbean island territories, although several projects have targeted certain ecosystems and taxonomic groups. One of the most successful research programmes to date (1993 to present) is the Caribbean Coastal Marine Productivity Program (CARICOMP), which covers islands throughout the Wider Caribbean (e.g., Barbados, Dominican Republic,

Jamaica, Puerto Rico (Mona Island) and Trinidad and Tobago) and has over 30 participating institutions. The project datasets include: percentage coral cover, sea urchin density, gorgonian density, seagrasses (growth, biomass and leaf area), mangrove forest structure and productivity, sea water temperature, salinity and clarity, daily maximum and minimum air temperature, and rainfall.

Furthermore, the Atlantic and Gulf Rapid Reef Assessment (AGRRA) Program is an international collaboration of scientists and managers aimed at determining the regional condition of reefs in the Western Atlantic and Gulf of Mexico and includes some Caribbean territories. Additionally, the Northern Caribbean and Atlantic node of the Global Coral Reef Monitoring Network (GCRMN) monitors coral reefs and their status in the Bahamas, Bermuda (United Kingdom), Cayman Islands (United Kingdom), Cuba, the Dominican Republic, Haiti, Jamaica and the Turks and Caicos Islands (United Kingdom). The Centre for Marine Sciences (CMS) at the University of the West Indies (UWI), at Mona, Jamaica, is the repository for these three databases (CARICOMP, AGRRA, GCRMN). Reef Check is another coral programme and is active in: Anguilla (United Kingdom), Antigua and Barbuda, Bahamas, Barbados, Belize, Dominica, Grenada, Haiti, Jamaica, Montserrat (United Kingdom), St. Kitts and Nevis, St. Lucia, St. Vincent and the Grenadines, and Trinidad and Tobago.

The Caribbean Sea Ecosystem Assessment (CARSEA) was a sub-global assessment (2005 to 2008) out of the global Millennium Ecosystem Assessment (MEA, 2001 to 2005) which made a major contribution to Caribbean biodiversity knowledge, and provided analytical status reports, including trends in some populations such as fish and coral reefs. The Census of Marine Life resulted in a detailed review of the known marine biodiversity of several Caribbean islands, including Bermuda (United Kingdom), , Cuba, the Dominican Republic, Jamaica and Puerto Rico (United States) and of the marine biodiversity along the Caribbean coasts of Colombia, Costa Rica, Mexico and Venezuela (Miloslavich and Klein, 2005). The nearshore (NaGISA) project followed shortly thereafter, with biodiversity surveys in Colombia, Cuba, Trinidad and Tobago, and Venezuela. This assessment examined patterns of biodiversity at both global and local scales on rocky shores and seagrass beds and made a major contribution to marine biodiversity (Miloslavich et al., 2010).

Overall, within the larger assessments (CARICOMP, CARSEA, CoML), certain ecosystems (mangroves, coral reefs, seagrass beds and rocky shores) have been studied in detail and certain marine taxonomic groups (marine mammals, turtles, seabirds, fish, corals, sponges) have also been comprehensively reviewed/assessed by local researchers, scientists and post-graduate students. Macrobenthic organisms for both Trinidad and Tobago and Jamaica, and plankton (for Jamaica) have been well documented. These important baseline data were improved by later surveys by the Institute of Marine Affairs in Jamaica (IMA) during the period 1980 to 1992.

Despite these efforts, there are still many gaps in our knowledge of Caribbean biodiversity (e.g. offshore and deep regions, small sized taxonomic groups) (Miloslavich et al., 2010). To fill these gaps and build regional capacity, almost all Caribbean

countries have strengthened their environmental institutions (e.g., Coastal Zone Management Institute-Belize; Coastal Zone Management Authority-Barbados; Darwin Initiative by the Smithsonian Tropical Research Institute) and administrative capacities (e.g., the Environmental Management Authority-Trinidad and Tobago), to integrate environmental considerations into physical planning. Another initiative that has improved capacity building and aimed towards maintaining functional and structural integrity and biodiversity in this region is the Caribbean Large Marine Ecosystem Project (CLME). While not a monitoring programme, the CLME Program has one pilot project on Reef Biodiversity and Reef Fisheries which implemented the ecosystem-based approach for the conservation and effective management of coral reef ecosystems and associated resources.

3.6 *North Atlantic: Oceans around Europe*

There is early evidence of European marine biota assessments from the 3rd century B.C., but formal scientific studies did not begin until the 18th century in the Mediterranean region and early 19th century throughout the remainder of Europe (Coll et al. 2010, Ojaveer et al., 2010). For several taxa these early works provide historical baselines against which to compare contemporary biodiversity data.

In the European Atlantic, as mentioned earlier in the plankton section, the longest time-series sets exist for planktonic organisms. Regarding benthic organisms, in shelf seas, such as the North and Baltic Seas, benthic survey and monitoring programmes have been in place. One of the priority research areas, directly linked to provision of management advice, in European seas has been commercial fish and fisheries. The related surveys include egg and larval fish surveys, young fish surveys, experimental bottom trawl surveys and, more recent hydro-acoustic surveys. Some of these data-sets date back to before the 1950s. However, information on non-commercial fish is scarce and incomparable and should be considered as a major drawback in drawing conclusions about the spatio-temporal patterns and dynamics of fish communities. A representative overview of the status and trends of non-indigenous species in European waters is assembled in the database “Information system on aquatic non-indigenous and cryptogenic species in Europe”, AquaNIS.

In the North-East Atlantic, the Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR, formerly the Oslo-Paris Convention) established in 1972, is aimed towards the conservation of the marine environment and its resources. As such, OSPAR has pioneered ways of ensuring monitoring and assessment of the quality status of the seas, including the implementation of a Biodiversity and Ecosystem Strategy under the coordination of the Joint Assessment and Monitoring Program (JAMP).

3.7 North Pacific: focus on the West Coast of the United States

3.7.1 The Gulf of Alaska

There have been many scientific expeditions to the Gulf of Alaska over the years since early times and a historical review of scientific exploration of the North Pacific Ocean from 1500 to 2000 is available. Early explorations were carried out mostly for mapping and species identification (i.e. fishes, birds, and invertebrates). Marine survey expeditions in the late 1800s include the United States steamer *Tuscarora* in the Aleutian Trench, the *Albatross*, and the Harriman Alaska Expedition from Seattle through Prince William Sound, out to the Aleutians, and north along the Russian Federation coast of the Bering Sea. In the 1950s, major expeditions were carried out by NORPAC (North Pacific), the Japanese research vessel *Oshoro Maru*, the University of Washington's *Brown Bear*, the Russian Federation research vessel *Vityaz*, the Bering Sea Commercial Research Expedition, and the Pacific Research Institute of Fisheries and Oceanography (TINRO). Recent survey programmes are funded by MMS and NOAA. The MMS Outer Continental Shelf Environmental Assessment Program (OCSEAP) began in 1974 and is still active. The bottom trawl surveys run by NOAA collect information on fishes and many species from the Bering Sea, the Aleutians and Gulf of Alaska to support fishery management decisions by the North Pacific Fishery Management Council and the United States Secretary of Commerce. Biodiversity information has also been collected by the *Exxon Valdez* Oil Spill Trustee Council in Prince William Sound, continuous plankton recorder surveys across the North Pacific, Seward Line zooplankton collections in the Gulf of Alaska, and Hokkaido University's annual training cruises on the *Oshoro Maru* to the Bering Sea and Strait and, less frequently, to the Chukchi Sea. More recently, the NOAA Office of Ocean Exploration supported cruises (2002-05) to study biodiversity implementing the use of ROVs.

Large-scale research programmes off Alaska (see, e.g., the joint National Science Foundation–North Pacific Research Board Bering Sea study at <http://bsierp.nprb.org>) contribute to broader knowledge of biodiversity, and continue adding to the many efforts over the past 40 years to enumerate species from the coastal rocky headlands to the deep ocean and even in sea ice. However, no species inventory of all realms exists for any region of Alaska. Important databases containing biodiversity information are listed in Fautin et al. (2010) and efforts are underway to compile data in databases (e.g., Alaska Resources Library and Information Services - ARLIS; the *Exxon Valdez* Oil Spill Trustee Council - EVOSTC).

3.7.2 The California Current ecosystem:

Early surveys in this region began in the late 1700s and 1800s by European explorers, including Cook, La Perouse, Vancouver, and Bodega y Quadra. In the 1800s, United States naval expeditions collected information on fishes and whales. In the 1900s, marine research laboratories were established (e.g., Hopkins Seaside Laboratory in Monterey, California) which today form the Monterey Bay Crescent Ocean Research Consortium. Today, 40-50 marine research facilities operate in the region under the umbrella of the Western Association of Marine Laboratories. At present, many of the

available long-term data are a product of fishery management efforts, mostly funded by NOAA. Biodiversity databases of this region are listed in Fautin et al. (2010). Two major assessments in this region are the California Current Ecosystem Long Term Ecological Research (CCE LTER) and the California Cooperative Oceanic Fisheries Investigations programme (CALCOFI), both focused on the pelagic realm. The CalCOFI programme is a 60+ year survey including zooplankton with strong relations to biodiversity and a world-recognized data base allowing analysis of temporal trends (Kang and Ohman, 2014).

3.7.3 *Insular Pacific–Hawaiian Large Marine Ecosystem:*

Initial surveys of the Hawaiian Islands began in the early 1800s by French, Russian, and United States expeditions. The first plankton samples were taken by the *Challenger* in mid-1875, while major collections from Hawaii were initiated by the *Albatross* Expedition in the early 1900s. Between 1923 and 1924, four trips were made with the *Tanager* to survey 13 Hawaiian Islands, Johnston Atoll and Wake Island. Results from the *Tanager* expedition were published in *Marine Zoology of Tropical Central Pacific*, and included crustaceans, echinoderms, polychaetes, and foraminiferans. Between July and September 1930, an expedition led by P.S. Galtsoff to Pearl and Hermes, surveyed the abundance of pearl oysters for potential commercial use, and also noted the corals, algae, sponges, molluscs, crustaceans, and echinoderms.

Since these early cruises, conducting inventories of the biota of Hawaii has largely been the responsibility of the Bishop Museum, which at present has been designated the Hawaii Biological Survey (HBS). Surveys have occurred in targeted sites in the main Hawaiian islands, such as Kaneohe Bay and Pearl Harbor on the island of Oahu, and waters around the island of Kahoolawe.

Since 1995, surveys have also covered Midway Atoll, French Frigate Shoals, and Johnston Atoll. Electronic datasets for Hawaiian marine biodiversity include: <http://hbs.bishopmuseum.org/> (Hawaii Biological Survey); <http://cramp.wcc.hawaii.edu/> (Reef Assessment and Monitoring Program); http://www.nbio.gov/portal/community/Communities/Geographic_Perspectives/Pacific_Basin/ (National Biological Information Infrastructure (NBII), Pacific Basin Information Node); and [http://www.nbio.gov/portal/community/Communities/Habitats/Marine/Marine_Data_\(OBIS-USA\)/](http://www.nbio.gov/portal/community/Communities/Habitats/Marine/Marine_Data_(OBIS-USA)/). Intensive biological inventories have been carried out on fishes, stony corals, crustaceans, and molluscs (Fautin et al., 2010).

3.8 *North Pacific: focus on Japan*

In Japan, nationwide censuses of biodiversity of coastal areas, such as tidal flats, coral reefs, seagrass and algal beds, were conducted by the Ministry of the Environment, and showed long-term decline of these important habitats during the 1970s-1990s. However, the survey frequency was insufficient to identify the causal mechanisms of changes in relation to various environmental factors. Since 2002, the Ministry started a new type of monitoring programme, called "Monitoring Sites 1000" which aims to monitor the 1000

most important ecosystems in Japan over the whole 21st century. In this programme, ca. 50 coastal sites, including tidal flats, rocky intertidal shores, seagrass beds, algal beds and coral reefs are being monitored annually over the long term. These data will be utilized for various purposes, such as the prediction of coastal ecosystem response to global climate changes and other more local factors, as well as the impact assessment of the catastrophic disturbance by the 2011 earthquake and tsunami.

However, the number of sites is too small to set out in detail the changes in the coastal areas of the entire Japanese coast. In the meantime, local prefectural governments, fisheries agencies and certain NGOs have been conducting assessments of local coastal habitats of their areas, although the systems for sharing the information gathered are not well established at present. Certain ongoing network activities, such as the Japan Biodiversity Observation Network (JBON) and the Japan Long-term Ecological Research Network (JaLTER), are expected to collect this scattered information for use in developing integrated analyses of coastal ecosystem changes (Fujikura et al., 2010) (see Appendix 1-Japan for a list of assessments).

3.9 North Pacific: focus on China

The marine biological investigations in China started late. Until the early twentieth century, only limited areas had been explored and scattered taxonomic groups had been collected and researched. Additionally, due to the lack of special research institutes and taxonomists, many precious samples were lost.

From 1919 to 1949, some independent investigations and research on marine biological work in China were conducted. This period saw the real beginning of marine biological research in the country; the first qualitative benthic trawling investigation was launched in this time. But research conditions were very precarious and no research vessels for marine or fisheries science existed; therefore, surveys were relatively limited. During this period, research mainly focused on the coastal areas of Qingdao, Yantai, Xiamen, Beidaihe and Hainan Island.

Since the establishment of the People's Republic of China in 1949, many marine research institutions were set up gradually (e.g. Chinese Academy of Sciences - Institute of Oceanology (IOCAS) and South China Sea Institute of Oceanology (SCSIOCAS), State Oceanographic Administration (SOA), Ocean University of China (OUC), Chinese Academy of Fishery Sciences, etc.). Comprehensive oceanographic surveys were carried out from the 1950s to the 1980s. The National Comprehensive Oceanographic Survey (1958-1960; the First National Marine Census) was the first large-scale national comprehensive marine survey with participation of over 60 organizations and more than 600 researchers, which covered most coastal areas of the China seas north to the Taiwan Strait and most parts of the northern South China Sea. The biological investigation of this survey included assessments of plankton, benthos and nekton. More than 200,000 biological specimens were collected.

Other large-scale comprehensive marine surveys include the National Coastal Zone and Beach Resources Comprehensive Survey (1981-1987) and the First National Island Resources Comprehensive Survey (1988 -1996). These two surveys covered over 50,000 km², and involved microbial, planktonic, benthic and nektonic community investigations. These surveys investigated the coastal and island natural environments from China, and comprehensively evaluated the quantity, quality and distribution of biological resources. By the late 1980s, most of the waters under the jurisdiction of China had been investigated, and the diversity, distribution and utilization of the main marine biological species were roughly identified.

From the 1990s to date, large-scale comprehensive marine surveys include: the Continental Shelf Environment and Living Resources Survey (1997-2000), the National Offshore Comprehensive Oceanographic Survey and Evaluation (2004-2010), also referred to as the Second National Marine Census, and the ongoing Second National Island Resources Comprehensive Survey. These surveys were very intensive and thorough, providing supplemental data to the earlier efforts.

In the past 20 years, more regional investigations, including assessments in Bohai Gulf, Liaodong Bay, Jiaozhou Bay, Changjiang Estuary, Dayawan Bay, Quanzhou Bay, Hainan Island, and some islands in the South China Sea have been performed, with continued study in several regions. More studies were focused on particularly diverse habitats, such as coral reefs, mangrove forests and seagrass beds. Oceanographic exploration is reaching further into areas adjacent to China's seas, including in the West Pacific Ocean, Indian Ocean, even the North and South Poles, as well as cold seeps and seamounts in the deep sea of South China Sea.

Although significant advances have been made in marine biodiversity research in China since the 1950s, much insufficiency still remains. First, the marine biological specimen collection and biodiversity research is considered inadequate, especially from coral reefs, the deep sea and other special habitats. Second, the current investigations are considered as lacking systematic and thorough data publication. Third, the phylogenetic and biogeographic studies on marine living organisms are insufficient. Last, supervision and conservation are weak, and many species are critically endangered (Liu, 2013) (see Appendix 1-China, for a list of assessments).

3.10 Indian Ocean: focus on India

The two major institutions concerned with surveys and inventories of the fauna and flora in India are the Zoological Survey of India and the Botanical Survey of India, along with other research organizations, such as the Central Marine Fisheries Research Institute and the National Institute of Oceanography.

The published literature on coastal and marine biodiversity of India comprises an inventory indicating that 17,795 species of faunal and floral communities were reported from seas around India (see Appendix 1-Species diversity India). The taxonomy of many of the minor groups, particularly invertebrates (especially sponges, octocorals,

ctenophores, tunicates, polychaetes and other worms, as well as small size invertebrates) remain a challenge to specialists; as a result these taxa continue to be inadequately known from Indian seas. However, considerable knowledge on the taxonomy of groups, such as seaweeds, seagrasses, mangroves, scleractinian corals, crustaceans, molluscs, echinoderms, fishes, reptiles and marine mammals, is available in India.

Most of the marine biodiversity data come from surveys that sample up to 200 meters. There are large data gaps for smaller taxa and for large parts of the shelf and deep sea ecosystems, including seamounts (Wafar et al., 2011). The data provided in this paper warrant continued taxonomic research on the least-studied and unknown groups, in light of current threats to marine biodiversity. The full extent of biodiversity in any of the world's oceans may never be known, and the rate at which our understanding is increasing (Keesing and Irvine, 2005) is likely to be lowest in Indian seas. The impacts of climate change will alter coastal marine ecosystems, affecting the range of species and their ecology at a rate faster than it is possible to record their presence and abundance (Keesing and Irvine, 2005). In conclusion, it is evident that comprehensive taxonomic coverage of the marine biota of the entire region remains a monumental task, beyond the capacity of existing local taxonomic expertise.

Thus, to gain an appreciable knowledge on the patterns of diversity in the region, it will be necessary to identify indicator species to assess responses to unpredictable climate change. It would be quite appropriate to plan systematic studies rather than continue the present system of haphazard and opportunistic description of new species as and when they are discovered.

Within the largest Indian Ocean basin, the International Indian Ocean Expedition (IIOE) was held during years 1962-1965. This expedition was one of the greatest international, interdisciplinary oceanographic coordinated research efforts to explore the Indian Ocean in almost all disciplines in the marine sciences. The culmination of IIOE led to birth of the National Institute of Oceanography at Goa, the first regional institute for oceanographic research. At present, the plan for a second International Indian Ocean Expedition (IIOE2) has been drafted by the Science Council for Oceanic Research (SCOR) and will include more biological aspects than the first, particularly in marine biodiversity. The need for these expeditions as well as other continued studies are of overall importance in a region recognized by having growing concerns on food security, biodiversity loss, coastal erosion and pollution, along with a pressing need of conservation for tourism and sustainable fisheries.

3.11 Sub-Saharan Africa

Along the coastline of Sub-Saharan Africa, states of knowledge of marine biodiversity vary dramatically between the east, southern and west coasts of Africa. The biota of the east coast is moderately known. A general field guide to marine life in the region exists and two reviews have attempted to tabulate and assess states of knowledge of regional

marine biodiversity. However, this listing is far from complete. Some well-known taxa, such as reptiles, birds and mammals, are simply omitted from the tabulation. Other larger and/or more economically valuable taxa, such as seaweeds, flowering plants, fishes, corals, larger molluscs and crustaceans, etc., are probably fairly accurately represented.

However, many smaller and difficult-to-identify taxa are not included in the lists at all (for example, Nematoda, Copepoda and Ostracoda) or are likely to be severely under-represented, and probably less than half of the actual numbers of marine species present in the region have been described. Notable regional differences in sampling effort are found: Kenya, United Republic of Tanzania and southern Mozambique are the best-sampled regions, and northern Mozambique and especially Somalia are the least studied. In all regions, sampling effort declines rapidly with depth and distance from the coast; the deeper continental slope and abyssal habitats are almost completely unexplored. Regional taxonomic capacity is very limited and adequate marine collections in regional museums are lacking.

The marine biota of South Africa is by far the best known on the continent. The region has a relatively strong history of marine taxonomic research and a reasonably comprehensive and well-curated museum collection network, totalling some 291,000 marine records. South Africa has more than a dozen institutions with a strong focus in marine science (e.g. South African Institute of Aquatic Biodiversity or SAIAB, formerly the JLB Smith Institute of Ichthyology), with the largest concentration of marine scientists found in the Cape Town region.

Several regional guides to marine life, such as Branch et al. (2010), list more specialized taxonomic monographs. The regional data centre, AfrOBIS, houses some 3.2 million records of more than 23,000 species. These are derived from the wider African region, although the vast majority of data points originate from within South Africa. The total number of recorded marine species stands at 12,914 and these are tabulated by taxonomic group by Griffiths et al. (2010), who also list taxonomic resources and experts for the region. Many groups, particularly of smaller invertebrates, still remain poorly studied, however. In terms of regional coverage, shallow waters have been relatively well sampled, but sampling effort declined dramatically with increasing depth: 99 per cent of all samples have been taken in depths shallower than 1000 m. The 75 per cent of the EEZ that lies deeper than 1,000 m thus remains extremely poorly explored and is a priority for future research.

The marine biota of West Africa is poorly known. No regional marine guide exists and no comparative analyses of regional marine biodiversity have been compiled. Some reports purport to list the biodiversity for various individual countries in the region, but these are clearly superficial and fail to adequately reflect the diversity of smaller taxa. For example, in the Namibian EEZ, only 1,053 species are documented, of which more than half are fishes. This amounts to less than 10 per cent of the total known from South Africa, where fish comprise less than 20 per cent of the recorded taxa, indicating that the Namibian estimate is strongly biased towards larger, more conspicuous taxa. Similar

biases are evident in other national estimates, which appear to radically underestimate smaller, less conspicuous components of the biota and to concentrate on fishes and other 'target species'. This entire region probably remains amongst the least explored of coastal marine areas and a pressing need remains for taxonomic study of most invertebrate groups in the region. As with other regions sampling effort in waters deeper than 1,000 m is particularly lacking (see Appendix 1-Africa for a summary of assessments).

3.12 *South Pacific: focus on Australia and New Zealand*

3.12.1 *Australia*

Although Australia has the world's third largest EEZ, extending more than 5,000 km from the tropics (9°S) to temperate latitudes (47°S), it has a comparatively small marine survey capacity. At the same time, Australia has been very active in progressing marine conservation planning (called Marine Bioregional Planning), including the identification of a network of representative marine reserves covering 36.4 per cent of the EEZ. The need to support marine bioregional planning encouraged researchers to recover, validate and make accessible older surveys going back to the 1950s. Some of the most widespread data are associated with 4,000 exploratory demersal trawls by Russian Federation fishing vessels for the period 1965-78. Cooperation with scientists in Vladivostok, in the Russian Federation, and in Australia enabled data for earlier surveys to be made accessible and, where necessary to be aligned with modern taxonomy.

Aboriginal people accumulated much knowledge of Australia's flora, fauna, and ecological systems, including those of its "sea country," over the last 40,000 to 60,000 years, but much of this knowledge and understanding remains cryptic (Butler et al., 2010). European scientific study began with the first scientifically staffed voyages of discovery, notably those of James Cook in 1770, Nicolas Baudin in 1801–03, and Matthew Flinders in 1802. Charles Darwin visited Australia in the *Beagle* in 1836. The voyage of HMS *Challenger*, 1872–76, included Australian samples in its global investigation of the deep sea, and its reports are a basis of many disciplines. Soon after the British established the colony of New South Wales in 1788, scientific societies and natural history museums entered an active period of research. Discovery in the sea was more difficult and more limited than on land, but there was much activity during the twentieth century.

The taxonomy and descriptive ecology of organisms on accessible shores were an early focus, which has developed into a strong tradition of experimental ecology on seashores and in shallow water, as well as a determined effort to produce identification guides (Butler et al., 2010). The study of plankton and of benthopelagic coupling is less well developed than the study of benthos in Australia. Publications on phytoplankton have been available in Australia since the 1930s, but species lists are available only for limited locations. Research on zooplankton ecology has increased recently and several transects are now surveyed regularly with the Continuous Plankton Recorder. Mesopelagic

organisms are being assessed on several cross-Tasman transects from commercial vessels using standardized mid-water acoustic survey techniques supported by periodic mid-water trawls. These two standardized approaches are part of the Integrated Marine Observing System (IMOS; www.imos.org.au).

The diversity of sources from which Australian marine biodiversity data are obtained means that there are few repeat surveys – typically each survey has set out to answer a particular research question with scant regard to long-term comparison. A notable exception is the Australian Institute of Marine Science (AIMS) Long-Term Monitoring Program; it recently analyzed 2,258 standardized surveys from 214 different reefs between 1985 and 2012 and showed that coral cover had declined from 28.0 per cent to 13.8 per cent (0.53 per cent y⁻¹). This programme, together with the much newer IMOS, are the only long-term sustained monitoring programmes in Australian waters, although individual researchers have conducted repeat surveys using standardized sampling techniques for individual research projects, or have collated a variety of historical data sources to answer particular questions. Australian scientists recognize the need to develop longer time-series of survey data to support national State of the Environment reporting and to measure the effectiveness of the marine reserve network. This will require increased capabilities and capacity for biological sampling, which need to be brought to a similar level of standardization, replication, sustainability, interpretation and communication, as has been achieved by physical oceanographers.

Beginning in the first half of the twentieth century, energetic research was targeted at fisheries by Australian state agencies and by CSIRO's Division of Fisheries and its predecessors (Mawson et al., 1988). Although searching for commercial prospects, this work collected many non-commercial fish and invertebrates that were lodged in museums throughout the country, including the Australian National Fish Collection at CSIRO Marine and Atmospheric Research (CMAR). These fish collections have recently provided the most comprehensive and useful biological dataset for bioregionalization of Australian waters. In the 1960s, a period of intensive environmental research began, targeting in particular, bays, estuaries, and continental shelf near major capital cities (Wilson, 1996).

More recent work has explored deeper waters, with interests in exploration, the conservation of biodiversity and research on sustainable fisheries, more recently as part of the Australian Government's National Environmental Research Program Marine Biodiversity Hub (and predecessors), set up to provide the scientific information to support government policy and decision-making. Thus, museums are building important collections of Australian specimens from depths as great as 2,000 m and, in restricted parts of the shelf and slope, quite comprehensive faunal collections. An important component of the taxonomists' work, besides describing the 30-50 per cent of species that are new to science found on each survey, has been to provide regionally consistent descriptions of species so that broader bioregional patterns can be established. Although this has been available for fish species for many years, supported by genetic barcodes, it has only recently been possible for some invertebrate taxa.

With the declaration of Australia's Commonwealth Marine Reserve network (<http://www.environment.gov.au/marinereserves/>), survey emphasis is shifting from discovery to monitoring (or establishing the first quantitative baseline). Non-destructive sampling approaches, including autonomous underwater vehicles (e.g., www.imos.org.au/auv) and possibly genetic approaches, will be important additions to what will remain Australia's most prevalent deepwater activity – commercial fisheries which will continue outside the marine reserve network and inside the network in multiple-use areas, collecting data from their fishing operations and additionally, through cooperation with scientists, to routinely collect scientific information. In shallower waters it is likely that standardized citizen science will become increasingly valued.

3.12.2 New Zealand

The New Zealand's EEZ is one of the largest in the world. Despite important exploration efforts begun more than 200 years ago by James Cook followed by Louis Duperry and Dumont D'Urvillefor, Charles Darwin, the Challenger, and continued at present, much of this region remains unexplored biologically, especially at depths beyond 2,000 m. The major oceanographic data repository is the National Institute of Water and Atmospheric Research (NIWA), which is also data manager and custodian for fisheries research data owned by the Ministry of Fisheries. Museum collections in New Zealand hold more than 800,000 registered lots representing several million specimens. During the past decade, 220 taxonomic specialists (85 marine) from 18 countries engaged in the review of New Zealand's entire biodiversity, which ended in a major three-volume publication (Gordon, 2009). Current marine biodiversity in New Zealand surpasses the 17,000 species, and a list of all described New Zealand marine Animalia is available through OBIS (Gordon et al., 2010).

Multiple surveys (2000-2008) have been commissioned by the Ministry of Agriculture and Forestry Biosecurity New Zealand (MAFBNZ) in ports to detect alien species which have generated baseline information of species composition in these areas. At present, marine research (including marine biodiversity assessments) has a significant momentum in New Zealand with funding from the Ministry of Fisheries, the Foundation of Research, Science and Technology, the Ministry of Agriculture and Forestry, Biosecurity New Zealand, and the Universities Performance Based Research Fund. The Ocean Survey 20/20 programme(administered by Land Information New Zealand), could perhaps be noted as one of the most significant biodiversity assessments carrying out biodiversity sampling and habitat mapping in the New Zealand EEZ and Ross Sea/Southern Ocean on a yearly basis. Large areas have been surveyed on the Chatham Rise, Challenger Plateau (down to about 1,200 m), the Ross Sea and Southern Ocean (down to about 3,500 m), and currently in a large area of the northeastern North Island shelf out to 200 m. Data from many of these surveys is still being processed (Gordon et al., 2010).

3.13 Oceans around South America

The first studies of the South American coastal biota were carried out during a series of expeditions by European and North American researchers in the late 1700s and the first half of the 1800s, with naturalists Alcide d'Orbigny, Alexander Von Humboldt, Aimé Bonpland, and Charles Darwin, among others. In the late 1800s, several other important oceanographic expeditions, including the HMS *Challenger*, collected samples along the coasts of Ecuador, Peru, Chile, Argentina, Uruguay, and Brazil. In the 1900s, the Deutsche Südpolar Expeditions in 1901–03, the Swedish Lund University expedition to Chile in 1948–49, the Royal Society Expedition to Southern Chile, the Soviet Antarctic Expedition in 1955–58, and the Calypso campaigns in 1961–62 were among the most significant European expeditions to South America. Other important campaigns during the second half of the twentieth century which increased the knowledge of marine biodiversity and strengthened the local research capacities were carried out by the R/V *Academik Knipovich* (1967), the R/V *Almirante Saldanha* (1966), the R/V *Atlantis II*, (1971), the R/V *El Austral* (1966–67), the R/V *Vema* (1962), and the R/V *Walther Herwig* (1966–71). At present, the oceanographic vessel *Polarstern* from the Alfred Wegener Institute (Germany) has been carrying out exploration voyages to the southern regions of the continent and the Southern Ocean for more than 20 years.

In the northern latitudes of the continent, the Tropical Eastern Pacific (TEP) Biogeographic Region has a rich history of oceanographic and biological explorations dating back to the voyage of Charles Darwin to the Galápagos Islands aboard the HMS *Beagle* in 1835 and the Eastern Pacific Expedition of the United States National Museum of Natural History in 1904 aboard the United States Fish Commission steamer *Albatross*. A series of research cruises and expeditions organized by North American institutions in the first half of the twentieth century contributed greatly to the discovery and knowledge of the marine fauna and flora existing in the rich area between the low-tide mark and 200 m of depth in the Panama Bight, including Panama, Colombia, and Ecuador (e.g., the *Saint George* to Gorgona Island in 1927, the Allan Hancock cruises aboard the *Velero III* and *IV* vessels (1931–1941), the Askoy Expedition of the American Museum of Natural History in 1941). Taxonomic and ecological studies have been carried out in the last three decades in Costa Rica, Panama, Colombia, and Ecuador, mostly in the Gulf of Nicoya, the Bay of Panama, the Pearl Islands, the Bay of Buenaventura, Gorgona Island, and the Gulf of Guayaquil.

Important collections or libraries of regional marine fauna are maintained by the Los Angeles County Museum, the Scripps Institution of Oceanography at La Jolla, California, the California Academy of Sciences in San Francisco, and the Smithsonian Tropical Research Institute (STRI) in Panama City.

In the Tropical Western Atlantic (TWA), the natural history of Guyana (formerly British Guiana) was described by early explorers Sir Walter Raleigh (circa 1600) and Charles Waterton (early 1800s), who reported his discoveries in the book “Waterton's Wanderings in South America”. In French Guiana, the first studies were carried out after World War II, for fish inventories and later, in the 1950s, on benthic (mostly shrimps)

and demersal continental shelf fauna, from 15 to 100 m depth. The Venezuelan Atlantic Front was until recently almost completely unexplored, and the little information available concerned commercially valuable species of fish and shrimp.

In the southern part of the continent, the local and regional academic community also had important historical representatives and in the 1900s, research on coastal biodiversity received a strong stimulus due to the immigration of many European scientists who contributed to knowledge and capacity-building mainly through their involvement in local universities and natural science museums. Although a few research institutions were established in the region early in the twentieth century, such as the Smithsonian Tropical Research Institute (STRI) in Panama (1923), the most important stimulus to regional, autochthonous marine science was given by the establishment of several marine research institutions, mostly in the 1950s and 1960s. These institutions changed the way that marine science was done by incorporating time series of the environmental variables and their effect on biodiversity into the traditional taxonomic studies.

In the 1960s, the Food and Agriculture Organization of the United Nations began to develop projects giving an impetus to fisheries, especially in the southwest Pacific, an upwelling zone of extraordinary productivity that was responsible for 20 per cent of the world's fisheries by the end of that decade. In the 1980s and 1990s, centres for marine biodiversity research were created along the coasts of several countries, especially Brazil, Argentina, and Chile. The natural history museums in South America have been fundamental to preserving the regional marine biodiversity patrimony, both in collections and in the literature, and are considered to be taxonomically indispensable.

Some of the most relevant museums are the Museo de La Plata and the Museo Argentino de Ciencias Naturales (Argentina), the Museo de Historia Natural (Quinta Normal) in Chile, the Museo Dámaso Larrañaga and the Museo de Historia Natural in Uruguay, and the Museo de Boa Vista (Brazil). Other important collections are held at research institutions such as the STRI in Panama, the Instituto del Mar del Perú (IMARPE) in Peru, the Instituto de Investigaciones Marinas y Costeras (INVEMAR) in Colombia, and at universities.

Today, South America benefits greatly from regional cooperation. One example of cooperation was the Census of Marine Life that incorporated the region into several of its field projects (e.g., Shore Areas, Antarctic Life, Continental Margins, Marine Microbes (ICoMM), and the Mid-Atlantic Ridge Ecosystem (MAR-ECO) projects), which all contributed greatly to increasing the knowledge of marine biodiversity in the region. South America also has contributed nearly 300,000 records to OBIS from almost 7,000 species through its regional node.

At present, some of the main marine biodiversity assessments carried out in the region are:

- (1) SARCE: South American Research Group in Coastal Ecosystems (regional); since 2010. Aimed to study biodiversity and ecosystem function in the intertidal zone of rocky shores: <http://sarce.cbm.usb.ve/>;
- (2) Pampa Azul: South Atlantic (Argentina, approved in 2014). Aimed to carry out research for conservation purposes along with technology development and outreach;
- (3) SIMAC: Sistema Nacional de Monitoreo de Arrecifes Coralinos en Colombia; since 1998. Yearly sampling to monitor state of coral reefs. Taxa monitored include corals, macroalgae, invertebrates, and fish;
- (4) IMARPE (Instituto del Mar del Perú) and Universidad Nacional Mayor de San Marcos have initiated at least four projects characterizing marine biodiversity in several areas along the Peruvian coasts since 2009/2010 focused on benthic groups.
- (5) The Colombian National Authority for Aquaculture and Fisheries (AUNAP) in conjunction with INVEMAR carry out scientific research programmes to evaluate the Colombian potential to take advantage of new marine fishery resources such as tuna, dolphin fish, billfish, snappers, groupers and other fish of high commercial importance.

The objective of these programmes is to establish the current status of these resources in order to take management measures to promote the extraction of unconventional resources and discourage fishing pressure on those resources that are over-exploited. These studies provide not only information on highly important commercial species, but also a characterization on the status of marine biodiversity in the exclusive economic zone of Colombia.

3.14 *The Southern Ocean*

Whilst the economic exploitation of Antarctica's marine resources dates back to the 18th century, scientific research on its marine ecosystems only began in the mid-19th century. The HMS *Challenger*, the *Belgica* and the *Discovery* Investigations were among the first to undertake systematic sampling of the marine biology in the region. Taxonomic studies from these early expeditions provide the foundations of modern taxonomy in the Southern Ocean. Advances in technology, such as SCUBA diving, ice-capable research vessels and underwater imagery from remotely operated vehicles, have heralded a new era for marine ecological work in polar regions. Together with the recognition by the Scientific Committee on Antarctic Research (SCAR) and some national agencies of the importance of fundamental taxonomy, the rate of discovery and description of new species in the Southern Ocean has increased significantly.

In the framework of the Census of Marine Life a Decade of Discovery, life in the world's oceans has been investigated and questions about the known, the unknown and the unknowable have kept marine researchers busy. Many resources were made available for future research within the CoML community, but also for the public and policy-

makers. One of the flagship projects was the five-year Census of Antarctic Marine Life (CAML), which investigated the distribution and abundance of Antarctica's marine biodiversity, how it is affected by climate change, and how change will alter the nature of the ecosystem services currently provided by the Southern Ocean for the benefit of mankind. In this framework and within the International Polar Year 2007-2009, 19 research voyages were coordinated by CAML, involving more than 400 biologists from over 30 nations.

The CAML community explored the unknown bathyal and abyssal Southern Ocean (SO) and many shallow sites. Within the project about 16,000 SO taxa were identified and included in a database of Antarctic Marine Life; see the SCAR-Marine Biodiversity Information Network (www.scarmarbin.be). The CAML projects barcoded more than 3,000 species, a SO Plankton Atlas was established, life underneath the collapsed Larsen A and B ice shelves was studied and many scientists worked on the biodiversity, biogeography and conservation of various marine taxa.

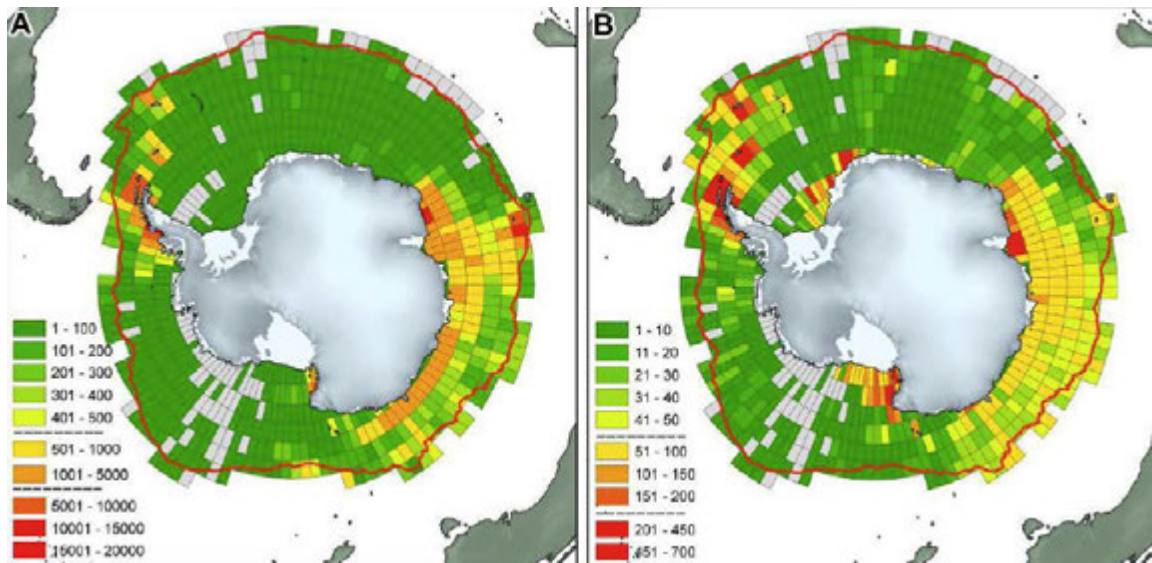

Moreover, more than 700 species new to science were discovered (Brandt et al., 2007) and new and unknown habitats were explored, e.g., the SO deep sea, and the Amundsen Sea. The lasting legacy of CAML is a benchmark, a system (or database) for monitoring change in the SO. Another major legacy of the CAML project and the SCAR Marine Biodiversity Network is the Biogeographic Atlas of the Southern Ocean (De Broyer and Koubbi, 2014) which compiles in more than 80 chapters an extensive review of the state of knowledge of the distributional patterns of the major benthic and pelagic taxa and of the key communities in the SO within an ecological and evolutionary framework. The Atlas relies on vastly improved datasets, and on insights provided by innovative molecular and phylogeographic approaches, and new methods of analysis, visualisation, modelling and prediction of biogeographic distributions. A dynamic online version of the Biogeographic Atlas will be hosted on www.biodiversity.aq.

The development of molecular techniques is a technical advance which promises to revolutionize work on the diversity and biogeography of Antarctic marine biota. CAML supported these efforts through its DNA Barcoding program. This technology is rapidly evolving and becoming ever more sophisticated. In particular such work is starting to uncover a wealth of cryptic species within what were once regarded as single, widely distributed species. Not only does this work increase the known species richness of the SO, but it also changes biogeographic patterns (typically reducing the range size or depth range) and hence affects our interpretation of the evolutionary history of the fauna. Along with these techniques, recent advances in satellite and aerial imagery will also become important for mapping and visualization and will help improve knowledge of marine ecosystems in the Southern Ocean. The Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) is regarded as a model for regional cooperation and maintains scientific research programmes (including ecosystem monitoring) to address risks to commercially exploited fish stocks in the SO using an ecosystem-based approach.

Despite the recent outstanding progress, some problems, gaps in knowledge and questions remained unaddressed (Griffiths et al., 2011). Besides obvious geographic and sampling gaps which still exist in the SO (East Antarctic, the Amundsen and Bellingshausen Seas and the SO deep sea, Figure 5), the extent of our knowledge of the biology, distribution, zoogeography, and evolution of Antarctic species is size-dependent.

The smaller the species are (nano-, meiobenthos, <1mm), the less is known about them. This also includes a lack of information on species' life histories and their diets, as our knowledge of the SO food web is mainly based on the diets of large pelagic predators. It is largely unknown what bottom dwellers feed on. This might be due to the fact that scientific effort and sampling of the benthos has predominantly concentrated on the continental shelves. Besides this bias in sampling depths, additional knowledge gaps are due to bias in the sampling gear used, with different gear considered as being either quantitative or qualitative (corers vs. trawled gear). Different working groups and expeditions have used different mesh sizes (not all scientists use fine mesh-sized gear and sieves), protocols and fixation methods.

In many marine areas (especially in the deep sea) more than 50 per cent of all species are rare and occur in samples as singletons. The fact that species occurrences are unevenly distributed – depending on their evolution and the availability of food sources – makes it difficult to understand the phenomena of patchiness and/or rarity. Very little is known at the community level about the potential effects of ongoing environmental change in the region. Although some shallow-water species have been physiologically investigated (and physiological adaptations are known for certain single species), community-scale effects of stressors, such as temperature rise, ocean acidification, increased frequency of iceberg scouring, etc., are very little known completely unknown (See Appendix 1-Southern Ocean for a summary of assessments).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 5. The total number of all marine sample sites and species found within each cell of a 3° of latitude by 3° of longitude grid, from distribution records in SCAR-MarBIN. The red line indicates the mean position of the Antarctic Polar Front, which defines the maximum northern extent of this study. A. Sample sites. B. Species richness (total number of all marine species recorded in that cell). Taken from Griffiths, 2010.

4. Status of Knowledge of Marine Biodiversity: A Synthesis United the Ocean Biogeographic Information System (OBIS)

4.1 Taxonomic completeness

Appeltans et al. (2012) estimated at about 226,000 the number of eukaryotic marine species described. More importantly, these authors report that more species were described in the past decade (about 20,000) than in any previous one and that the number of authors describing new species has been increasing at a faster rate than the number of new species described in the past six decades, demonstrating that progress has been made globally. Despite this, between one-third and two-thirds of marine species may be undescribed, representing a major gap. Costello et al. (2010), based on the regional reviews of the state of knowledge of marine biodiversity compiled worldwide by the Census of Marine Life, provided a global perspective on what is known and what the major scientific gaps are. They concluded that although there have been significant surveys and research efforts over the years, many habitats had been poorly sampled, especially in the deep sea, and several species-rich taxonomic groups, especially of smaller organisms, were still poorly studied. The best-known groups, which together comprise more than 50 per cent of total known biodiversity across regions, are

crustaceans, molluscs, and fishes. However, knowledge of marine biodiversity is not only related to surveys but also to the availability of local and regional taxonomic expertise, and to commercial value (e.g. fish and crustaceans). Here we examine the current global availability of biogeographic knowledge across all major marine taxa, using OBIS (OBIS; IOC of UNESCO, 2014) data.

Overall, the figure includes data for 228,935 accepted marine species across all taxonomic kingdoms (Figure 6). Forty per cent (90,921) of these species, including at least one representative from each major taxonomic group, contribute to the total of 28,369,304 OBIS distribution records. This figure shows that very few groups have more than 50 per cent of their species represented in OBIS (mammals, birds, bony fish, sharks and rays, and other fishes among the vertebrates and echinoderms, cephalopods, corals and anemones among the invertebrates). For example, over 80 per cent (13.7K) of the 16.7K known species of bony fish have a record in OBIS; on average these 13.7K species are known from between 10 and 100 distribution records (median = 25). The maximum number of records in OBIS is 849,179 and corresponds to the Atlantic cod *Gadhus morhua*. The typical species occurring in OBIS has just 6 distribution records, and 20 per cent of them (18,181 species) are represented by only a single record. Nonetheless, 27 of the 30 groups considered here include at least one species with >1,000 distribution records, with 17 and 7 groups, respectively, including species with >10,000 and >100,000 records.

Figure 6. Summary of the current global availability of biogeographic knowledge across all major marine taxa, using Ocean Biogeographic Information System data. The left-hand panel shows, for each taxonomic group, the proportion of all known species within that group which have at least one distribution record in OBIS ($P_{\text{species in OBIS}}$), with the solid vertical line indicating data available for 50 per cent of species. The thickness of each bar is scaled to the number of described species in each group, according to the World Register of Marine Species (WoRMS; WoRMS Editorial Board, 2014). The right-hand panel shows for each group the number of records across all species occurring in OBIS (N_{OBIS}). The solid bar is the median, the coloured box shows the interquartile range, and the lines extend to the minimum and maximum number of records for each group. Colours indicate: red (vertebrates), blue (invertebrates), orange (fungi), green (plant and algae), purple (protozoans), yellow (bacteria and archaea).

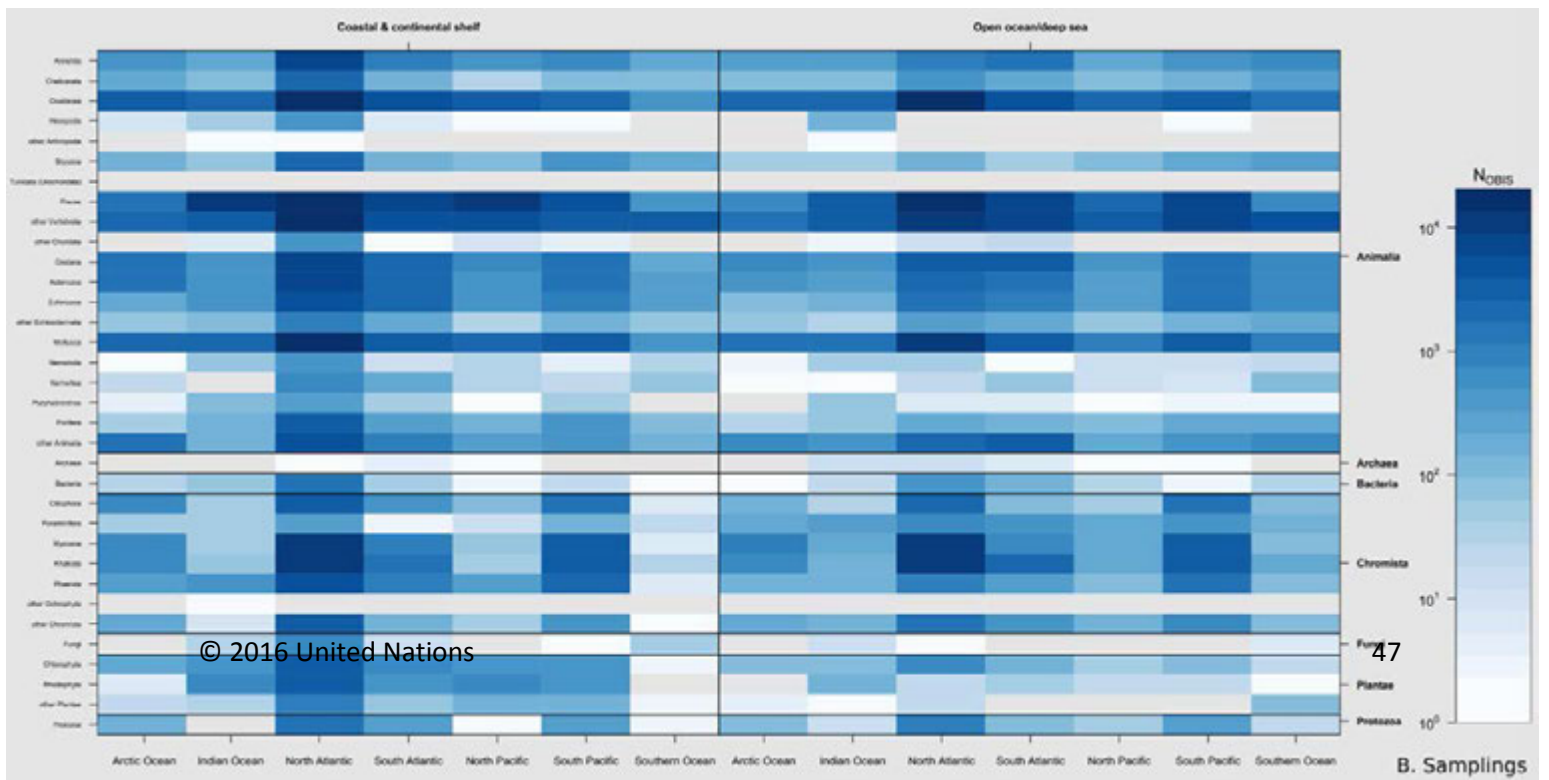

Figure 7 provides a visual representation of our knowledge measured as number of observations for species (7A), sampling (7B), and records (7C) for the different taxonomic groups comparing coastal and continental shelf environments versus open ocean and deep sea waters for the seven ocean basins. In general, it is clear from Figure 7A that fishes, along with crustaceans and molluscs, are the most diverse groups in all ocean basins. Figures 7B and C show that the North Atlantic is the best-known ocean basin for all groups. (www.iobis.org). These figures also demonstrate that, for each of the ocean basins, knowledge is significantly higher in the coastal and continental shelf environments in comparison to the open ocean and deep sea environments which reflects the same situation exposed by Costello et al. (2010), four years later despite important efforts in advancing deep sea research. To analyse geographic completeness, we show an estimate of the number of species using the Chao index for the different seas within the seven ocean basins using the OBIS database. It is evident from this graph that the best sampled areas have been in the northern hemisphere, and that the southern hemisphere, with the exception of the Southern Ocean, has been poorly sampled (Figure 8).

Figure 8. Estimate of the number of species, using the Chao index, for the different seas within the seven ocean basins using the OBIS database (www.iobis.org).

Final remarks

Marine biodiversity assessments are very variable among taxonomic groups and among ecosystems. Best assessed are groups such as fish, sea mammals, sea birds, turtles, and plankton, and ecosystems such as coral reefs. However, assessments are mostly limited in time, as very few have long term series data (as, for example, the CPR -Continuous Plankton Recorder has), and are limited by geographic range and taxonomic representation. Regarding taxonomic representation, for example, among fish efforts are mostly focused on commercial species (stock assessments) and top predators.

Among large vertebrates, efforts are focused on “iconic” and/or under-threat large species such as whales and turtles. Regarding geographic range, there is a considerable amount of information on coastal shelves and slopes along developed nations (e.g. Europe, United States, Canada, Australia, Japan, South Africa), however, even in these regions, knowledge is patchy in time (very few sustained long term efforts) and space (concentrated in particular areas of those coasts). The Arctic and Southern Ocean have received considerable attention (again the “charismatic” reason), but due to habitat complexity and logistical challenges, knowledge is fragmented, with some areas very poorly known. A generalized problem common to developed and developing countries, is that there is much unpublished data (at least not available through open access databases).

In addition, the ecosystem-approach type of assessment leading to an integrated management strategy is very recent, and still not widely used. Coral reefs may be the pioneer ecosystems in which this approach has been used, as monitoring programmes measure live cover, abundance and biomass in addition to biodiversity. This approach is also extending to other shallow water communities such as rocky shores through the integration of data and the creation of international networks. In the deep sea, seamounts seem to be the best assessed ecosystems, again maybe due to their potential economic value for fisheries or other extractive harvests such as minerals, as well as their potential to support significant biodiversity. This creates the urge to understand what they have in terms of living resources so that they can be managed properly before serious exploitation begins. On geologically active ecosystems such as vents and seeps, no assessments have been carried out, and information about these is very recent, very patchy, and very scarce.

We continue to stress the importance of taxonomy, systematics, and studies of biodiversity to advance our knowledge of ecology, ecosystem-based management, and understanding/valuation of ecosystem services. These are especially needed with increasing extinction rates, continued anthropogenic pressures on biodiversity, and the consequences of human-induced climate change. In this sense, biogeographic information is of fundamental importance for discovering marine biodiversity hotspots, detecting and understanding impacts of environmental changes, predicting future distributions, monitoring biodiversity, or supporting conservation and sustainable management strategies. The major challenges and needs for obtaining a more comprehensive overview of global marine biodiversity are the need to: (1) invest in taxonomy and capacity-building; (2) standardize methodologies to ensure proper

comparisons; (3) increase sampling effort, exploring new habitats, and identifying and mapping biodiversity hotspots; (4) make historical and new data increasingly more accessible through open access data portals such as OBIS; (5) quantify ecosystem services and the impact of loss of biodiversity on these goods and services in different marine habitats and ecosystems across regions, and analyze how cumulative and synergistic anthropogenic impacts may affect these services; and (6) continue to enhance the importance of biodiversity in marine management policy decisions.

Chapter 36A. North Atlantic Ocean

Writing team: Jake Rice (Convenor and Co-Lead member), Christos Arvanitidis, Laura Boicenco, Panagiotis Kasapidis, Robin Mahon, Thomas Malone, William Montevecchi, Marta Coll Monton, Fabio Moretzsohn, Patrick Ouellet, Hazel Oxenford, Tim Smith, John Wes Tunnell, Jan Vanaverbeke, Saskia Van Gaever (Co-Lead member)

1. Introduction

The North Atlantic is characterized by relatively wide continental shelves, particularly in its northerly portions, with steep slopes to the abyssal plain¹. The width of the shelf decreases towards the south, with typical boundary current systems, characterized by strong seasonal upwelling, off the Iberian Peninsula and northwest Africa. Two chains of volcanic islands, the Azores and the Canaries, are located in the east central North Atlantic, and a large number of islands of volcanic origin, many with associated warm water coral reefs, are found in the southwest portion of the North Atlantic. In the far north of the region is the world's largest island, Greenland, primarily of Precambrian origin, whereas Iceland and the Faroe Islands are of more recent volcanic origin. All have rugged coastlines with rich faunas.

The biota of the North Atlantic is strongly influenced by both the warm Gulf Stream flowing north-eastward from the Gulf of Mexico and the Caribbean to northwest Europe, and the cold, fresh Labrador Current flowing south from the Canadian Archipelago and Greenland to the northeast coast of the United States. Major oceanographic and associated biotic regime shifts have been documented in the North Atlantic, but not with the frequency or scale of the North Pacific.

Around the coasts of the North Atlantic are a number of semi-enclosed seas. These seas have distinct oceanographic and bathymetric regimes, and ecosystems with many characteristics determined by local-scale processes and pressures. Hence each of these semi-enclosed seas, including the Black Sea, Mediterranean Sea, Baltic Sea (and similar coastal estuaries of the United States), the Caribbean Sea, and the Gulf of Mexico, receive some individual consideration in this assessment. Within the North Atlantic, there are several habitat types of special importance for biodiversity, such as seagrass beds and cold- and warm-water corals. Since these are important where they are found on the globe, they are treated in an integrated manner, respectively, in chapters 47, 42-43, rather than separately.

Coastal areas of the Northeast Atlantic have been settled in and used for several millennia. Commercial fisheries, both coastal and, as technology developed, offshore, have exploited fish and shellfish resources for centuries as well (Garcia et al., 2014), with

¹ Biodiversity of the abyssal plain and mid-Atlantic Ridge that divides the eastern and western Atlantic is dealt with in Chapter 36F.

periods of widespread overfishing in the twentieth century. Industrialization developed first in northwest Europe and eastern North America, and land-based pollution and coastal infrastructure have been significant pressures on coastal biodiversity of the North Atlantic for nearly two centuries. Large urban centres developed on the coasts of the North Atlantic at the time of industrialization, and below the boreal latitudes most of the North Atlantic coastal areas have been altered by various combinations of urban or municipal development, industry, agriculture, and tourism. Although some tens of kilometres of coasts and a few hundreds of square kilometres of coastal seabed are now protected in various ways, almost all biotic communities have been altered by centuries of pressures from human uses.

2. Coastal and Shelf Holoplankton

2.1 Status²

2.1.1 Phytoplankton

Diatoms and dinoflagellates account for most phytoplankton species ($> 2 \mu\text{m}$) in coastal and shelf waters of the North Atlantic (Tables 36A.1 and 36.2)³, with diatom blooms typically peaking during spring and dinoflagellate blooms during summer (cf., McQuatters-Gollop et al., 2007). The ubiquitous prokaryotic species *Synechococcus* spp. ($< 2 \mu\text{m}$) also peaks in abundance ($> 10^7$ cells liter⁻¹) during summer (cf., Wang et al., 2011). On a decadal time scale (1960-2009), dinoflagellate species richness has increased while abundance has decreased relative to diatoms in the North-East North Atlantic and North Sea, a trend that has been attributed to the combined effect of increases in sea surface temperature (SST) and wind shear during the summer (Hinder et al., 2012).

2.1.2 Mesozooplankton (200 - 2000 μm)

Calanoid copepods dominate the holoplankton in coastal and shelf waters throughout the North Atlantic (Table 36A.3). Many of these species are cosmopolitan, e.g., > 60 per cent of the species described from the Caribbean Sea and Gulf of Mexico are also found in the North-East Atlantic (Park, 1970). A decadal scale (1958 – 2005) progressive increase in the abundance of warm-temperate calanoid species (e.g., *Calanus helgolandicus*, *Centropages typicus*) and a decline of cold-temperate calanoid species (e.g., *Calanus finmarchicus*, *Euchaeta norvegica*) has been documented in the North-East North Atlantic (Beaugrand et al., 2002, 2009; Chust et al., 2014). Coincident with

² Sampling for species identification employs different techniques (e.g., water samples, net samples, continuous plankton recorder) and, therefore, are not comparable from region to region in terms of species richness.

³ Note that the lists of abundant taxa in Tables 36A.1 and 36A.2 are not meant to be comprehensive. For example, a phytoplankton check list for the Baltic Sea describes over 1,500 species (Hällfors, 2004).

this trend, the mean size of copepods decreased as their species diversity increased and SST increased (Beaugrand et al., 2010).

2.2 Long-Term (multi-decadal) Trends and Pressures in Holoplankton

2.2.1 Regime Shifts: Overfishing and Climate Change

The primary pressures responsible for regime shifts in shelf ecosystems are overfishing and climate-driven changes (hydro-climate pressures including Arctic ice melting, ocean warming, and mode variability) in the marine environment (Steele, 2004; Edwards et al., 2006; Kane, 2011). Synchronous, system-wide regime shifts in plankton communities were initiated during the late 1980s and early 1990s in the Baltic Sea, North Sea, Scotian Shelf and Gulf of Maine (Reid et al., 2001; Edwards et al., 2002; Alheit et al., 2005; Record et al., 2010; Kane, 2011; Möllmann, 2011). In each case, synergies between trophic cascades triggered by overfishing and changes in hydro-climate were the primary pressures with overfishing reducing resiliency and hydro-climate forcing initiating the regime shift (Drinkwater, 2005; Beaugrand et al., 2008; Fogarty et al., 2008; Hilborn and Litzinger, 2009; Möllmann, 2011).

Gulf of Maine – During 1961-2008, the annual cycle of species richness and abundance was characterized by a seasonal peak during spring when diatoms dominated (Kane, 2011). The most abundant taxa were *Thalassiosira* spp., *Rhizosolenia hebetate*, *Phaeoceros* spp., *Thalassiothrix longissima*, and *Thalassionema nitzschioides*. On a decadal time scale, Kane (2011) documented three consecutive multi-year periods of varying species richness and abundance: below average (1961 – 1989), above average (1990 – 2001), and average (2002 – 2008). Decadal changes were more pronounced for diatoms than dinoflagellates (Möllmann, 2011), and the most striking feature in the time-series was the persistent positive anomaly of the 1990s.

Zooplankton species richness and abundance also increased sharply during the 1990s as the abundance of smaller copepod species increased and larger species declined (Pershing et al., 2005; Kane, 2007; Record et al., 2010). Increases in zooplankton and phytoplankton stocks were also reported during this period over the Newfoundland and Scotian shelves as Arctic species originating from the Gulf of St. Lawrence and the Labrador Current (e.g., *Calanus glacialis*, *Calanus hyperboreus*) became more abundant and warmer water species (e.g., *Calanus finmarchicus*, *Centropages typicus*, *Metridia lucenss*, *Temora stylifera*) became less abundant (Head and Sameoto, 2007; Möllmann, 2011). This inter-decadal zooplankton biodiversity signal was significantly correlated with phytoplankton biomass (Record et al., 2010).

North Sea – As indicated by rapid changes in plankton biomass and species diversity, a regime shift was initiated between 1983 and 1988, apparently as a consequence of increases in SST, a positive phase of the North Atlantic Oscillation (NAO), and increases in advection from the North-East North Atlantic (Beaugrand, 2004;

McQuatters-Gollop et al., 2007). Mean phytoplankton chlorophyll levels peaked in 1989 (Reid et al., 1998), and the new regime (1990 - 2003) maintained 13 per cent and 21 per cent higher chlorophyll concentrations in open and coastal waters, respectively (McQuatters-Gollop et al., 2007). The regime shift was also marked by increases in the abundance and diversity of dinoflagellates relative to diatoms, decreases in the abundance of *Ceratium* spp. (e.g., *C. furca*, *C. fusus*, *C. horridum*, *C. tripos*, *C. lineatum*), increases in diversity and abundance of warm water calanoid copepod species (e.g., *Rhincalanus nasutus*, *Eucalanus crassus*, *Centropages typicus*, *Candacia armata*, *Calanus helgolandicus*), decreases in cold water species (e.g., *Heterorhabdus norvegicus*, *Euchaeta norvegica*, *Calanus finmarchicus*), and increases in the frequency of jellyfish outbreaks (most notably the hydrozoan *Aglantha digitale* and the scyphozoan *Pelagia noctiluca*) (Attrill et al., 2007; Beaugrand et al., 2009, 2010; Edwards et al., 2009; Richardson et al., 2009; Licandro et al., 2010).

2.1.2 Toxic Phytoplankton Blooms: Invasions, Eutrophication and Climate Change

The frequency of toxic phytoplankton blooms has increased over the last three decades in coastal waters of both the western and eastern North Atlantic (Anderson et al., 2012). Toxic taxa include dinoflagellates (*Alexandrium* spp., *Gymnodinium catenatum*, *Karenia mikimotoi*, *Karenia brevis*, *Dinophysis* spp., *Prorocentrum crassipes*, *Prorocentrum* spp.), diatoms (*Pseudo-nitzschia* spp.), and microflagellates (*Chrysochromulina polylepis*, *Chattonella* spp., *Fabrocapsa japonica*).⁴ Increases in toxic events associated with these species have been attributed to more frequent and comprehensive observations, the dispersal of invasive toxic species via the ballast water of ships, coastal eutrophication, and climate change (Skjoldal and Dundas, 1991; Hallegraeff and Bolch, 1992; Belgrano et al., 1999; Anderson et al., 2002; Sellner et al., 2003; Glibert et al., 2005; Dale et al., 2006; Edwards et al., 2006; Moore et al., 2008; Fu et al., 2012). The risk of harmful phytoplankton blooms in the future has increased due to synergy between climate-driven changes and anthropogenic nutrient inputs (Hallegraeff, 2010).

2.1.3 Invasive Species: Ballast Water, Aquaculture and Climate Change

Large numbers of non-indigenous species have been introduced to coastal marine and estuarine ecosystems, largely due to transoceanic shipping (ballast water) and aquaculture (cf., Reise et al., 1999; Gollasch et al., 2009). Many of these species become invasive. Four ecologically significant invasions have been unequivocally documented (Birnbaum, 2006; Javidpour et al., 2006; Reid et al., 2007; Riisgård, 2007). The nuisance diatom (produces mucilage), *Coscinodiscus wailesii*, was introduced in the 1970s. The increase in abundance and geographic expansion of this species from the English Channel into the North Sea over the last three decades is a prototypical example of a planktonic species invasion. Likewise, by the 1990s the cladoceran *Cercopagis pengoi* and comb jelly *Mnemiopsis leidyi*, both voracious planktivores with the potential to disrupt trophic dynamics, had spread from the Gulf of Riga into the Baltic Sea and Gulf

⁴ http://www.marbef.org/wiki/OSPAR_eutrophication_assessment;
<http://www.whoi.edu/redtide/species/by-syndrome>

of Finland. These species appear to have been introduced via ballast water. The Pacific diatom *Neodenticula seminae* was transported into the Labrador Sea via the Canadian Arctic Archipelago in the late 1990s. It has since spread south to Georges Bank and further east, south of Iceland. The geographic expansion of this species portends of more trans-Arctic invasions from the Pacific Ocean as climate-driven Arctic ice melt continues.

2.1.4 Jellyfish: Overfishing, Eutrophication and Climate Change

Jellyfish blooms have increased in frequency in the northeast North Atlantic since 2002, e.g., *Pelagia noctiluca*, *Aglantha digitale*, and *Physalia physalis* outbreaks in the North-East North Atlantic (Attrill et al., 2007; Doyle et al., 2007; Richardson et al., 2009; Licandro et al., 2010), and mounting evidence suggests that these outbreaks may lead to trophic shifts from fish to jellyfish and other gelatinous zooplankton as the dominant consumers (Richardson et al., 2009). Primary pressures leading to a more gelatinous state include overfishing (Lynam et al., 2006; Bakun and Weeks, 2006; Roux et al., 2013), coastal eutrophication and hypoxia (Purcell et al., 2001; Condon et al., 2001), and climate-driven ocean warming and mode variability, e.g., the NAO (Purcell et al., 2001; Attrill et al., 2007; Gibbons and Richardson, 2008; Doyle et al., 2007), although decline in predation by sea turtles has also been implicated as a factor in the outbreaks.

2.1.5 Calcifying Plankton: Climate Change

A multi-decadal time series (1960-2009) for the North-East North Atlantic region shows that changes in the abundance and distribution of foraminifera (*Globerigina* spp.), coccolithophores (*Emiliania huxleyi*), pteropods (*Clione limacine*, *Limacina helicina*), non-pteropod molluscs and echinoderm larvae were positively correlated with decadal changes in annual SST and the Atlantic Multidecadal Oscillation and negatively correlated with pH, i.e., abundance increased as pH decreased (Beaugrand et al., 2013). Beare et al. (2013) found no statistical relationship between the abundance of calcifying plankton in the North Sea and pH, although *Globerigina* spp, *Emiliania huxleyi* and echinoderm larvae increased during the period, and pteropods and bivalve larvae decreased. Thus, although acidification may become a serious threat to calcifying plankton, observations to date suggest that the primary driver of calcifying plankton abundance has been ocean warming.

3. Benthos

Most studies dealing with “benthos” in the North Atlantic focussed on macrobenthos (i.e., metazoan animals living in the seafloor and retained on a sieve of 500-1000 µm). Studies on meiobenthos are more scattered, and often targeted towards the dominant meiobenthic taxon: the nematodes.

Much of the available information has been compiled at the beginning of this century, in the framework of large-scale projects including the Census of Marine Life (CoML, 2000-

2010), and the European Network of Excellence MarBEF (2004-2009). MarBEF was highly successful in compiling data on coastal benthos of the North-East Atlantic, and CoML captured many data of the deeper parts of the Atlantic in general.

3.1 *Coastal Benthos*

Within MarBEF, a large database (MacroBen), consisting of more than 460,000 distribution records on the distribution of 7,203 taxa from almost 23,000 stations was compiled (Gage et al., 2004; Vanden Berghe et al., 2009). Data were collected between 1972-2005 in the North-East Atlantic and adjacent semi-enclosed seas (North Sea, Baltic Sea, Mediterranean Sea) in a depth range of 0-450 m. Highest sampling density was in the North Sea and North-East Atlantic. As the analysis of this entire database reduces the potential problem of a disproportionally large effect of site-specific features on large-scale patterns (Renaud et al., 2009), and as the analyses of this database took into account methodological issues related to sampling and treatment of samples, the findings from these analyses are taken to reflect the general trends in macrobenthic communities in the North Atlantic. A first macro-ecological analysis showed that most macrobenthic communities follow the same right-skewed frequency distribution known from terrestrial ecosystems, revealing that most species are rare, and only few species have a wide distribution (Webb et al., 2009). Except for polychaetes, macrofaunal communities on a geographical scale of tens of km² or less are not random subsets of a species list at a wider geographical scale: species belonging to the same community tend to be more closely related to each other than would be expected when communities were randomly assembled from a regional species pool (Sommerfield et al. 2009). Hence, community composition for most taxa is determined by regional processes, whereas random assembly, followed by local environmental and ecological processes, is more important for polychaete communities.

After removal of the confounding effect of depth, sampling effort and the low diversity in the Baltic, Renaud et al. (2009) demonstrated a modest increase in diversity with increased latitude. Much stronger effects were observed for the diversity-depth gradient where a unimodal trend with water depth (within the 0-450 m depth range) was observed: species richness peaked at 100-150 m depth, and maximum values for the expected number of species in a sample with 50 individuals (ES (50)) were observed at 200-350 m (Escaravage et al., 2009). Diversity was negatively related to the fraction of primary production reaching the seafloor, corresponding with the decreasing part of the unimodal productivity-diversity curve (Escaravage et al., 2009).

3.2 *Offshore Benthos*

General patterns on the offshore benthos from the eastern and western part of the North Atlantic, here defined as the macrobenthos from continental slopes and the deep sea, have been investigated in relation to both latitudinal and depth-related patterns. However, data are scarce in comparison with the more shallow areas, and trends have

been deduced from a limited number of studies, focusing on a limited number of taxa. A poleward decrease in diversity was observed for deep-water molluscs and crustaceans (Rex et al., 1993) and cumaceans (Gage et al., 2004). Trends for the cumaceans were stronger in the eastern part of the basin. Data seem to be too scarce at the moment to make statements about the mechanisms behind the patterns (Narayanaswamy et al., 2010). Trends in the relationship between diversity and depth differ between sites for the same taxon: bivalve diversity (measured as ES (50)) is a significant unimodal function of depth, with diversity peaking at mid-bathyal depths in the western part of the North Atlantic, whereas the diversity-depth relationship can be described as a significant, linear function of depth (Brault et al., 2013) in the eastern part. The absence of the unimodal relationship between depth and diversity has been described for other taxa in other areas as well (Narayanaswamy et al., 2010). However, “depth” itself is not the explanatory variable, as it covaries with a variety of environmental characteristics and not always in the same manner (Narayanaswamy et al., 2010). Strong differences exist in the flux of organic carbon to the seafloor between the eastern and the western part of the Atlantic at depths > 3800m, where the flux of organic carbon is 56 per cent higher in the eastern basin, which is probably reflected in the macrofaunal densities and the feeding mode composition of bivalves (Brault et al., 2013). Although the flux of organic matter is indeed important, processes regulating diversity at local, regional and global scales in the deep sea are multivariate, and smaller-scale processes are hierarchically embedded in larger-scale processes and tend to occur at faster rates (Levin et al., 2001). Processes at the local scale involve biological interactions (competition, facilitation, and predation), patch type characteristics (biogenic structures, nutrient concentrations, topography) and disturbance and recruitment. All of these are hierarchically embedded in environmental gradients at the regional scale, dispersal, metapopulation dynamics and gradients in habitat heterogeneity. Processes at the global scale include, amongst others, speciation/extinction, large-scale disturbances and large-scale environmental gradients.

Apart from patterns in diversity, the relationship between biomass and depth received considerable attention as well. The decrease in total biomass with increasing depth has been observed at both sites of the Atlantic Ocean (i.e., Heip et al., 2001; Rex et al., 2006), and is explained by a decreased flux of organic matter when depth increases (Johnson et al., 2007). A global-scale analysis (Wei et al., 2010) showed that this decrease in total biomass is related to a decrease in individual size of the organisms.

3.3 *Dominant Pressures*

Many human activities have been documented to have impacts on benthic communities (Rice et al., 2010). Effects of mobile bottom-contacting fishing gear on coastal and shelf benthic communities have been documented essentially everywhere that such gear has been used. However, the nature of those impacts and their duration have been shown in many reviews to depend on the type of substrate and frequency of trawling (Collie et al., 1997; FAO, 2009; Hiddink et al., 2006; Kenchington et al., 2007; National Research

Council, 2001), with the longest-lasting impacts on hard-bodied biogenic structures, such as corals and glass sponges (see chapters 42 and 43). Recovery of benthic communities following cessation of bottom trawling has also been documented in several studies (Grizzle et al., 2009; Kaiser et al., 2006). Similar effects have been documented for other physical disturbances, such as aggregate extraction (Barrio Froján et al., 2011), with moderate recovery rates from local extraction events (Boyd et al., 2005), although such disturbances are usually concentrated in coastal areas (ICES, 2009).

Coastal benthic communities are also documented to be affected by pollution from land-based and coastal sources (see Chapter 20), such as nutrient runoff from the land, and shoreline alteration for human recreation and infrastructure. These impacts are nearly universal where pollution and nutrient inputs occur, and where coastlines are urbanized or adapted for tourism. However, their nature depends on the type, intensity, and duration of the pollution or nutrient input and extent of alteration, although persistent pressures of this type can greatly alter the species composition and biomass of benthos directly and indirectly through processes such as hypoxia (Borja et al., 2008; Gagné et al., 2006; HELCOM, 2009a; Middelburg and Levin, 2009). These effects can be specific enough that benthic community composition and/or productivity is often used as an indicator of ecosystem stress from pollutants or nutrient inputs (Borja et al., 2009; Quintaneiro et al., 2006; Solimini et al., 2006).

Climate change, including multi-year climate variability, is another major and growing pressure on the benthos. Not only are there effects of coastal warming, but the dependency of deep-sea benthos on the export of organic matter from the ocean surface seems to be at the basis of possible large-scale changes in biomass distribution under future climate scenarios (Jones et al., 2013). Surface ocean warming can result in increased stratification and a less efficient nutrient supply for primary production, leading to a projected decrease in upper ocean biomass (Joos et al., 1999; Steinacher et al., 2010), and a subsequent decrease in organic matter flux to the open ocean seafloor communities (McClain et al., 2012). Jones et al. (2012) modelled particulate organic carbon (POC) fluxes to the seafloor and the resulting macrofaunal biomass distribution under future climate scenarios (RCP 8.5 and RCP 4.5). Under the more severe RCP 8.5 scenario, global macrofaunal biomass is predicted to decrease by 3.771 per cent as a result of decreased organic matter fluxes. Both the greatest negative (-49.7 per cent) and positive (+36.79 per cent) change are predicted for the North Atlantic, with positive changes mainly located on the western side and major negative changes to the east. These shifts can result in range changes of species and facilitate colonization by invasive species in certain areas (Thatje, 2005). The reduction in total biomass of macrofauna will coincide with a size-shift toward smaller organisms (Jones et al., 2012, 2013), which has important biological consequences, including increasing respiration rates and reduction in overall biomass production efficiency (Brown et al., 2004; McClain et al., 2012; Smith et al., 2008) and a reduced energy transfer to higher trophic levels (Brown et al., 2004). Ocean acidification is an increasing threat to coastal marine benthos. Species having calcareous exoskeletons may have particularly high vulnerability to acidification, but it

has been found to affect many species of benthos (Andersson et al., 2011). It can be concluded that climate change, through its effect on primary production, is likely to have an important impact on the deep-water benthos, as well as coastal and shelf benthic communities.

4. Fish Communities

Much has been written about the status, trends and drivers of North Atlantic fish communities. These fish communities have been exploited for centuries, and have experienced additional pressures from coastal development, land-based inputs to the seas, and climate variation and change. Much effort has been devoted to teasing apart the influences of exploitation and environmental conditions as drivers of change in fish populations and communities, but definitive answers are elusive. Although long time-series of survey data and commercial catches exist, most effort has gone into assessing the status of commercially exploited populations.

Studies of fish biodiversity in the wider sense are much less numerous, and usually restricted to portions of the North Atlantic only. Thus general patterns have to be assembled from multiple studies, with many differences among them. Consolidating results of multiple studies as a basis for inferences on status, trends and pressures on fish communities has risks, because of the need to account for differences in the catchability of various species (Fraser et al., 2008), the underrepresentation of smaller fish in surveys (Cook and Bundy, 2012), the large sampling effort needed to document fish diversity (Greenstreet and Piet, 2008), and the dependence of inferred patterns of community change on the spatial scale of the analyses (Gaertner et al., 2007). Hence there will be many exceptions to generalizations and many gaps in knowledge. Some species groups, such as tuna and other large pelagics, and elasmobranchs, are addressed in separate chapters of this Assessment, and should be reviewed there. Likewise the parts of this Chapter on the several semi-enclosed seas have information on fish communities at those scales, and should also be consulted. The rest of this section looks at general patterns of near-coastal and shelf fish communities more generally.

4.1 Coastal Fish Communities

The need to piece together emergent messages from numerous separate studies is particularly true for near-coastal fish communities, where time series are usually much shorter and of localized spatial coverage. Most studies devote more attention to explaining variation among coastal fish community properties relative to features of the physical and chemical habitats, including temperature, salinity, oxygen and nutrient levels, clarity of and pollutants in the water column, and to depth, sediment types, benthic communities, contaminant levels, oxygen levels, and disturbance regimes of the

seafloor. All of these factors have been shown to influence fish community composition and structure in at least some coastal areas around the North Atlantic.

A few generalizations can be drawn from the diversity of results, but many are common sense. Studies have documented that when any of a large number of environmental factors are altered substantially from values historically characteristic of a coastal area, fish communities are highly likely to be altered as well. Large effects have been documented for factors like oxygen depletion (Oguz and Gilbert, 2007; Stramma et al., 2010), eutrophication (Buchheister et al., 2013; Olsen et al., 2012), sedimentation (França et al., 2012; Jordan et al., 2010; Kopp et al., 2013), and contaminants (Bergek et al., 2012; McKinley et al., 2011; Pato et al., 2008). Emergent macroalgae are an important determinant of coastal fish community diversity and fish abundance, and correspondingly many studies have documented that altering aquatic vegetation can have large effects on fish community status (Pihl et al., 2007; Waycott et al., 2009; York et al., 2012).

However, effects are often situation-specific, and multiple factors interact. For example, coastal flow regimes can dominate over nutrient loading, possibly through ensuring reoxygenation of water and sediments (Kotta et al., 2009; Reiss et al., 2010). Scales of wave energy can also influence how strongly local perturbations of habitat conditions are reflected in changes in fish communities (Jordaan, 2011). The local scale at which fish community structure is determined and variation is documented (e.g., Bonaca and Lipej, 2005) can be amplified, because many drivers of change in coastal fish communities are either both local in scale, such as coastal infrastructure development (e.g., Bulleri et al., 2012) or episodic, such as major oil spills (e.g., Mendelssohn et al., 2012).

Unfortunately the local scales at which coastal fish communities are structured, and where many impacts are experienced, means that it is not possible to present a quantitative accounting of trends in coastal fish communities on regional or North Atlantic scales. Long-term or large-scale studies do document that effects of major oceanographic drivers, such as warming or cooling trends, can be seen in coastal fish communities, documenting that large-scale as well as local factors affect community status (Henderson et al., 2011; Hurst et al., 2004). Species composition generally will react to such large-scale drivers at greater rates than more integrative community metrics (Bui et al., 2010; Hurst et al., 2004).

Given the intensification of use of coastal areas for aquaculture (Chapter 12), infrastructure (several chapters in part V), and land-based inputs to coastal areas (Chapter 20), it is likely that overall the status of coastal fish communities around the North Atlantic has been altered, and in areas with high human use and large habitat changes, the alterations could be large, with a reduction in species diversity and simplification of community structure (Lotze et al., 2006; Waycott et al., 2009). In addition, invasive species can have a large impact in coastal fish communities, and in cases such as the lionfish invasion of Caribbean and coastal southern northern American waters, may spread rapidly from multiple points of initial establishment, seriously

disrupting native fish communities (Whitfield et al., 2007; Muñoz et al., 2011). Such changes would, in turn, have consequences much wider than the local scale of the impacts, given the important role of coastal systems as nursery habitats (Beck et al., 2001; Persson et al., 2012).

Consequently, even if the overall trends in coastal fish communities cannot be quantified on the scale of the North Atlantic, the impacts of many pressures on these communities have been documented, as have the effects of larger-scale oceanographic and climatic drivers. With the increase in intensity of human activities causing many of these pressures (Sections IV and V) and a background of a changing ocean climate, there is ample justification for attention to the conservation of these systems. The evidence also indicates that appropriate management regimes need to be designed and implemented on local scales, to accommodate local communities and pressures, even if the overarching policies are developed at larger scales (*sensu* FAO Ecosystem Approach to Fishing (Staples and Funge-Smith, 2009)).

4.2 *Shelf Fish Communities*

A few studies have reconstructed fish communities and their variation over centuries into the past, albeit usually for just a few selected species and using catch records, sediment layers, or middens for local areas. These studies have consistently shown major changes in the composition of the fish community over the full time series, sometimes in regime-like ways. Likely impacts of overfishing were already evident early in the second half of the previous millennium (Mackenzie et al., 2007; Poulsen et al., 2007), but changes to the fish community associated with warmer and cooler periods of the North Atlantic are documented for the last several centuries (Enghof et al., 2007).

The current status of shelf fish stocks is best evaluated by the assessments done by the major fisheries management authorities around the North Atlantic. When data are sufficient, assessments provide estimates of fishing mortality and biomass, and interpret these relative to sustainability benchmarks. The biomass benchmarks reflecting that a stock is not overfished vary among jurisdictions and often are based on data series that do not extend back to a time when the stocks were unexploited (Lotze and Worm, 2009; Greenstreet et al., 2012). Nevertheless, Table 36A.4 presents the evaluations for most of the major assessment jurisdictions. The general messages are clear: many stocks are overfished and/or experiencing current overfishing, based on their current status relative to their management benchmarks, and the status of a number of other exploited stocks is not known. However, that only reflects part of the picture. For a large fraction of these stocks, the severe overfishing occurred in the 1990s and 2000s, and their status is improving. The improvement is consistently attributed to reductions in fishing effort (ICES and NOAA websites).

Of course the status of exploited stocks is only part of the fish diversity of the North Atlantic shelf systems. Many studies have analysed trends in the properties of fish communities, but these studies have varied greatly in the time intervals used, the parts

of the North Atlantic examined, the metrics of community status quantified, and the species included in the metrics. Given that the results of community analyses are scale-dependent (e.g., Gaertner et al., 2007), metrics are often partially redundant but not interchangeable (e.g., Greenstreet et al., 2012), and both fishing pressure and environmental conditions have changed substantially over the past several decades (ter Hofstede et al., 2012), only a few broad generalizations can be drawn from the diversity of results reported (Table 36A.5).

Based on Table 36A.5 and consistent with other overviews (ICES annual reports, NOAA annual reports), it is without question that in nearly every area of the North Atlantic examined, even moderate fishing pressure has been associated with a decrease in the proportion and absolute number of large fish in the community. Everywhere that heavy fishing was reported, not only does the size composition of the community continue to be truncated, but dominance usually declines as the most common species are reduced in abundance and species of lower or no commercial importance increase in at least relative and often absolute abundance. Whether this changes the diversity metrics depends on case-specific properties of the fish community (how dominant were the most dominant species) and fishing pressure (how intense, how sustained, and how selective).

It is also without question that for every time series of even moderate (decadal) length, effects sought of changing oceanographic conditions on fish community have been documented (e.g., Perry et al., 2005; Lucey and Nye, 2010; Pinsky et al., 2013). Warming is usually associated with increases in richness and diversity metrics, as the pool of warm-water species that can move into an area from the south during warm periods is almost always larger than the pool of cold-water species that can move in from the north during cold periods. Occasionally one of these environmentally sensitive species becomes very abundant (e.g., the Snake Pipefish outbreak in the North Sea around 2005, Harris et al., 2007), affecting diversity and evenness metrics. However, a number of studies report a negligible or even no trend in community metrics over moderate periods of varying environmental conditions, yet report large changes in the species composition of the community underlying the aggregate metrics. This highlights the strong buffering capacity that is increasingly being argued, where functional redundancy (Schindler et al., 2010; Widemann et al., 2012) gives resilience to fish communities, even if the species composition is changing substantially and without strong structuring processes (Rice et al., 2012).

In a few cases, time series of several decades are available. In all these reports the effects of both changes in fishing effort and in oceanographic conditions are apparent. These can be seen in individual species (e.g., herring, Harma et al., 2012; Larsson et al., 2010; cod, Drinkwater, 2010; Eero et al., 2011; Lilly et al., 2013; sole, Horwood, 2010) and such metrics of community as can be assembled from samples over long time periods (Foch et al., 2014; Greenstreet et al., 1999; ter Hofstede and Rijnsdorp, 2011; Shackell et al., 2012).

Bringing together the results of studies that look at how environmental drivers and fisheries have affected North Atlantic fish communities, the key messages include:

(i) Essentially every shelf fish community in the North Atlantic has been altered by decades to centuries of fishing. For many areas, excessive fishing persisted long enough for target species to be depleted to states where recovery has been slow, and whole communities have had their diversity reduced, with size metrics showing the greatest effects at community scales. However, in the twenty-first century, fishing effort has been reduced in most parts of the North Atlantic shelves, particularly where stocks and communities were most stressed, and there is evidence of recovery in most of these areas, albeit at different rates for different species, with some species having recovered to target levels.

(ii) Where data have been examined, every shelf fish community has had its species composition change as oceanographic conditions have changed. Responses to warming and cooling trends seem to be most prevalent, but these also have been looked for most often. Regime-like changes in fish community composition have been documented often, but they are not universal. Aggregate community metrics have often changed much less than the abundance of the species contributing to them.

(iii) On case-by-case examples it is often hard to definitively untangle the effects of fishing and of environment on fish communities although some at least partial successes are being reported (Bell et al., 2014). However, unless fishing is kept at a sustainable level, community-scale effects of depletion of target species are highly likely, and may reduce resilience to environmental drivers (Shackell et al., 2012).

5. Seabirds⁵

5.1 North Atlantic Overview

Overall, populations of breeding seabirds in the North Atlantic appear to be decreasing. This contention is the outcome of an integration of negative trends in both the North Atlantic Fisheries Organization (NAFO) and the International Council for the Exploration of the Sea (ICES) Regions. Most of the uncertainty about the Iceland population centres on estimates of the very abundant auk species which drive the overall population patterns. Further resolution of these estimates is essential.

Trends are considered for all species and for diving and surface-feeding taxa, which often have different sensitivities to climatic and anthropogenic environmental changes. Considerations of marine bird biodiversity are swamped by these most abundant species, although some aspects of species trends and community changes are addressed in the appended regional accounts.

⁵ Information in this subchapter is based on the appended spreadsheets of regional trends, numbers and sources, and can be modified as gaps are filled and new information obtained. Trends in breeding seabird populations from the 1970s/80s through the 2000s are reported where possible, although more often only the most recent decade[s] is available.

The overall picture here indicates that surface-feeders (storm-petrels, gulls, terns) drive the negative NAFO trend, and diving auks (Dovekie *Alle alle*, Thick-billed Murre *Uria lomvia*, Common Murre *Uria aalge*) in Iceland drive the negative ICES trend, with the ICES decrease being six times greater than that reported for NAFO.

Within regional trends considerable variation is observed (Table 36A.6), with different areas exhibiting increasing trends (E Baffin Island, Newfoundland/Labrador, E Canada + US, Faroes) or decreasing trends (W Greenland, Gulf of St. Lawrence, Caribbean, E Greenland, Iceland, Norwegian and North Seas).

5.2 NAFO Area

The negative trend in the NAFO Region is driven by surface-feeding species (gulls, terns, petrels) that are decreasing in eastern Canada (Cotter et al., 2012) and in the Caribbean (Bradley and Norton, 2009). The decline is also driven by an inferred decreasing trend in a diving planktivore (Dovekie) in Western Greenland based on North American Christmas Bird Counts (BirdLife International, 2014). Otherwise, divers are increasing in all regions, with the exception of the Caribbean, where a small population of Brown Pelicans (*Pelecanus occidentalis*) is declining (Bradley and Norton, 2009). Decreasing trends in surface-feeders and increasing trends in diving species are associated with fisheries closures in eastern Canada and the concurrent cessation of discards and gill-net removals (Bicknell et al., 2013; Regular et al., 2013). Surface-feeders are vulnerable to sea-surface temperature perturbations (Schreiber and Schreiber, 1984) and long-line fishing (Zydulis et al., 2009). Some ocean regions, notably the Gulf of Mexico, are data-deficient.

5.3 ICES Area

The decreasing trend in the ICES Regions is overridden by the uncertain negative Icelandic estimates. Positive trends are reported for the Faroes Island (Denmark)/Western United Kingdom and for the Barents Sea (which is excluded from consideration as it is in the Arctic rather than in the North Atlantic region).

Decreasing trends in auks in the Norwegian Sea (Anker-Nilsen et al., 2007) are associated with warming ocean trends and the consumption of forage prey by warm-water predatory fishes (e.g., Atlantic mackerel) moving into the region (T. Anker-Nilsen, pers. comm.).

6. Marine mammals

Many marine mammals primarily inhabit the margins of the North Atlantic Ocean, especially the continental shelf and within the many semi-enclosed regional seas. Other species primarily occupy the North Atlantic gyre, bounded by clockwise flowing currents

most famously defined by the Gulf Stream in the north and the Canary Current in the east (Figure 36A.1). Many of these latter species also utilize habitats in areas further north and south of the gyre, at least seasonally.

The gyre species as identified here include many historically subjected to whaling, including slower whales such as right whales, humpback whales and sperm whales, all targeted by open boat whalers through the nineteenth century. Faster whales, such as blue whales and fin whales, were targeted beginning in the late nineteenth century. Several medium-sized whales were also subject to whaling, with some continuing to be so down to the present, including long-finned pilot whales (targeted, for example, for a millennium in a drive fishery in the Faeroe Islands), the northern bottlenose whale (targeted from ships from the mid-nineteenth to the mid-twentieth century), and minke whales (targeted from ships by twentieth- and twenty-first-century whalers). The effects of whaling range from slight for species such as long-finned pilot whales (Taylor et al., 2008) to near extinction for right whales (Reeves et al., 2007). In recent decades, species such as humpback whales that migrate across the North Atlantic gyre from breeding grounds near islands in the Caribbean have recovered from earlier effects of whaling. However, those humpbacks breeding near the Cabo Verde islands apparently have not (Reilly et al., 2008).

Other gyre cetaceans include short-finned pilot whales, killer whales, pygmy killer whales, various other bottlenose whales and common dolphins. Generally these have not been subject to intense whaling.

In addition to the effects of historical and ongoing whaling, cetaceans in the North Atlantic are subject to various forms of disturbance (see Chapter 37). For example, disturbance and sometimes injury of individual animals by noise, including sound generated from military operations and from seismic operations has been demonstrated for some species of beaked whales (Cox et al., 2006; Whitehead, 2013). Similarly, mortality from ship strikes and entanglement in fishing gear have been demonstrated for humpback whales and right whales in the North Atlantic, and, especially for the small population of right whales that survived whaling, such mortality can be significant (Laist et al., 2001).

Harbour porpoise and common dolphin occupy continental shelf regions in the North Atlantic, and also occur further north. These have been subject to entanglement in fishing gear in many areas, especially bottom-tending gill nets (NOAA, 2014). Pinniped species, such as harbour seals, gray seals and harp seals, generally occur further north, but also occupy northern continental shelf regions around New England in the west and the United Kingdom of Great Britain and Northern Ireland in the east. They are dependent on haul-out areas, beaches and ice cover, and have often been thought to compete with fishermen for prey. Gray and harp seals have been subject to predator control programmes and, especially in the western North Atlantic, commercial harvests. However, both have increased in abundance in recent decades to relatively high levels. For example, in the northwest North Atlantic, gray seals have increased, reaching roughly half a million animals in 2014 (Figure 36A.2).

7. Specific areas of the North Atlantic

The predominance of semi-enclosed seas with characteristic biota around the North Atlantic, particularly the more southern and central portions of the region, and the concentration of human pressures around these seas, result in many important trends in biodiversity being observed most clearly at the scale of these seas. Hence this chapter includes brief summaries of the main patterns of and pressures on biodiversity for a number of these regional seas.

7.1 Black Sea

The Black Sea is a very deep inland sea with an area of 432,000 km². The thin upper layer of marine water (up to 150 m) supports the unique biological life in the Black Sea ecosystem. The deeper and more dense water layers are saturated with hydrogen sulphide, that over thousands years, accumulated from decaying organic matter in the Black Sea. Due to the unique geomorphological structure and specific hydrochemical conditions, specific organisms, basically on the level of protozoa, bacteria, and some multi-cellular invertebrates inhabit the deep-sea waters. Knowledge about biological forms of life in the deep waters of the Black Sea is very limited. The disturbance of the natural balance between the two layers could trigger irreversible damage to the people and ecosystem of the Black Sea⁶.

The recently published evidence raises the number of species, including supra-specific taxa, inhabiting the Black Sea to 5,000 (Gomoiu, 2012).

The distribution diagram of different physiological types of species from the Black Sea fauna shows the coexistence of four categories of species, according to a salinity gradient: (1) marine species, (2) freshwater species, (3) brackish water species, and (4) Ponto-Caspian relic species (Skolka and Gomoiu, 2004). The Black Sea biota consist of 80 per cent of Atlantic-Mediterranean origin species, and 10.4 per cent and 9.6 per cent of species of freshwater and Ponto-Caspian origin, respectively (Shiganova and Ozturk, 2010). The eastern sector is one of the biologically richest regions on Earth and is recognized as a biodiversity hotspot, along with other parts of the Caucasus Biodiversity Hotspot Region (Kazanci et al., 2011).

Genetic studies confirm the recent origin of many Black Sea marine taxa from the Mediterranean. The majority of these taxa most probably entered the Black Sea through the Marmara Sea and the Straits linking the Black Sea and the Marmara Sea after the last glacial maximum, when a connection between the Mediterranean and the Black Sea was re-established (Ryan et al., 1997). For this reason, these Black Sea populations are genetically similar to the Mediterranean ones, although in some cases they have already diverged, implying reduced genetic connectivity (e.g., Durand et al., 2013). There are also cases of Black Sea taxa, such as the copepod *Calanus euxinus*, to which the species

⁶ http://www.blacksea-commission.org/_geography.asp

status has been attributed, although they have only recently diverged (Papadopoulos et al., 2005). On the other hand, genetic studies have confirmed the ancient origin of the Ponto-Caspian species and have even revealed an additional diversity in the form of cryptic species (Audzijonyte et al., 2006).

The migration of marine species from the Mediterranean is hampered by a number of ecological barriers: (1) low salinity and ionic composition and the difference in the thermal conditions, (2) the presence of hydrogen sulphide in the Black Sea bottom areas, and (3) the lack of tides (Skolka, 2004; Gomoiu, 2004).

Our current knowledge on the biodiversity of certain taxa in the region shows a well-defined zoogeocline from the Marmara Sea and Bosphorus Strait to the inner parts of the region (Azov Sea), depicted both as a pattern in overall species composition and species (or taxa) numbers. As a general trend, species numbers decrease along with the decrease in salinity towards the inner parts of the basin. The trend is homologous to that seen in the benthic invertebrate inventories of all the major European semi-enclosed regional seas. Salinity and food availability appear to be the dominant abiotic factors correlated, though weakly, with the various patterns deriving from the taxonomic/zoogeographic categories (Surugiu et al., 2010).

The invasion of the basin by alien species began in the Middle Ages, with the bivalve *Teredo navalis*, as the first one recorded. The anthropogenic disturbance gradually increased and reached an unprecedented amplitude, becoming evident during the 1950s, concurrently with the penetration of the Indo-Pacific predator gastropod *Rapana thomasi*, which has severely reduced stocks of native oysters - *Ostrea sublamellosa* (Gomoiu, 1998; Skolka, 1998).

The invasive species may affect not only the ecosystem but also various sectors of the economy, with devastating effects for some of these sectors. This is the case of the American comb jelly, *Mnemiopsis leidyi*, accidentally introduced into the Black Sea by ship ballast water in the early 1980s. The introduced comb jelly nearly led to the collapse of pelagic fish populations (over 26 commercial Black Sea fish stocks), and finally caused a major shift in the marine ecosystem. Only after the penetration of a new warm-water ctenophore, *Beroe ovata*, ten years later, did the *M. leidyi* population diminish, allowing the ecosystem to recover its entire trophic web.

Another particularly important case of accidental immigration is that of toxic microscopic algae, whose outbreaks produce the so-called toxic blooms. The biotoxins produced inside the algal cells (i.e., domoic, okadaic, yessatoxine or azaspiracids acids), can have toxic effects on the other taxa and even on humans. The vast majority of these species, such as *Noctiluca scintillans*, also can reduce or deplete the oxygen concentration in the water column and sediments, leading to hypoxia or anoxia.

During recent decades, the temperature increased both in the surface mixed and in the cold intermediate water layers. This has been shown to be another factor accelerating the establishment of more thermophilic species populations, promoting their northward expansion from the Mediterranean (Shiganova and Ozturk, 2010).

In the conditions present during periods after major eutrophication outbreaks have returned towards more typical states, two antagonistic and synergistic processes have taken place: (a) the penetration of some opportunistic species, and (b) the disappearance of some economically valuable native species. In 1999, the first Black Sea Red Book was issued, which includes 160 endangered and rare plant and animal species. Sturgeons are the most endangered species, along with those that inhabit shallow coastal waters (turbot, sharks), seals, shrimp and oyster species.

The same critical status is also attributed to most of the coastal margin neritic and open sea habitats, and to 13 out of 37 benthic habitats. Among the habitats at risk are included the neritic water column, coastal lagoons, estuaries/deltas and wetlands/saltmarshes (Goriup, P., 2009).

In the Black Sea Region, almost a quarter of the habitat types listed in the European Union (EU) Habitats Directive can be found. Many are located in the intertidal zone and are consequently heavily influenced by the presence of salt water and continuous wave action. They include extensive areas of mud and sand flats, salt meadows and marshes, and long stretches of white sandy beaches (Sundseth and Barova, 2009).

Coastal forests are also well represented, especially on the low-lying hills in the south of Bulgaria and within the Danube Delta. They include a variety of rare habitat types listed in the Habitats Directive, such as the Western Pontic beech forests, as well as floodplain forests, alluvial and mixed riparian forests, all of which are important roosting and resting habitats for bats and birds (Sundseth and Barova, 2009).

7.2 *Mediterranean Sea*

The Mediterranean Sea is a marine biodiversity hot spot. Approximately 17,000 marine species have been reported from the Mediterranean Sea (Coll et al., 2010). Of these, at least 26 per cent are prokaryotic (Bacteria and Archaea) and eukaryotic (Protists) marine microbes. Phytoplankton includes more than 1,500 species. Macrophytes include approximately 850 species. Among microzooplankton, the foraminifera are the main group with more than 600 species, and about 100 species are commonly present in Mediterranean waters (Dolan, 2000). However, it is within the Animalia group that there is published evidence for the majority of the species so far reported (~11,500) with the greatest contribution coming from the Crustacea (13.2 per cent) and the Mollusca (12.4 per cent), followed by the Annelida (6.6 per cent), the Platyhelminthes (5.9 per cent), the Cnidaria (4.5 per cent), the subphylum Vertebrata (4.1 per cent), the Porifera (4.0 per cent), the Bryozoa (2.3 per cent), the subphylum Tunicata (1.3 per cent), and the Echinodermata (0.9 per cent). With regard to the Vertebrata, there are ~650 marine species of fish, of which approximately 80 are elasmobranchs and the rest are mainly from the Actinopterygii class (86 per cent). Nine species of marine mammals (five belong to the dolphins, Delphinidae, and one each to the Ziphiidae, Physteridae, Balaenopteridae, and Phocidae (seals)) and three species of sea turtles (the green *Chelonia mydas*, the loggerhead *Caretta caretta* and the leatherback *Dermochelys*

coriacea) are regularly recorded in the Mediterranean Sea. A total of 15 species of seabirds frequently occur in the Mediterranean Sea (Coll et al., 2010).

However, estimates of marine diversity are still incomplete as yet-undescribed species will be added in the future (Coll et al., 2010; Danovaro et al., 2010). In many cases, several cryptic species, mainly invertebrates, have been revealed through molecular approaches (Calvo et al., 2009), thus increasing the number of reported species. Moreover, diversity for microbes is substantially underestimated, and the deep-sea areas and portions of the southern and eastern regions are still poorly known (Coll et al., 2010). The next generation of sequencing data are already producing a wealth of unique sequences, in unprecedented rates, many of which are new operational taxonomic units (OTUs). Tens of thousands of OTUs are produced in the context of minimal monitoring projects (Pavloudi et al., in press), a fact which will soon alter the numbers so far reported. In addition, the invasion of alien species is a crucial factor that will continue to change the biodiversity of the Mediterranean (Zenetos et al., 2010), mainly in its eastern basin, where invading species can spread rapidly northwards and westwards due to the warming of the Mediterranean Sea (Lejeusne et al., 2010).

Genetic diversity, especially the presence of genetically distinct populations within a species, is another important component of biodiversity. Although the lack of strong physical barriers in the marine environment and the high dispersal ability of many marine taxa tend to diminish genetic differentiation, several marine species within the Mediterranean exhibit a strong genetic structure as a result of their life history traits and of the complex geography and hydrography of the Mediterranean. Diverse taxa, from small pelagic fish, like anchovy (Magoulas et al., 2006), to molluscs (Cordero et al., 2014) have been shown to consist of genetically distinct populations, with low connectivity, which calls for more local-scale management and conservation actions, especially for commercially exploited or vulnerable species. This differentiation often occurs across well-known biogeographic barriers, like the Almeria-Oran front (Patarnello et al., 2007) and the Siculo-Tunisian strait (Mejri et al., 2009).

Spatial patterns of species diversity show a general gradient characterized by the decreasing number of species from the west to the east (Arvanitidis et al., 2002, 2009; Coll et al., 2010). For certain taxa such as polychaetes, indications of habitat diversification, such as the average island distance from the nearest coast, number of islands and island surface area, have been reported to be best correlated with their multivariate community patterns (Surugiu et al., 2010). The decrease in species richness gradient has also been attributed to a synergy of variables, such as food availability, salinity (Surugiu et al., 2010) and current knowledge gaps with regard to the biota over large sectors, such as the northern African and eastern coasts (Coll et al., 2010; Coll et al., 2012). Lower productivity rates (oligotrophism) are related to the significantly lower size of the species in the eastern basin, a phenomenon known as “Levantine nanism” (dwarfism) (Por, 1989). Biodiversity is also generally higher in coastal areas and continental shelves, and with some exceptions it decreases with depth (Coll et al., 2010; Danovaro et al., 2010). However, fish biodiversity components, measured as species

richness of total, endemic and threatened coastal fish assemblages, as well as their functional and phylogenetic diversity, have been mapped and described as spatially mismatched between regions of the Mediterranean Sea (Mouillot et al., 2011).

The Mediterranean Sea is also diverse in terms of habitats and ecosystem types, due to its unique biogeography (Bianchi et al., 2012). Although empirical data are insufficient to have a full representation of habitat types (Danovaro et al., 2010; Levin et al., in press) and are only fully available for some coastal habitats (Giakoumi et al., 2013), a series of surrogates or modelling techniques are used to characterize marine habitats in the whole Mediterranean basin (Micheli et al., 2013; Martin et al., 2014).

Temporal trends have indicated that overexploitation of some fish and macro-invertebrates and habitat loss have been the main human drivers of historical changes in biodiversity (Coll et al., 2010; Lotze et al., 2011; Coll et al., 2012). At present, habitat loss and degradation, followed by fishing, climate change, pollution, eutrophication, and the establishment of invasive species, are the most important factors that affect most of the taxonomic groups and habitats (Claudet and Fraschetti, 2010; Coll et al., 2010; Abdul Malak et al., 2011; Lotze et al., 2011; Bianchi et al., 2012; Coll et al., 2012; Micheli et al., 2013). All these impacts are expected to grow in importance in the future, especially climate change and habitat degradation.

7.3 *Baltic Sea*

The Baltic Sea is a small sea on a global scale, but as one of the world's largest and most isolated bodies of brackish water, it is ecologically unique. Eutrophication, caused by nutrient pollution, is a major concern in most areas of the Baltic Sea. The biodiversity status was classified as being unfavourable in most of the Baltic Sea, as only the Bothnia Sea and some coastal areas in the Bothnian Bay were classified as having an acceptable biodiversity status. The results indicate that changes in biodiversity are not restricted to individual species or habitats; the structure of the ecosystem has also been severely disturbed (Helcom, 2010).

Baltic Sea biodiversity and human pressures on it have been summarized for all components except bacteria in Helcom (2009a) integrated thematic assessment. Alongside the general deterioration of the Baltic Sea biodiversity positive signs were also found for grey seals and some fish and bird species. A recent expert evaluation of endangered species in the Baltic Sea by Helcom (2013) shows the risk for extinction among a number of plant and animal species still existing.

The Baltic Sea is characterized by large areas (ca 30 per cent) that are less than 25 m deep, interspersed by a number of deeper basins with a maximum depth of 459 m. The western and northern parts of the Baltic have rocky seabeds and extended archipelagos; the seafloor in the central, southern, and eastern parts consists mostly of sandy or muddy sediment (ICES, 2008b).

The Baltic Sea phytoplankton community is a diverse mixture of microscopic algae representing several taxonomic groups, with more than 1,700 species recorded. The species composition of the phytoplankton depends on local nutrients and salinity levels and changes gradually from the southwest to the northeast. Primary production exhibits large seasonal and interannual variability (Helcom, 2002). In the southern and western parts, the spring bloom is dominated by diatoms, and by dinoflagellates in the central and northern parts (Helcom, 2002, 2009a).

Cyanobacteria are a natural component of the phytoplankton community in most parts of the Baltic Sea area. They usually dominate in summer in the coastal and open areas of most sub-basins of the Baltic Sea, with the exception of the Belt Sea and the Kattegat. Cyanobacterial blooms in the Baltic Proper are typically formed by the diazotrophic species *Aphanizomenon flos-aquae*, *Anabaena* spp. and *Nodularia spumigena* that can fix molecular nitrogen. *N. spumigena* blooms are potentially toxic, whereas no toxic blooms of *A. flos-aquae* have been recorded in the Baltic Sea. The blooms of N₂-fixing cyanobacteria as such do not necessarily indicate strengthened eutrophication (Helcom, 2009b).

The zooplankton of the Baltic Sea is dominated by calanoid copepods and cladocerans. The species composition is influenced by the salinity gradient. Generally marine species (e.g., *Pseudocalanus* spp.) prevail in the southern more saline part, while brackish species (e.g., *Eurytemora affinis* and *Bosmina longispina maritima*) dominate in the northern areas (ICES, 2008b). The latitudinal distribution of marine macrozoobenthos in the Baltic Sea is limited by the gradient of decreasing salinity towards the north. The decreasing salinity reduces macrozoobenthic diversity, affecting both the structure and function of benthic communities. In addition, the distribution of benthic communities is driven by strong vertical gradients. Generally, the more species-rich and abundant communities in shallow-water habitats (with higher habitat diversity) differ from the deep-water communities, which are dominated by only a few species (Helcom, 2009a).

The composition of the benthos depends both on the sediment type and salinity level, with suspension-feeding mussels important on hard substrata and deposit feeders and burrowing forms dominating on soft bottoms. The species richness of the zoobenthos is generally poor and declines from the southwest towards the north due to the drop in salinity. However, species-poor areas and low benthos biomass are also found in the deep basins in the central Baltic due to the low oxygen content of the bottom water (ICES, 2008b).

The distribution of the roughly 100 fish species inhabiting the Baltic is largely governed by salinity levels. Marine species (some 70 species) dominate in the Baltic proper, and fresh-water species (some 30–40 species) occur in coastal areas and in the innermost parts (Nellen and Thiel, 1996, cited in Helcom, 2002). Cod, herring, and sprat comprise the large majority of the fish community in both biomass and numbers. Commercially important marine species are sprat, herring, cod, various flatfish, and salmon. Sea trout and eel, once abundant, are now in very low populations. Sturgeon was a very important component of local exploited fish fauna for centuries, especially in the

southern Baltic. Currently, sturgeon is a red-listed fish in the Baltic Sea and a reintroduction programme has been initiated (Helcom, 2009a). The seabirds in the Baltic Sea comprise pelagic species like divers, gulls, and auks, and benthic-feeding species like dabbling ducks, sea ducks, mergansers, and coots (ICES, 2003). The Baltic Sea is more important for wintering (ca 10 million) than for breeding (ca 0.5 million) seabirds and sea ducks. The common eider exploits marine waters throughout the annual cycle, but ranges from being highly migratory (e.g., in Finland) to being more sedentary (e.g., in Denmark).

The marine mammals in the Baltic consist of gray (*Halichoerus grypus*), ringed (*Phoca hispida*), and harbour seals (*Phoca vitulina*), and a small population of harbour porpoise (*Phocoena phocoena*). Seals and harbour porpoise were much more abundant in the early 1900s than they are today (Elmgren, 1989; Harding and Härkönen, 1999) where their fish consumption may have been an important regulating factor for the abundance of fish (MacKenzie et al., 2002). Baltic seal populations – harbour seals, gray seals, and ringed seals – are generally increasing. The recent abundance of the harbour porpoise in the Baltic Proper is low (Helcom, 2009a).

7.4 North Sea

The North Sea is a large semi-enclosed sea on the continental shelf of northwest Europe, formed by flooding in the Holocene period. The sea is shallow, deepening towards the north. The seabed is predominantly sandy, but muddy in deeper parts and in southern coastal areas with extensive river influence.

The strong coupling between benthic and pelagic communities in the shallow parts of the North Sea makes it one of the most productive marine areas in the world, with a wide range of plankton, fish, seabirds and benthic communities.

The most commonly found zooplankton genus in the North Sea is of the copepod *Calanus*. Hays et al. (2005) observed between 1960 and 2003 a clear decrease in the abundance of *Calanus finmarchicus*, and an increase in *C. helgolandicus*, with a marked overall decrease in both species combined. Beaugrand et al. (2002) also found a decrease in the abundance of cold water and Arctic zooplankton species and an increase in warmer water ones.

The 50-m, 100-m, and 200-m depth contours broadly define the boundaries between the main benthic communities in the North Sea (Künitzer et al., 1992; Callaway et al., 2002). Bottom temperature, sediment type, and trawling intensity have been identified as the main environmental variables affecting local community structure. Epifaunal communities are dominated by free-living species in the south and by sessile species in the north.

Throughout the year, the pelagic fish component is dominated by the herring *Clupea harengus*. The mackerel *Scomber scombrus* and the horse mackerel *Trachurus trachurus* are mainly present in summer, when they enter the area from the south and from the northwest. Dominant gadoid species are the cod *Gadus morhua*, the haddock

Melanogrammus aeglefinus, the whiting *Merlangius merlangus*, and the saithe *Pollachius virens*; the main flatfish species are the common dab *Limanda limanda*, the plaice *Pleuronectes platessa*, the long rough dab *Hippoglossoides platessoides*, the lemon sole *Microstomus kitt*, and the sole *Solea vulgaris*. The major forage fish species are the sandeel *Ammodytes marinus*, the Norway pout *Trisopterus esmarki*, and the sprat *Sprattus sprattus*, but juvenile herring and gadoids also represent an important part of the forage stock. However, large annual variations in species composition occur as a consequence of natural fluctuations in the recruitment success of individual species. Fish species richness is highest around the edges of the North Sea (particularly along the coast of Scotland, in the Southern Bight, and in the Kattegat) and lowest in the central North Sea (ICES, 2008).

Certain highly migratory species that historically were fairly common in the North Sea have become very rare (e.g., tunas and the halibut *Hippoglossus hippoglossus*). The stocks of most elasmobranchs are at low levels (ICES, 2008). The spurdog (*Squalus acanthias*) was the most common shark species, but is now considered to be depleted to approximately 5 per cent of its virgin biomass in the whole Northeast Atlantic (Hammond and Ellis, 2005). Decades of intensive fishing have been shown to have altered both the species (ICES, 2008; Piet et al., 2009; Greenstreet et al., 2010) and size composition (Daan et al., 2005) in the North Sea, with greatest effects where fishing has been most intense. There is some evidence that these effects are being reversed since fishing pressure was reduced in the late 2000s, but community metrics are still far from their values observed prior to the 1970s (Greenstreet et al., 2011).

About 2.5 million pairs of seabirds, belonging to some 28 species (ICES, 2008) breed around the coasts of the North Sea. Although most species breed in dense colonies along the coast, they make very different use of the marine ecosystem. During the breeding season, some species depend on local feeding conditions within tens of kilometres around their colony, whereas others may cover several hundreds of kilometres during their foraging trips. Outside the breeding season, some species stay quite close to their breeding grounds, and others migrate across the North Sea or elsewhere, even as far as the Antarctic. Feeding habits also diverge. Auks and cormorants dive from the surface, gannets and terns use plunge diving, and gulls feed mostly from the surface. A few (especially skuas) are kleptoparasites (Dunnet et al., 1990). Their food resources vary accordingly, ranging from plankton to small schooling fish and discards. Because of all these differences, seabirds do not represent a single homogeneous group that responds to fisheries in a uniform way. A few species profit directly from human consumption fisheries, either discards or offal, e.g., fulmars and gulls. Current seasonal distributions, status, and trends of these species have shown an increasing trend over the last century. Auks and cormorants are now protected in some areas (e.g., the southern North Sea and Kattegat). Gull numbers have been controlled in many areas. Fulmars may have benefited from the expansion in fishing. Skuas may have profited directly from the increase in population size of seabirds in general. On a shorter time scale, 12 out of 28 species show an increasing trend during the last decade and

four a decreasing trend; four appear to be stable and for another four the situation is unknown (ICES, 2008).

Many cetacean and pinniped species have been observed within the North Sea, but most of these must be considered vagrants and only a few are resident representatives of the North Sea ecosystem. Harbour *Phoca vitulina* and gray *Halichoerus grypus* seals have undergone large population changes over the past century. Populations of harbour seals along the continental coast reached an all-time low in the 1970s. Subsequently, these populations increased steadily at an annual rate of 4 per cent, with two major interruptions in 1988 and 2002, when the populations were hit by outbreaks of the phocine distemper virus (ICES, 2008).

Although several cetacean species visit the North Sea, the dominant species are minke whales *Balaenoptera acutorostrata*, harbour porpoises *Phocoena phocoena*, and whitebeaked dolphins *Lagenorhynchus albirostris*. Preliminary abundance estimates from a survey conducted in 2005 indicate the *status quo* for all these species. Harbour porpoises, however, have shifted their focal distribution from the northern part of the North Sea to the southern part. The reasons for this southward shift of harbour porpoise distribution are unknown; however, a change in distribution and availability of prey species is considered the most likely explanation, although other explanations are possible (ICES, 2008).

A number of sand banks across the North Sea qualify for protection under the European Union Habitats Directive, mainly along the UK coast, the eastern Channel, the approaches to the Skagerrak, and the Dogger Bank. Extensive biogenic reefs of *Lophelia* have recently been mapped along the Norwegian coastline in the eastern Skagerrak, and *Sabellaria* reefs have been reported in the south, although their distribution and extent are not known. Gravel deposits also qualify for protection, but comprehensive maps at a total North Sea scale are not readily available (ICES, 2008).

7.5 Gulf of St. Lawrence

The Gulf of St. Lawrence (hereafter the Gulf) is a relatively small (236,000 km²) sea located along the southern Canadian Atlantic in the Northwest Atlantic connected to the ocean by the shallow (60 m) and narrow (17 km) Strait of Belle Isle in the northeast, where dense Labrador Shelf water enters the Gulf and the deep (480 m) and wide (104 km) Cabot Strait in the south (Figure 36A.2bis). The Gulf receives large quantities of freshwater from the St. Lawrence River system, more than half of the freshwater inputs from the east coast of North America, which gives the Gulf an estuarine-like circulation. The Gulf has a complex geomorphology, with a broad shallow shelf (<100 m) in the south and a northern region characterized by narrow coastal shelves and deep (>300 m) channels. The environment is influenced by climate variability in the Northwest Atlantic. The seasonality is characterized by severe winters with low temperatures and ice covering a large surface from December to April, and by warm surface water in summer. The sea surface temperature differences between winter (less than 0°C) and summer (close to 20°C in the south) are among the largest recorded around the Atlantic. The

Gulf's multilevel complexity provides the conditions for a highly diverse fauna, with a mixture of boreal, temperate and sub-tropical species, and productive biological communities (Benoît et al., 2012).

Global climate change, including ocean warming affects the Gulf as indicated by a clear decreasing trend in winter ice coverage and volume and increasing sea surface temperatures in recent years (DFO, 2013). The characteristics of the deep layer are influenced by the quality and relative proportions of the deep Atlantic water masses from which it originated. Low levels of dissolved oxygen (and associated low pH levels) are found in the deep channels and some areas (e. g., the head of the Laurentian Channel) have been hypoxic (oxygen concentration < 20 per cent) since the mid-1980s (Benoît et al., 2012). Appropriate oxygen and pH levels are important conditions for the health of the organisms; the observed levels have been attributed in part to local biological oxygen consumption in the deep layer, but also to changes in the source water masses from the North Atlantic. About 1 M people live in periphery of the Gulf and depend (82 per cent of regional employment, 79 per cent of regional GDP) directly on marine activities (DFO, 2013). The St. Lawrence River upstream and other tributaries from the urban and industrial zones are sources of contaminants that, combined with human activities in the coastal zone (e.g., agriculture/aquaculture, habitat destruction/modification, nutrient loading), can have disturbing effects on the ecosystem. The Gulf is also an important maritime route and the heavy commercial shipping connecting the Atlantic (and other oceans of the world) with the Great Lakes industrialized region in mid-North America represent another pressure (e.g., noise, potentially invasive species from ballast water) on the ecosystem. Human activity may have directly contributed to the establishment of 20 non-indigenous (alien) aquatic species in the Gulf; half of these since 1994 (SOTO, 2012). For decades, if not centuries, the principal human activity in the Gulf has been fishing, both commercial and recreational. That may change in the near future, however, with the development of oil and gas exploitation projects.

The timing of the phytoplankton bloom is affected by the timing of the winter ice retreat and water stratification. The bloom may have been earlier in the late 1990s than today, but no clear trend in timing and intensity is detected (Dufour et al., 2010). However, systematic monitoring of the lower level of the ecosystem (phytoplankton, zooplankton) is recent, less than 20 years, for the Gulf, and temporal trends are difficult to detect from the important interannual variability. Phytoplankton community structures vary regionally but, generally, diatoms (the group of phytoplankton typically associated with intense spring blooms in productive northern seas) and small-celled planktonic organisms (e.g., dinoflagellates) are found in equal proportions (Bérard-Therriault et al., 1999). Recently, decreasing diatom/dinoflagellate and flagellate ratios have been observed due to an increase in dinoflagellates and flagellates that may reflect increasing stratification, temperature and nutrient loading in the system (Dufour et al., 2010). Ecosystems dominated by dinoflagellates and flagellates are less productive. The Crustacea are the most important group (60 per cent) in the zooplankton, and the Copepoda account for 70 per cent of all species (Brunel et al., 1998). There are close

associations between the abundance of some small copepod species, the young stages of larger species and feeding by young fish. In the Gulf, all copepods seem to have increased around 2005, but the abundance of the key species *Calanus finmarchicus* has been below average since 2009 (DFO, 2013). Although there are important uncertainties about total biomass and trend, high concentrations of krill (Euphausiids) are found at specific sites and large numbers of blue whales from the Northwest Atlantic population migrate to the Gulf to feed (Gagné et al., 2013). At least 12 species of whales migrate to the Gulf every year, which makes the Gulf (and the Estuary) one of the best whale-watching sites in the World. In addition, the head of the Laurentian Channel in the Estuary is the refuge of an endangered Beluga whale population. Despite conservation efforts (control on contaminants, noise, and a protected areas project), the Beluga whale population shows no sign of increase; at present it is, at best, stable.

The total number of fish and invertebrates species is approximate, due in part to the poor sampling of the shallow or coastal zones. The current inventory lists some 2200 marine invertebrate species (Brunel et al., 1998). An analysis of scientific bottom trawl survey records indicates that ~130 species of fish may be present in the northern Gulf alone (Dutil et al., 2006, 2009). The total fish biomass is dominated by a small number of large species, most of commercial interest; hence many species are relatively rare or occasional visitors. Nonetheless, the importance of the habitat is shown by at least 48 species of ichthyoplankton (eggs and larval fish) recorded in the Gulf. As for the Canadian shelf regions, dramatic shifts to both the northern and southern Gulf ecosystems occurred in the late 1980s, particularly in response to fishing and, to a lesser extent, to changes in environmental conditions. These shifts include changes in species abundance and/or biomass and food web structure and functioning (Savenkoff et al., 2008) (Figure 36A.3). The ecosystems that were dominated by large demersal fish predators (e.g., Atlantic cod, redfish and white hake) are today dominated by small-bodied forage species and invertebrates. The biomass of shrimps (close to 20 species) has increased since the early 1980s and at an accelerated rate beginning in the early 1990s. Despite a 15-year moratorium on harvesting, the ecosystem structure has not returned to its previous state. In the southern Gulf, the natural mortality of cod remained high, causing a decline in their abundance. Evidence is mounting that predation by top predators (e.g., seals, whose abundance has been increasing) is the cause of this mortality (Benoît et al., 2012).

Fishing can affect population structure, entire communities, and the habitat itself. The only important bottom trawl use remaining in the northern Gulf is by the northern shrimp fishery. The fishery is well regulated and the use of a separator grate is mandatory to reduce the catch of large fishes. Nonetheless, an analysis in 2012 showed small specimens from 69 taxa (the majority in low numbers) as remaining in the catch (Savard, 2013).

7.6 *Chesapeake and other coastal estuaries and bays of the United States*

The Chesapeake Bay estuarine system⁷ supports more than 3,000 species of plants and animals (Table 36A.7). A subset of species has been identified as being *ecologically valuable*⁸ (Table 36A.8), based on their importance in (1) regulating the flow of carbon through the food web, (2) providing habitat, and/or (3) supporting ecosystem services (Baird and Ulanowicz, 1989; Costanza et al., 1997; Jordán, 2001; Martínez et al., 2007; Koch et al., 2009). Marshall et al. (2005) documented 1454 phytoplankton species in the Bay during 1984-2004; diatoms were the most abundant taxon (Table 36A.6). The ratio of planktonic centric diatom species to benthic pennate diatom species increased from ~ 1 prior to European settlement to ~ 5 today (Cooper and Brush, 1991), a trend that coincided with a decrease in species richness and an increase in phytoplankton biomass due to increases in anthropogenic nutrient loading and a rapid decline in the abundance of filter feeders (oysters) during the twentieth century (Newell, 1988; Cooper and Brush, 1991; Marshall et al., 2003; Kemp et al., 2005). Projected increases in water temperature and winter-spring precipitation associated with climate change are likely to enhance these trends and promote the growth of toxic dinoflagellates (Pyke et al., 2008).

Species richness is correlated with fisheries productivity (Worm et al., 2006). Historically important fisheries in the Bay included striped bass (*Morone saxatilis*), Atlantic sturgeon (*Acipenser oxyrinchus*), American shad (*Alosa sapidissima*), Atlantic menhaden (*Brevoortia tyrannus*), blueback herring (*Alosa aestivalis*), alewife (*Alosa pseudoharengus*), soft-shelled clam (*Mya arenaria*), eastern oyster (*Crassostrea virginica*), and blue crab (*Callinectes sapidus*). Of these, landings of sturgeon,⁹ shad,¹⁰ soft-shelled clams¹¹ and eastern oysters (Rothschild et al., 1984; Wilberg et al., 2011) experienced dramatic declines (> 98 per cent) during the twentieth century due to overfishing and habitat loss. Herring¹² and menhaden¹³ landings have declined by ~80 per cent.

Habitat loss has been expressed primarily in terms of increases in the spatial extent of summer hypoxia and decreases in the spatial extent of tidal marshes, submerged vascular plant beds, and oyster reefs. Oyster reefs, submerged vascular plant beds and

⁷ Chesapeake Bay (including tidal waters of its tributaries) is the largest estuary in the U.S. (~ 320 km long, 11,700 km²). It is a partially stratified, coastal plain estuary (drowned river valley) with a mean depth of 8.4 m and three salinity zones: oligohaline, 0 – 10 psu; mesohaline, 11 – 18 psu; and polyhaline, 19 – 36 psu (Schubel and Pritchard, 1987). Eleven major rivers flow into the Bay through six states and a drainage basin of 172,000 km². River flows are typically highest during spring and lowest during summer. The climate is moderate with mean water temperatures ranging from a winter low of ~ 5°C to a summer high of ~25°C. With a large ratio of watershed to estuarine area (14:1), the Bay is closely connected to the landscape. With a relatively long residence time of water (~ 6 months), the Bay is susceptible to impacts from land-based inputs of nutrients and toxic contaminants (Kemp et al., 2005).

¹³ <http://www.asmfc.org/species/atlantic-menhaden>

tidal marshes support high species diversity (Heck and Orth, 1980; Orth et al., 1985; Newell, 1988; Chambers et al., 1999; Coen et al., 1999; Jackson et al., 2001; Wyda et al., 2002; USACE, 2009; Philine et al., 2012). During the course of the twentieth century, the spatial extent of these habitats declined significantly: oyster reefs by 92 per cent (USACE, 2009; Wilberg et al., 2011), submerged vascular plants by 65 per cent (Kemp et al., 1983, 2005; Orth and Moore, 1983, 1984) and marshes by 60 per cent.¹⁴

Sea level rise is expected to result in even greater losses of marshes, putting hundreds of species of fish, invertebrates and birds at risk (Titus and Strange, 2008), and estuarine acidification poses a significant threat to oyster restoration efforts in the Bay (USACE, 2009; Waldbusser et al., 2011; Sanford et al., 2014). Loss of these habitats exacerbates the impacts of overfishing and is one of the main pressures on species richness, often leading to species extirpation (Orth and Moore, 1983, 1984; Ruiz et al., 1993; Duarte et al., 2008; Heck et al., 2008; Keppel et al., 2012).

Recurring deep-water hypoxia (Cooper and Brush, 1991; Malone, 1991)¹⁵ represents a major loss of pelagic and benthic habitat during a critical period for reproduction and growth of benthic macrofauna and fish, resulting in declines in their abundance (Llansó, 1992; Ruiz et al., 1993; Baird et al., 2004; Kemp et al., 2005; Buchheister et al., 2013) and the threat of extirpation of commercially valuable species that have been overfished, e.g., *Acipenser oxyrinchus* (Secor et al., 2000) and *C. virginica* (Wilberg et al., 2011). Projected increases in climate-driven water temperature and winter-spring precipitation over the twenty-first century may increase the pressure of summer hypoxia on species richness (Pyke et al., 2008), an impact that may be exacerbated by the direct effects of rising water temperatures: e.g., *M. arenaria* is near its southern distribution limit and may be extirpated if summer temperatures approach and remain near 32°C, and temperate fish species such as white perch (*Morone americana*), striped bass (*Morone saxatilis*), and summer flounder (*Paralichthys dentatus*) may experience similar fates (Najjar et al., 2010).

More than 170 known or possible non-native species have invaded the Bay.¹⁶ Of these, at least eight are potentially major threats to species richness in the Chesapeake Bay estuarine system (Table 36A.7).¹⁷

Given the collective importance of vegetated habitats and oyster reefs as refugia for a broad diversity of species and the impacts of fishing, seasonal hypoxia and invasive species, it is highly likely that the species diversity of the Chesapeake Bay estuarine system significantly declined during the 20th C. Continued declines in habitat extent, combined with the impacts of seasonal hypoxia and climate-driven sea level rise, estuarine warming, and acidification, portend increases in the rate of extirpations and declines in species diversity during the twenty-first century. Given similarities in

pressures, all of the estuaries of the Virginian Province¹⁸ (Hale et al., 2002) are likely to exhibit similar trends in their capacity to support species diversity.

7.7 Caribbean Sea

The Caribbean is the most biologically diverse area of the Atlantic Ocean, hosting approximately 10 per cent of the world's coral reefs, including the Mesoamerican Barrier Reef System; extensive coastal mangroves and shallow banks with seagrass communities; as well as sandy beaches, rocky shores and many bays, lagoons and brackish estuaries. The Caribbean also has open-ocean and lesser-known deep-sea environments, and has been listed as a global-scale hotspot of marine biodiversity (Roberts et al., 2002).

The Caribbean Sea receives primarily oligotrophic, high-salinity North Atlantic water from the North Equatorial Current, but it also receives South Atlantic water entrained in North Brazil Current rings which transport water from the Amazon into the Caribbean basin via the Guiana Current (Cowen et al., 2003). The persistent through-flow of the warm Caribbean Current is modulated by a highly complex and variable pattern of mesoscale eddies (Lin et al., 2012) and upwelling along the South American coastline. Two significant South American rivers, the Orinoco and the Magdalena, also discharge directly into the southern Caribbean. The considerable spatial heterogeneity of physical environments and habitats across the Caribbean Sea influences the distribution, population connectivity and biodiversity of marine organisms found there. Several significant barriers to gene flow in Caribbean reef populations have been recognized (Cowen et al., 2006). This has led to relatively high levels of endemism. Miloslavich et al. (2010) estimate a value of 25.6 per cent regional endemism across 21 of 78 marine taxa examined in the Caribbean, with values ranging from 45 per cent for fish, 26 per cent for molluscs and 2 per cent for copepods. They also summarize the diversity, distribution and key threats to marine biota in the Caribbean and conclude that the 12,046 species currently reported is a gross underestimation, considering that the marine biota is far from well known in this area.

The significant drivers of declines in Caribbean marine biodiversity are overexploitation and environmental degradation. These are being exacerbated by external drivers, including climate variability and change, and alien species invasions. Iconic Caribbean mega-vertebrates have suffered from historical overexploitation (Jackson, 1997), including the now extinct West Indian monk seal (*Monachus tropicalis*); the endangered Caribbean manatee (*Trichechus manatus manatus*); the North Atlantic humpback whale (*Megaptera novaeangliae*); and marine turtles, of which five species are found here, all endangered. The number of fishery stocks that are fully exploited or overexploited has grown over the last few decades and total landings have declined significantly since the late 1980s, driven by increasing market demand, inadequate fisheries management, and

¹⁸ Chesapeake Bay, Delaware Bay, Hudson-Raritan system, and Long Island Sound
© 2016 United Nations

exacerbated by habitat degradation (Salas et al., 2011; Sea Around Us Project, www.seaaroundus.org).

The abundance of reef fishes has decreased region-wide (Paddack et al., 2009). Most fishable reef species are fully exploited or overexploited; those most vulnerable to fishing are now rare (Roberts, 2012). Notable is the Nassau grouper (*Epinephelus striatus*), once of great commercial importance and now endangered (Sadovy, 1999). There is concern regarding the decline of key functional groups on reefs, especially herbivores, such as parrotfishes, that are vital to reef resilience (Mumby et al., 2006). Large highly migratory pelagic species, such as the billfishes (swordfish and marlins), have suffered significant population declines from fishing by foreign fleets operating in the Atlantic.

Caribbean coral reefs are considered globally unique (UNEP, 2005). Overexploitation and deterioration of coastal water quality (primarily due to high nutrient, sediment and bacterial loads, and toxins from domestic, agricultural and industrial activities in coastal watersheds) have altered reef communities and resilience, leading to region-wide decreases in live coral cover (Gardner et al., 2003; Jackson et al., 2014) and reef structural complexity (Alvarez-Filip et al., 2009) over the last three decades. Concomitant increases in disease epidemics (Rogers, 2009) and in macro-algae (Bruno et al., 2009) have resulted in ecosystem shifts from coral-dominated to algal-dominated reefs (Hughes et al., 2007). The once dominant *Acropora palmata* was severely reduced by coral disease from the late 1970s through the 1980s, and this genus is now listed as endangered in the United States Caribbean (<http://www.nmfs.noaa.gov/pr/laws/esa/>). The 1982-1984 mass die-off of the *Diadema antillarum* sea urchins left Caribbean reefs without a keystone herbivore (Jackson et al., 2014). Pioneering coral species, such as *Porites astreoides*, are becoming more prevalent (Green et al., 2008). The degradation is exacerbated by global climate change resulting in warming causing mass coral bleaching and associated coral mortality (Eakin et al., 2010), physical destruction from more intensive storms (Gardner et al., 2005; Wilkinson and Souter, 2008) and the threat of ocean acidification. Caribbean reef biodiversity is being further affected by the alien invasive Pacific red lionfish (*Pterios volitans*), which has spread across the Caribbean in the last decade (Schofield, 2010).

Mangroves and their associated biodiversity occur throughout the insular and continental Caribbean coastlines (Bossi and Cintron, 1990). The Caribbean has nine mangrove tree species (Polidoro et al., 2010), but is reported to host the world's richest mangrove-associated invertebrate fauna (Ellison and Farnsworth, 1996). Mangrove area has declined by about 1 per cent annually over the last three decades, representing the second highest loss rate globally (FAO, 2007). *Pelliciera rhizophorae*, endemic to Central America, is now listed as vulnerable (Polidoro et al., 2010). Mangrove declines are driven by exploitation (of timber); deteriorating water quality (especially petroleum pollution); and coastal development (aquaculture ponds, marinas, reclamation for coastal construction and agriculture); and climate change (Ellison and Farnsworth, 1996; Polidoro et al., 2010).

Seagrass communities occur throughout the Caribbean and support a high diversity of epiphytic and other species (van Tussenbroek et al., 2010). Seven native seagrass species are known from the region; two (*Halophila engelmanni* and *H. baillonii*) are considered to be near-threatened and vulnerable, respectively. A recently introduced species, *Halophila stipulacea*, is spreading rapidly through the Lesser Antilles (Willette et al., 2014). CARICOMP found that most study sites showed a decline in seagrass health between 1993 and 2007 (van Tussenbroek et al., 2014).

Caribbean seabirds comprise 25 breeding species, of which seven are regionally endemic species or subspecies: the abundant laughing gull subspecies *Larus atricilla atricilla*; the rare and declining white tailed tropic bird subspecies *Phaethon lepturus catesbyii*; the near threatened Audubon's shearwater *Puffinus lherminieri lherminieri*; the endangered brown pelican subspecies *Pelicanus occidentalis occidentalis*; the critically endangered black capped petrel *Pterodroma hasitata* and black noddy subspecies *Anous minutus minutus*; and the probably extinct Jamaica petrel *Pterodroma caribbaea* (Lee and Mackin, 2012). Most of the 25 species including both surface feeders and divers are declining, threatened by human disturbance and nest predation by introduced species; pollution of ocean waters; and fishery by-catch impacts (Schreiber and Lee, 2000; Lee and Mackin, 2012).

Caribbean economies are the most tourism-dependent in the world (CLME, 2011). Declining marine biodiversity will have enormous social and economic consequences, through loss of goods and critical ecosystem services. Caribbean-wide degradation of coral reef, mangrove and seagrass ecosystems, ecosystems that are fundamental to the Caribbean tourism product and at the core of the region's ability to cope with climate change sea level rise, will mean annual losses amounting to billions of United States dollars (CARSEA, 2007; Burke et al., 2011).

7.8 Gulf of Mexico

The Gulf of Mexico is a semi-enclosed sea and one of the most economically and ecologically productive bodies of water in the world (Tunnell, 2009). The Gulf is connected to the Caribbean Sea through the Yucatan Channel between the Yucatan Peninsula and Cuba, where warm, tropical water flows into the Gulf and forms the Loop Current, the dominant Gulf current, and then exits via the Florida Straits between Florida and Cuba into the Atlantic Ocean, where it forms the Gulf Stream, one of the world's strongest and most important currents.

As a large receiving basin, the Gulf of Mexico receives extensive drainage from five countries (the United States, Canada, Mexico, Guatemala, and Cuba). The Mississippi River dominates this drainage, which includes over two-thirds of the U.S. watershed in the north, and the Grijava-Usumacinta River System dominates in the south. Thirty-three major rivers and 207 estuaries and lagoons are found along the Gulf coastline (Darnell and Defenbaugh, 1990; Tunnell, 2009).

Biologically, the shallow waters of the northern Gulf are warm-temperate (Carolinian Province) and those in the southern Gulf are tropical (Caribbean Province) (Briggs, 1974). Oyster reefs and salt marshes are the dominant estuarine habitat type in northern, low-salinity estuaries, and seagrass beds are common in clearer, more saline bays. In the tropical southern Gulf, mangroves line bay and lagoon shorelines; some oyster reefs, salt marshes, and seagrasses are distributed in similar salinity conditions as in the northern Gulf. Offshore, coral reefs are common in the Florida Keys, Cuba, and the southern Gulf off the state of Veracruz and on the Campeche Bank (Tunnell et al., 2007; other topographic highs or hard bottoms are sporadic on the normally smooth, soft substratum of the continental shelves (Rezak and Edwards, 1972; Rezak et al., 1985). Unique, recently discovered, and highly diverse habitats in deeper Gulf waters include chemosynthetic communities and deepwater coral communities (*Lophelia* reefs) (CSA International Inc., 2007; Brooks et al., 2008; Cordes et al., 2008).

Regarding the biodiversity of the Gulf of Mexico, the Harte Research Institute for Gulf of Mexico Studies at Texas A&M University-Corpus Christi recently led a multi-year, multi-international effort (Biodiversity of the Gulf of Mexico Project) involving 140 taxonomists from 80 institutions in 15 countries to prepare a comprehensive list of all species (Felder and Camp, 2009). This list of 15,419 species with range, distribution, depth, habitat-biology, and updated taxonomy was subsequently added to GulfBase in 2011 at <http://www.gulfbase.org/biogomx/biosearch.php>, where it is openly accessible and completely searchable by any topic or species. The database has since been used in two major papers comparing biodiversity of other United States regions (Fautin et al., 2010) and four other global case studies in marine biodiversity (Ellis et al., 2011).

Several Gulf of Mexico iconic or well-known species are of historical, social, and economic importance (Davis et al., 2000). The West Indian monk seal (*Monachus tropicalis*) was probably the first large animal to become extinct because of human activity in the Gulf and Caribbean region. It was last seen on the Campeche Bank islands in the Gulf in 1948 and in the Caribbean in the early 1950s (Wursig et al., 2000). Other species that have become endangered include the Kemp's Ridley sea turtle (*Lepidochelys kempii*), brown pelican (*Pelecanus occidentalis*), and whooping crane (*Grus americana*). Restoration programs for each of these have increased their populations in recent decades. West Indian manatees (*Trichechus manatus*) are greatly reduced, and they only exist now in certain drainage areas along the west coast of Florida. The largest commercial fishery by weight in the Gulf is for menhaden (*Brevoortia patronus*), and the penaeid shrimp fishery is the largest by value (the white shrimp *Litopenaeus setiferus*, the pink shrimp *Farfantepenaeus duorarum*, and the brown shrimp *Farfantepenaeus aztecus*).

Predominant commercial estuarine shellfish in the northern Gulf include the eastern oyster (*Crassostres virginica*) and blue crab (*Callinectes sapidus*) (Nelson, 1992; Patillo et al., 1997). In the tropical southern Gulf, spiny lobster (*Panulirus argus*) and queen conch (*Eustrombus gigas*) are taken. However, these are now commercially extinct in many

areas and are taken only by recreational fishers, sometimes under strict regulations (Tunnell et al., 2007).

The Gulf-wide bottlenose dolphin (*Tursiops truncatus*) is probably the single most recognizable Gulf species by the public, as it is abundant in coastal bays and estuaries, as well as offshore in the northern Gulf (Wursig et al., 2000).

Gulf-wide biodiversity patterns cannot be completely explained, for lack of complete information, although we do know that the Gulf of Mexico exhibits great habitat complexity that probably supports high levels of biodiversity due to both endemic and cosmopolitan species (Rabalais et al., 1999). Linkage to the Caribbean Sea with large-scale circulation provides the southern and eastern Gulf with a distinct Caribbean biota. However, strong regional endemism appears to exist, as demonstrated in large-scale studies across the entire northern Gulf (Rabalais et al., 1999; Harper, 1991; Carney et al., 1993). Eventual analysis of databases from the Biodiversity of the Gulf of Mexico Project on GulfBase will provide considerable insight into the spatial distribution of species. Of the 15,419 species found, 1,511 (10 per cent) are endemic to the Gulf of Mexico and 341 (2 per cent) are non-indigenous (Felder and Camp, 2009). The most diverse taxa include crustaceans (2,579 species), mollusks (2,455), and vertebrates (1,975), and the least diverse include kinorhynchs (2 species), entoprocts (2), priapulids (1), hemichordates (5), and cephalochordates (5). In addition, other taxa are known to exist in the Gulf of Mexico (placozoans, orthonectids, loriciferans, and pogonophorans), but representatives have not yet been identified (Felder and Camp, 2009; Fautin et al., 2010).

A recent ecosystem status report for the Gulf of Mexico, utilizing the DPSER (Drivers, Pressures, States, Ecosystem Services, Responses) conceptual modelling framework, gives a high-level overview of the state of the Gulf (Karnauskas et al., 2013). Major, large-scale climatic drivers include the Atlantic Multidecadal Oscillation, Atlantic Warm Pool, sea surface temperature, Loop Current, and geostrophic transport in the Yucatan Channel and Florida Current. Long-term trends or changes in these drivers in turn cause fluctuations or changes in selected pressures, such as hurricanes or hypoxic zones. Other pressures include contamination by pollution (e.g., mercury, cadmium), oil and gas exploration and production (including major oil spills, such as Ixtoc I in 1979 and Deepwater Horizon in 2010), bacterial water quality problems, and habitat destruction, mainly caused by coastal development. Harmful algal blooms (HABs), such as red tide and brown tide, are well documented in the Gulf, as are some invasive species (Tunnell, 2009; Fautin et al., 2010; Karnauskas et al., 2013).

The recent Deepwater Horizon oil spill prompted a study of the ecosystem services of the Gulf of Mexico by a leadership committee of the United States National Research Council (NRC). This comprehensive report utilizes the ecosystem services approach and frames for the first time the goods and services provided by the Gulf for an economically and ecologically healthy ecosystem (NRC, 2013).

8. Factors of Sustainability

The biodiversity of the North Atlantic has supported harvesting and trade by bordering cultures for millennia. Pressures from human uses both diversified and intensified with industrialization and associated coastal development already more than two centuries ago. Every form of direct use of North Atlantic biodiversity and every indirect effect of human activities on coastal populations and habitats have been unsustainable in at least some times and places. Some of these impacts, such as the depletion of populations of the great whales by overharvesting (section 36A.6) will take centuries to recover, even with effective policies and high compliance.

Efforts towards sustainability have been greatly aided by coordinated international efforts to provide scientific and technical information on the status and trends in biodiversity, and threats to sustainable uses. The Quality Status reports (QSRs) from the OSPAR Commission at the start of each of the past three decades have proven invaluable in assessing status and trends in many marine environmental indicators and the biodiversity they represent, and guiding policies and management measures to address poor or declining marine environmental quality in the northeast Atlantic (OSPAR, 2010, and earlier QSRs). Other examples of such efforts are the coordinated processes carried out within the framework of the Convention on Biological Diversity for identifying Ecologically and Biologically Significant Areas in the Northwest Atlantic (CBD, 2014a), and Mediterranean (CBD, 2014b), and the on-going process in the Northeast Atlantic (ICES, 2013a), and the processes to identify Vulnerable Marine Ecosystems in the NAFO (NAFO, 2013) and North-East Atlantic Fisheries Commission (NEAFC) (FAO, 2015).

Although there are well-documented examples in the sections above of cases where habitats, lower-trophic-level productivity, benthic communities, fish communities, or seabirds or marine mammal populations were severely altered by pressures from a specific activity, such as over-fishing, pollution, nutrient loading, physical disturbance, or transplanted species, many biodiversity impacts, particularly at larger scales, are the result of cumulative and interactive effects of multiple pressures from multiple drivers. It has repeatedly proven difficult to disentangle the effects of the individual pressures, impeding the ability to address the individual causes (Fu et al., 2012; Blanchard et al., 2005; ter Hofstede and Rijnsdorp, 2011). Particularly given that the North Atlantic is surrounded by many of the best marine research centres in the world, has many of the longest and most systematic data sets, and has an international science organization, the International Council for Exploration of the Seas (ICES), that has functioned for over a century to promote and coordinate scientific and technical cooperation among many of the circum-North Atlantic countries with the highest science capacities, this inability to consistently disentangle causation of unsustainable uses of, and impacts on, marine biodiversity may seem initially discouraging.

On the other hand, well-documented examples also exist of the benefits that can follow from actions to address past unsustainable practices. Many of the fish stocks depleted

by overfishing in both the Northeast and Northwest Atlantic have shown increasing trends in abundance and recovery of range when unsustainable levels of fishing effort have been reduced (Table 36A.4). Efforts to control pollution and nutrient inputs, driven by the EU Water Framework Directive and the United States Environmental Protection Act, have led to reduction in these pressures and in many cases to the commencement of the recovery of benthic communities (EEA, 2012). Coastal habitat restoration activities have also shown clear benefits in improved environmental quality and biodiversity measures in many coastal areas around the North Atlantic (Pendleton, 2010). All of these improvements have come with at least short-term costs, which are sometimes large, such as displaced or reduced fishing opportunity (see Part IV), the costs of pollution control and nutrient management in coastal areas and watersheds (costs summarized in the chapters of Part V), and the direct costs of habitat restoration, which may run to the millions of dollars for restoration projects of even moderate scale (Diefenderfer et al., 2011; Kroeger and Guennel, 2014).

In summary, the North Atlantic presents examples of both the extent to which unsustainable actions can adversely affect biodiversity and the benefits that can accrue from policies and programmes that are well developed, adequately resourced, and effectively implemented. The best examples of effective policies and programmes have been designed to address the dominant pressures from the twentieth century: overharvesting of living marine resources and pollution and excessive nutrient inputs from coastal and land-based sources. In the twenty-first century, additional pressures are growing, particularly climate change, invasive species (both responding to changing environmental conditions and transported by shipping), and in many areas, particularly at lower latitudes, ocean-based tourism. Lessons learned from dealing successfully with the earlier pressures, if applied proactively, may help safeguard biodiversity from unsustainable impacts, and result in healthy ecosystems producing many ecosystem services of value to the circum-Atlantic human populations.

Table 4. Tabulation of conclusions of assessment authorities on stock status. Each authority has its own standards for benchmarking status. Where quantitative reference points are not estimated, a stock was counted as “healthy or cautious” if abundance was reported as average or high, or as increasing if below average. Stocks reported as depleted or low and declining were counted as negative status. F = status relative to fishing mortality reference points; B = status relative to biomass reference points (,)

Authority	US-NMFS	Canada-DFO	NAFO	ICES
Positive or Cautious Status	195 (B) 290 (F)	72 Healthy 31 Cautious	5	60
Negative Status	38 overfished 27 overfishing	17	5	42
Unknown	247	35	4	75

Table 5. Tabulation of a number of primary publications documenting status and trends in fish community metrics for areas in the North Atlantic.

A large number of community metrics were used, and have been grouped into several categories: “size” includes metrics of body size; “diversity” includes any of the typical indices of species diversity; “richness” and “evenness” include numbers of species recorded and how numbers were distributed among species; “dominance” includes measures of how much the abundance of the few most common species in a community comprised of all the individuals in the community; “N” includes measures of total abundance of individuals in a community, “B” includes measures of community biomass; “slope” and “intercept” are parameters of community size spectra; “species composition” are diverse ways of reporting how the representation of particular species in the community changed. For reporting trends in the metric, “+” means an overall upward trend, “-” means an overall downward trend and “nt” means no overall trend, although there could be substantial interannual variation in the metric.

Location	Indicators and trends	Interval	Comments	Reference
Georges Bank	Size +, diversity+, Biomass/area+	1960s - 2009	Decline in F and effort	Collie et al. 2013

Chapter 36B. South Atlantic Ocean

Contributors: Alexander Turra, Angel Perez, Flavia Lucena-Frédou, Monica Muelbert, Andrea Raya Rey, Laura Schejter, Javier Calcagno, Enrique Marschoff and Beatrice Ferreira (Lead members)

1. Introduction

In this chapter we refer to the area of the Atlantic Ocean south of the Equator and north of the Polar Front (Antarctic Convergence). The main topographical feature in the South Atlantic is the Mid-Atlantic Ridge which runs between Africa and South America from approximately 58° South to Iceland in the north. A rift valley is associated with the Ridge. The Ridge is of volcanic origin and the development of transverse ridges creates a number of basins: the Argentine, Brazil, Guinea, Angola and Cape Basins.

The Atlantic coast of South America is influenced by three major rivers, Orinoco, Amazon and La Plata, that discharge large amounts of freshwater and sediment into the Atlantic Ocean. The Amazon discharges about one-fifth of the world's total freshwater runoff into the Atlantic (Curtin, 1986) and it is transported offshore up to 500 km seaward (Lentz, 1995). The heavy sediment discharge ($2.9 \cdot 10^8$ tons year⁻¹) is not deposited over the outer shelf, but is carried by the North Brazil Current to Guyana's shelf, where it forms extensive mud deposits (Gratiot et al., 2008). The continental shelf is wider along its West Coast, both in the north at the Amazon (≈ 300 km) and in southern Argentina, where it reaches up to 600 kilometres (Miloslavich et al., 2011). The shelf is narrower along the East Coast of the Atlantic and also along the east coast of Brazil, where riverine muds give way to calcareous deposits and the shelf in some areas reaches a minimum of 8 km width (Miloslavich et al., 2011).

The continental slope is cut by deep canyons connecting shelf and deep waters. High benthic richness was reported at the head of the submarine canyons, and about half of the species are shared with the shelf-break community (Bertolino et al., 2007; Schejter et al., 2014b). The ~ 7500 km of the Brazil coasts comprise a combination of freshwater, estuarine and marine ecosystems, with diverse but poorly known habitats in its northern part and with sandy beaches, mangrove forests, rocky shores, lagoons and coral reefs to the south (Miloslavich et al., 2011). Uruguay's coasts are dominated by sandy beaches; a narrow rocky portion has high biodiversity (Calliari et al., 2003). The coasts of Argentina are mostly sandy beaches, with some rocky formations located mainly at Mar del Plata, Peninsula Valdes and Tierra del Fuego; pebble beaches are common in Patagonia. The coasts of South Africa are part sandy beaches, rocks and rocks mixed with sand on the upper shore and a wave-cut rocky platform (Bally et al., 1984).

South Atlantic waters are characterized by the counterclockwise central subtropical gyre of surface and intermediate waters running close to South America and South Africa, with more complex currents developing on the coasts of both continents (Campos et al., 1995; McDonagh and King, 2005). The gyre is approximately 4,500 km in diameter and lies between the equator and 40° S (Piontkovski et al., 2003). The eastern (African) branch transfers warm water to the northern hemisphere and the western (South American) branch carries cold water from the north, both as part of the global circulation known as the Atlantic Meridional Overturning Circulation. The gyre is closed to the south by the subantarctic branch of the Antarctic Circumpolar Current (West Wind Drift). The gyre constitutes a biogeographic province with distinct physical and biological properties relative to adjacent regions (Longhurst, 1998).

The currents, closely linked to the topography, result in a series of surface fronts with varying depth expressions associated with the different ridges which effectively limit exchange of water among the different basins. The Benguela Current runs northward off the African continent carrying cold water towards the equator, with a coastal branch close to the continent (Griffiths et al., 2010). Its counterpart near South America is the Brazil current, which meets the northward current derived from the Antarctic Circumpolar Current (West Wind Drift) running close to the Patagonian shelf (see chapter 36H, Figures 1 to 3).

The offshore waters in the South Atlantic Gyre occupy more than half of the South Atlantic Ocean; the Gyre is characterized by low concentrations of nutrients, and low phytoplankton and zooplankton abundances. Along the South American continental shelf, circulation patterns are modified by topography, upwelling and continental runoff (Gonzalez-Silvera et al., 2004). The South Subtropical Convergence is the intersection point of low-macronutrient subtropical gyre waters and high-macronutrient Antarctic Circumpolar Current waters and therefore represents one of the most dynamic nutrient environments in the oceans (Ito et al., 2005).

On the African shelf, as in the South American coasts, the Agulhas retroversion, and the Benguela and the Angola Currents are responsible for upwelling processes and enhanced primary production (Lutjeharms and Ballegooyen, 1988). The different water masses resulting from these processes offer an ample variety of habitats for pelagic biodiversity. The Congo and, on the western side, the Amazon and the Plata plumes can also seasonally contribute to the enhancement of plankton, thus becoming one of the most productive marine areas of the Atlantic Ocean, which is essentially due to the presence of a great variety of frontal productive systems (Acha et al., 2004; da Cunha and Buitenhuis, 2013).

On the western coasts and shelves, the plumes of the Amazon and of the De la Plata Rivers extend up to 1000 km into the ocean, modifying coastal waters. The De la Plata River plume impinges on coastal and shelf waters of Argentina, Uruguay and Brazil (Muelbert et al., 2008). Lateral mixing results in a water mass typical of the De la Plata plume waters (Piola et al., 2008) with high nutrient concentrations and primary

productivity. The Amazon plume influence is felt on the northwest coast of Brazil and modifies the vertical structure of the Equatorial West Ocean (Hu et al., 2004).

Modelling and observed trends predict that the low-productivity subtropical gyre will expand as a result of climate warming. Such an increase will affect not only the plankton communities, but also fisheries on both sides of the South Atlantic Ocean. Since 1998, the gyre has been expanding at average rates between 0.8 per cent/yr and 4.3 per cent/yr. The rate of expansion is greater during the winter (Polovina et al., 2008; Henson et al., 2010).

2. Plankton and Nekton

Water-mass properties and movements are the main factors behind plankton distribution in the South Atlantic. The quantitative distribution of pelagic life in the South Atlantic parallels those found in the other oceans: a large area of poor central waters bound to the north and south by richer equatorial and subpolar bands, respectively, with the biologically richest sectors found in the coastal regions, especially along Africa (Boltovskoy et al., 1999). These conditions are exacerbated at the inshore component of the Benguela Current, which exhibits strong a wind-driven upwelling with a periodicity of 5 to 10 days; more intense in summer (Shannon and Nelson, 1996). Much of the organic matter associated with this high productivity sinks onto the relatively wide continental shelf, where decay results in the reduction of dissolved oxygen in bottom waters. Periodically, these low-oxygen conditions extend close inshore, sometimes reaching the shoreline itself and resulting in mass mortalities of fish, rock lobster, and other invertebrates (Griffiths et al., 2010).

In general, knowledge of the plankton taxonomy and ecology is relatively scarce in the South Atlantic, in particular the oligotrophic waters of the South Atlantic gyre are very little known; little sampling has been conducted there (Piontkovski et al., 2003). Table 1 presents a summary of the relevant parameters for different regions of the South Atlantic Ocean.

Table 1. Major structural-functional characteristics of the South Atlantic (0–100 m layer). Data presentation adapted from Greze (1984) and Boltovskoy et al. (1999) in Piontkovski et al., 2003.

Parameters	Benguela Current	South Equatorial Current	Brazil Current	West Wind Drift	Central Gyre
Extension of current (km)	4000	4000	4800	6400	
Current velocity (cm s ⁻¹)	50–150	40–70	150	50–65	
Primary production (mgC m ⁻² d ⁻¹)					
(1) Koblentz-Mishke (1977)	250–>500	150–250	<100–150	100–250	<100
(2) Greze (1984)	1000–5000	175–480	117–547	285–515	95–201
(3) Longhurst et al. (1995)	880	360–430	830	330–370	210

Chl a (surface) (mg m ⁻³)	3.0 ± 1.5	0.15 ± 0.05	0.30 ± 0.10	0.22 ± 0.10	0.09 ± 0.04
C:Chl a (0–100 m) (mg mg ⁻¹)	35	70	45	91	85
Phytoplankton total biomass (mgC m ⁻³)	105	15	14	18	13
>5-µm phytoplankton (mgC m ⁻³)	103	3	2.9	1.2	1
Species of >5-µm phytoplankton	110	264	155	70	233
Phytoplankton diversity (a)	13	49	46	27	56
Zooplankton biomass (mgC m ⁻³)	3.5	3.4	1.6	1.1	1.3
Copepod species (number)	176	215	280	161	300
Copepod diversity H' (bit ind ⁻¹)	3.1	3.9	4.4	2.5	4.5

Primary production values in the central gyre range around >0.1-0.2 g C m⁻² d⁻¹, with phytoplankton concentrations below 103 cells l⁻¹. In the vicinity of the equator, biological richness is enhanced by equatorial divergence and by seaward advection of nutrient- and biomass-rich Benguela upwelling waters (Boltovskoy et al., 1999). A 30-fold difference in mean surface chlorophyll and a 100-fold difference in phytoplankton biomass were found between the centre of the gyre and the Benguela Current waters (Piontkovski et al. 2003). The high productivity region extends to the north along the African coast. In the Southwestern Atlantic, primary production and chlorophyll-a measurements show a number of areas of enhanced phytoplankton output. Diatoms play an important role in this biomass build-up (Olguin et al. 2006).

Diversity increases in oligotrophic waters; the abundance in the Antarctic Circumpolar Current decreases from West to East, whereas the diversity index increases. In the Benguela Current, the number of species is similar to that in the Antarctic Circumpolar Current, but the diversity index is lower; the taxonomic composition of the South Equatorial Current and the central gyre are similar (Greze, 1984). South of the Subtropical Convergence, the primary limiting nutrient is Fe, whereas to the north the phytoplankton standing crop seems to be limited by macronutrients (Browning et al., 2014).

In general, the taxonomic study of plankton species in the South Atlantic is poor to average, approximately 2500 zooplankton species have been identified in the South Atlantic and it is expected to find 300 more (Boltovskoy et al., 2003). Copepods, in terms of numbers and biomass, are the main component of zooplankton; within this group the largest proportion is made up of the smaller copepods (less than 0.3 mm). Euphausiids and amphipods are important components, especially in neritic zones (Thompson et al., 2013).

Squid are important components of the South Atlantic marine ecosystem, for ecological and socioeconomic reasons. They show high predation rates and contribute substantially to the flux of energy and nutrients to higher trophic levels (Rosas-Luis et al., 2013). The Argentine shortfin squid (*Illex argentinus*) is a common species on the western shelf; mainly feeding on amphipods and euphausiids (Ivanovic, 2010), it sustains an important fishery by trawlers and jigging vessels, and *Doryteuthis gahi* is also

targeted by the commercial fishery with substantial annual catches (Arkhipkin et al. 2013). On the African coast, the chokka squid (*Loligo vulgaris reynaudii*) is closely linked to the Agulhas ecosystem; its catches and biomass are highly variable (Roberts, 2005) and, in the south Brazil ecosystem, *Loligo plei* is an important link between pelagic and demersal energy pathways (Gasalla et al. 2010), supporting small-scale fisheries around São Sebastião Island (Postuma and Gasalla, 2010). Other squid species, such as *D. gahi*, *Onykia ingens* and *Histioteuthis atlantica*, are important components of the ecosystem on the outer Patagonian shelf.

3. Benthos

In general, the development of the benthic communities is mainly linked to the availability of food (primary producers and nutrients), closely related with the development of the seasonal and permanent frontal systems, as well as upwelling processes. Benthic habitats are variable in the South Atlantic, with unique and highly diverse ecosystems (Miloslavich et al., 2011), such as kelp forests (Rozzi et al., 2012) and huge rhodolith beds (Amado-Filho et al., 2012). The services derived from benthic habitats (e.g., Copertino, 2011) support several human activities, such as fisheries (Salas et al., 2011) and tourism. Distribution patterns of the different taxa, benthic communities and assemblages mainly obey oceanographic conditions; the majority of them are distributed according to biogeographical regions (Kröncke et al., 2013), although patterns are not always clear because of the fragmented and unequal sampling effort along the total extent of the South Atlantic.

To date, benthos studies have been based on basic sampling methodologies, were usually limited to descriptive results, and population and ecological features were mostly studied in communities dominated by commercial species (mussels, scallops, oysters). There is still a lack of knowledge in coastal and mid-shelf waters, whereas benthic communities beyond the shelf-break are only poorly known.

The available information on the fauna inhabiting the deep basins is scarce: ophiuroids and surface deposit feeders are dominant in the Cape Basin, sponges, sipunculids and fish in the Angola Basin, asteroids, crustaceans and fish in the Eastern Guinea Basin, and sipunculids in the Western Guinea Basin. The content of chlorophyll in sediments is consistent with primary production and flux rate of organic matter in the three basins of the south-east Atlantic. The structure and function of the three basin communities correlate with the amount of seafood reaching the seafloor (Wei et al., 2010).

Along the South American coast, many research programmes have been developed that focus on individual, but mainly coastal, communities and species. Several adopted an integrated approach to the study of benthos in deep waters, such as the REVIZEE Programme (Programme for the Evaluation of the Sustainability Potential of Living Resources in the Exclusive Economic Zone), which so far is the most concerted effort to increase knowledge (see Lana et al., 1996, for a baseline of the REVIZEE) on the benthic

diversity on the continental shelf and slope, recording more than 1000 taxa in 322 samples. More recently, the Pampa Azul initiative focused on the interdisciplinary study of the marine environment in the South Atlantic (www.mincyt.gob.ar/accion/pampa-azul-9926). As part of the environmental requirements of the licensing policies, the offshore oil industry produced an important amount of data on benthos that are not yet available for scientific research purposes.

In coastal areas the benthos is better known; several research groups work along the South Atlantic, although with distinct hotspots of effort. Most of the information regarding benthic biodiversity, richness and distribution patterns must be obtained from publications devoted to a single taxonomic group or from local ecological studies.

Although there are areas with no information on benthic habitats and diversity, there are places where studies are concentrated. One example is the Aracá Bay, Southeastern Brazil, where 733 benthic species were historically recorded (Amaral et al., 2010) and where, in a recent and continued study, more than 1,000 species have already been recorded in this area. In the SW Atlantic Ocean, 134 echinoderm species have been identified from the five classes (Brogger et al., 2013; Souto et al., 2014), about 360 benthic molluscs (bivalves+gastropods) (Zelaya, 2014 and pers. comm.), of which 27 are of present or potential commercial interest (Roux et al., 2010), 102 crustacean decapod species, with five of commercial interest (Boschi, 2010), at least 212 amphipod species (López Gappa et al., 2006), at least 218 sponge species (López Gappa and Landoni, 2005; Schejter et al., 2006; Bertolino et al., 2007; Goodwin et al., 2011), 246 bryozoan species (López Gappa, 2000), 88 hydrozoan species (Souto et al., 2010) and at least other 27 cnidarian species, including corals (Zamponi, 2008), at least 70 polychaete species (Bremec et al., 2010) and 79 ascidians, including the records of exotic species (Tatián et al., 2013). Many other minor groups (e.g., brachyopods, nemertina, sipunculida, echiurida, other molluscs, etc.) contribute to the total richness of the benthic realm.

Studies on the deep benthic macro- and mega-fauna in the South Atlantic have concentrated on the South American and African continental margins; the deep central areas have remained one of the least studied areas of the world ocean (Perez et al., 2012). Much of the diversity data in the southern Mid-Atlantic Ridge, for example, still derive from large-scale expeditions conducted in the late nineteenth century, such as the *HMS Challenger* expedition, which recorded over 80 species of echinoderms, polychaetes and bryozoans (Murray, 1895), and surveys conducted by the former USSR in the second half of the twentieth century, which focused mostly on seamounts and trenches (e.g., Malyutina, 2004). Fishing surveys conducted on seamounts of the Walvis Ridge provided further descriptions of crustacean (McPherson, 1984) and scleractinian coral faunas (Zibrowius and Gili, 1990), including several new species and the extension of geographic distribution ranges of species from the North Atlantic and Southern Oceans.

More recently, efforts to increase knowledge on deep benthic fauna in the South Atlantic have derived from global initiatives such as the Census of Marine Life (e.g., German et al., 2011; Perez et al., 2012) on the Mid-Atlantic Ridge and Walvis Ridge.

Vent sites 3° – 7° south of the Equator were found to contain the mussel *Bathymodiolus puteoserpentis*, the vesicomylid clam *Abyssogena southwardae*, and the alvinocarid shrimp *Rimicaris exoculata*, also common in North Atlantic vent sites. These records imply that the Equatorial Fracture Zone may not be a significant barrier to dispersal of North and South Mid-Atlantic ridge fauna (German et al., 2011). Nearly 190 benthic species records were obtained in non-chemosynthetic environments of the Mid-Atlantic Ridge and Walvis Ridge, with particularly increased diversity found on the Romanche Fracture Zone (Perez et al., 2012). Among these records new species of Hemichordates, amphipods and caridean shrimp were recently described (Cardoso and Franssen, 2012; Holland et al., 2013; Serejo, 2014). Findings such as the ones described will tend to escalate as the deep areas of the South Atlantic are more and better sampled in the future.

National efforts to increase the knowledge on marine biodiversity are taking place in recent years. The Long-Term Ecological Studies Programme (PELD, in Portuguese), funded by the Brazilian National Science Foundation (CNPq), and the SISBIOTA Programme (National Biodiversity System), funded by national and state science-funding agencies, are examples of structured initiatives to produce relevant information on benthic habitats. Several groups are producing temporal series of benthic data to enable the understanding of the impacts of local and global changes. The Brazilian Network for Monitoring Benthic Coastal Habitats (ReBentos; rebentos.org) is a strategy to aggregate and support this kind of study, linking the scientific efforts to public policies related to marine conservation, such as the National System of Marine Protected Areas, the National Plans for Adaptation to Climate Changes, and the National Action Plans for Coral Reefs and Mangroves. Several research institutions operate along the coastline. A number of regions meeting the criteria set for Ecologically or Biologically Significant Marine Areas (EBSAs) of ecological and socioeconomic importance have been identified in the South Western Atlantic (Falabella et al., 2013); they contain mussel beds, reproductive areas for mammals and birds (Península de Valdés), high primary productivity (shelf-break frontal system), oceanic biodiversity, including corals and sponges (Namuncurá – Burdwood Marine Protected Area), king crab, mussel beds and corals (Beagle and Isla de los Estados). Along the southern South American Atlantic coast, the rocky intertidal community is dominated by the bivalves *Brachidontes rodriguezii* (north to 38°S, warm temperate waters), *Perumytilus purpuratus* (= *Brachidontes purpuratus*, ca. 42-44°S, cold temperate waters) or *Mytilus chilensis* (south to 47°S, cold waters) forming dense beds (Olivier et al., 1966; Penchaszadeh, 1973; Zaixso and Pastor, 1977; Zaixso et al., 1978; Sánchez and Zaixso, 1995; Adami et al., 2004; Bazterrica et al., 2007; Hidalgo et al., 2007; Kelaher et al., 2007; Liuzzi and López Gappa 2008).

On the eastern coast, the UNEP-CBD Regional Workshop (Anon., 2013) recognized the biological and ecological importance at the regional level of the Subtropical Convergence Zone, the Walvis Ridge and the Mid-Atlantic Ridge, and at the subregional level the Guinea-Canary Currents convergence, the migratory corridor along the Guinea Current, the seamounts facing the Congo Basin, the Congo Basin and adjacent canyons'

marine area, the Guinea-Benguela Currents convergence zone, and the equatorial production zone. This latter zone stretches along both sides of the Equator to the convergence of the Guinea-Canary Currents; the area was described for its high productivity. It is also a breeding ground and migration area for tuna and related species, as well as of marine mammals. Overall 45 areas of interest were identified as requiring further research in the fields of oceanography, geomorphology, ecology and taxonomy.

The benthic communities are subject to different natural and anthropogenic disturbances, depending on the area. Overfishing, trawling, chemical contamination in harbours and coastal areas, changes in the habitats due to the introduction of alien species, oil prospective and extractive activities are the main activities influencing benthic communities. Succession and stability in rocky intertidal communities are subject to artisanal shellfish gathering, which in some areas occurs so intensely that it may cause the local disappearance of these communities.

Global analyses of environmental impacts reveal that the South Atlantic is experiencing diffuse but increasing impacts that affect mainly the coastal areas (Halpern et al., 2008). Although the Central South Atlantic is characterized as subjected to a “low impact,” most of the region (about 70 per cent) exhibits indicators of higher impacts. “High” and “Very High” affected areas are spread along the coastal zones and concentrated close to the most urbanized and/or populated centres, such as Southeastern Brazil and the Gulf of Guinea. This scenario was also evident based on the Ocean Health Index (Halpern et al., 2012), which indicates the sustainable use of marine and coastal ecosystem services, with the Southeastern Atlantic and Gulf of Guinea presenting the worst performances. Several drivers are responsible for this scenario, which is in essence a consequence of public policy implementation gaps associated with evident indices of poverty. One element that directly influences the benthic habitats is the nutrient and sewage input in coastal areas. Diaz and Rosenberg (2008) reported the occurrence of several dead zones (areas with no oxygen to support life), along the Southwestern Atlantic Coast and the Gulf of Guinea.

Additionally, climate change and global warming are also acting in the South Atlantic Ocean. However, concerted efforts to understand the effects of global environmental changes on the South Atlantic lag behind other regions worldwide, leaving society ill-prepared to cope with future changes (Turra et al., 2013). In fact, the paucity of time-series data in the southern hemisphere is especially acute in developing countries (Rosenzweig et al., 2008).

Bottom fishing has represented a variable source of threats to benthic communities in deep areas of the South Atlantic. The development of deep water fishing in slope areas off southern Brazil may have produced significant impacts on benthic organisms as reported by Perez and Wahrlich (2005) and Perez et al. (2013). Further south, off the Patagonian Shelf, benthic communities along the shelf-break front are dominated by scallop beds (Bogazzi et al., 2005) that have been studied and exploited since 1996, when the Patagonian scallop fishery started (Lasta and Bremec, 1998; Bremec and Lasta,

2002). However, interactions of bottom trawling operations and vulnerable benthic communities were found to be generally low (Portela et al., 2012; Schejter et al., 2014a).

A limited number of vessels operate on seamounts of the Walvis Ridge aiming at bottom resources, most notably orange roughy and alfonsoino. Although a general paucity of data exists regarding ecosystem impacts of these operations (Bensch et al., 2008; Rogers and Gianni, 2010), catch reports made by different countries throughout the 1980s and 1990s suggest that some seamounts may have been heavily fished by bottom gear, producing an uncertain impact on benthic organisms, including scleractinian corals and sponges (Clark et al., 2007). Countries such as Spain and Namibia have made efforts to describe these communities in different deep fishing areas in the South Atlantic high seas and to identify those considered to be “vulnerable marine ecosystems” (VMEs), whose protection would be a priority in the process of managing deep sea fisheries worldwide (FAO, 2009; Durán Muñoz et al., 2012). In 2006, the Southeast Atlantic Fishery Organization (SEAFO) precautionarily adopted the closure of ten seamount areas for bottom fishing, which were reviewed in 2010 and some reopened (Weaver et al., 2011). Currently, a total of eleven areas are closed in order to protect VMEs (SEAFO Conservation Measure 29/14 Annex 2).

Offshore extraction of oil and gas may cause potential harm to deep benthic communities mostly in association with the production of waste deposits and discharges of chemical pollutants (Davies et al., 2007). Deep areas of Brazilian and West African margins have large reserves, which will be increasingly exploited in the next decade. Nearly 80 per cent of all oil produced annually in Brazil derives from deep oil fields in Campos Basin, off southeastern Brazil, where important efforts to describe benthic diversity and define environmental baselines have been undertaken (Lavrado and Brasil, 2010). It is critical that these efforts expand in the upcoming years, as an even greater offshore oil extraction activity is expected to develop in the large pre-salt reserves recently discovered in the Santos Basin (Abreu, 2013).

Deep mineral deposits have been prospected in the South Atlantic “Area,” particularly in association with abyssal plains (polymetallic nodules), the Mid-Atlantic Ridge (seafloor massive sulphides) and seamounts (cobalt-rich crusts) (Hein et al., 2013). In 2013-14 a first plan for exploration of cobalt-rich crusts in a large seamount area named Rio Grande Rise was proposed by Brazil and approved by the International Seabed Authority (ISA, 2014). This contract will aim, in a 15-year programme, to characterize virtually undescribed benthic communities and produce an environmental baseline and monitoring plan for the claimed area. This programme follows ISA regulations for contractors, which include assessing potential disturbances of benthic habitats and organisms caused by crust-removing activities on the seafloor. Although most claims for mineral exploration are currently concentrated in the Pacific Ocean, it may be expected that interest in other areas, such as the South Atlantic, will also develop as knowledge of the South Atlantic increases (Perez et al., 2012).

One promising tool to reconcile benthic conservation and industrial development is offered by the implementation of Marine Protected Areas (MPA) (Marone et al., 2010; Turra et al., 2013). Studies and efforts to increase the number of MPAs are ongoing, such as the survey of priority areas for marine conservation in Brazil (MMA, 2007). In fact, the pressure of particular stakeholders (as shrimp farmers) reduced the protection of mangroves and wetlands along the Brazilian coast (Rovai et al., 2012). In addition, the recent findings of high oil and gas reserves in the Pre-Salt layer off the Southern-Southeastern Brazilian coast, as well as the potential of mining activities, raise awareness about the conservation of the fragile deep-sea benthic habitats.

Due to growing maritime traffic, the record of exotic species is expected to increase. In the Southwest Atlantic, a survey of exotic species in coastal and shelf areas of Uruguay and Argentina revealed that 31 species were introduced and 46 were cryptogenic. Coastal ecosystems between La Plata and Patagonia have been modified. Only exposed sandy beaches appear to be free from the pervasive ecological impact of invasion by exotic species. Poor knowledge of the regional biota makes it difficult to track invasions (Orensanz et al., 2002). Alien species (more than 40 reported for Argentina) severely modified native habitats and may cause loss of biodiversity. The most significant examples are: the Japanese alga *Undaria pinnifcata* that highly transformed the benthic structure found in gulfs and bays in Patagonia (Dellatorre et al., 2012), the introduced barnacles that greatly modified hard substrates in harbours and surrounding areas, the polychaete *Ficopomatus enigmaticus* that built reefs in the coastal lagoon Mar Chiquita (Buenos Aires) (Schwindt et al., 2004), the alien oyster *Crassostrea gigas* that transformed and colonized coastal and intertidal areas in Buenos Aires and in Patagonia (Castaños et al., 2009; Giberto et al., 2012), the *Rapana venosa* with an increasing population (Giberto et al., 2006), a voracious gastropod that has already caused huge financial losses in other countries in scallop, mussel and oyster culture and natural populations. In Brazil, a recent report indicated the occurrence of 58 exotic species, with 9 considered invasive (MMA, 2009), one in the phytobenthos, the green alga *Caulerpa scalpelliformis* var. *denticulate*, and six in the zoobenthos: the cnidarian anthozoans *Tubastraea coccinea* and *Tubastraea tagusensis*, the mollusc bivalves *Isognomon bicolor* and *Myoforceps aristatus*, the crustacean decapod *Charybdis hellerii* and the ascidian *Styela plicata*.

Due to continental sources of materials (sediment) and pollutants, including chemicals, nutrients and solid wastes, as well as the strong and widespread impact of human occupation, fishing, mining and oil industry activities, benthic coastal habitats are in danger in the South Atlantic and deserve proper attention from governments and society.

4. Fish

4.1 *Status*

The area of direct influence of the Amazon and Tocantins rivers is highly heterogeneous in terms of the dynamics of sedimentary deposition and freshwater discharge. This determines the characteristics of its fauna (Coelho, 1980; Camargo and Isaac, 2001) and flora (Prost and Rabelo, 1996), including species richness and distribution patterns (Giarrizo and Krumme, 2008). This area supports high fish biodiversity. Camargo and Isaac (2003) estimated that >300 fish species inhabit this area from 23 orders and 86 families, with a high degree of diversification mainly of the families Sciaenidae and Ariidae, but also of Rajiformes, Pleuronectiformes and Tetradontiformes. Many fish species of these families were also reported in French Guyana, Suriname and Guyana (Lowe Mc-Connell, 1962; Planquette et al., 1996, Le Bail et al., 2000, Keith et al., 2000) and Venezuela (Cervigon, 1996). Souza and Fonseca (2008), who also included information on the shelf and shelf break, identified more than 500 species from 106 families. A river-ocean gradient in the distribution of different species reflects their capacity to tolerate varying levels of salinity. Seasonal changes occur in the composition of the fish community, with predominance of freshwater species during the rainy season and marine species during the dry season (Camargo and Isaac, 2001). The high productivity of the area offers a high potential for fishery activities due to the numerous rivers and estuaries that empty into the Atlantic Ocean, forming a complex aquatic environment with high biological productivity.

Further south along the east Brazil LME, fringing and barrier reefs occur along the coast and over the shelf, harbouring diverse reef fish communities (Maida and Ferreira, 1997; Floeter et al., 2001). Offshore are located a major oceanic plateau, the Ceara Rise, and the Fernando de Noronha Ridge, with a chain of seamounts and the only atoll in the South Atlantic Ocean, Atol das Rocas. The Southwestern Atlantic region (SWA; including Brazilian oceanic islands and Argentina) has an impoverished reef fish fauna in relation to the Northwestern Atlantic and Caribbean, with only over half (471) of the reef species richness and 25 per cent of endemic species distinguishing the 'Brazilian Province' (Rocha, 2003; Floeter et al., 2007).

The Amazon freshwater and sediment outflow is a strong (albeit permeable) barrier to shallow-water reef fish and other organisms, and it is probably responsible for most of the endemism found in Brazilian coastal habitats (Rocha, 2003). Where the continental shelf is narrower and unusually steep, reef formations on the shelf-edge zone and slope down to 500 m depth support important multi-species fisheries, harbour critical habitats for the life cycle of many reef fish species, including spawning aggregation sites (Olavo et al., 2011), serve as a faunal corridor that extends beyond the Amazon mouth area (Collette and Rutzler, 1977), including the hump of Brazil and connect cold habitats in southern Brazil and the Caribbean (Olavo et al., 2011). Snapper dominates the demersal fisheries in the region (Frédou et al., 2006). Further south the shelf widens and the Abrolhos Bank forms a

physical barrier to the Brazil Current, hence upwelling and land conditions create even more diversity, especially for the reef fauna.

The South Brazil Shelf Large Marine Ecosystem (LME) extends roughly over the entire continental shelf off southeastern South America. The shelf waters result from the mixing of several water types: coastal, sub-Antarctic, sub-tropical and mixed waters (Bisbal, 1995). The Rio de la Plata represents the greatest freshwater inflow to the region, discharging on average 22,000 m³/s (with an annual fluctuation of 22 per cent). About 185 species of fish have been identified in South Brazil and around 540 in Argentine and Uruguayan shelf areas (Miloslavich et al., 2011). Two of the most commercially important finfish species exploited from this system are common hake (*Merluccius hubbsi*) and Patagonian hake (*Merluccius australis*) (Bisbal, 1995). Many Sciaenid species are also important as a fishery resource. In this region more than 55 per cent of the stocks are overexploited (MMA, 2006).

At the mouth of the Río de la Plata, the fish fauna comprise 53 marine species (Nión, 1998). The most abundant species undergo migrations related to changes in hydrographic conditions. In the coastal zone fishes from the family Sciaenidae are dominant to a depth of 50 m (Calliari et al., 2003). South of the Rio de la Plata the patagonian shelf is much wider and highly productive with great fish diversity sustaining fisheries on more than 50 species. Common hake (*M. Hubbsi*), patagonian grenadier (*Macruronus magellanicus*), whitemouth croaker (*Micropogonias furneri*), sardinella (*Sardinella brasiliensis* and *S. aurita*), southern blue whiting (*Micromesistius australis*), anchovy (*Engraulis anchoita*), prawns (*Pleoticus muelleri*) and several species of skates and rays (<http://www.fao.org/fishery/statistics/en>).

Along the eastern margin of the South Atlantic, fisheries resources are highly productive, supported by the upwelling resulting from the Guinea and Canary Currents along the coast. Currently fish stocks in the area are already overexploited by the foreign distant-water fleets fishing in the Exclusive Economic Zone of West African countries (Alder and Sumaila 2004; Atta-Mills et al., 2004) under bilateral agreements with the European Union (Alder and Sumaila, 2004).

4.2 Pressures and Trends

Landings of fisheries in Brazil far exceeded sustainable target levels in the main portion of this area, according to the results from fisheries assessments from a multi-year Brazilian research programme called REVIZEE; the majority of stocks were either fully (23 per cent) or over-exploited (33 per cent) and little room remained for expansion into new fisheries (MMA, 2006). The decline of landings of many demersal stocks has been reported in the Southern areas of Brazil [Perez et al., 2003].

Brazilian marine fishes were regionally assessed according to the IUCN Red List criteria. For 151 marine Chondrichthyes species, 39 per cent were categorized as threatened, mainly due to intense and unmanaged fisheries (Peres et al., 2012), and 35 per cent marine teleost species were also assessed as threatened.

Some species in the south west Atlantic have experienced local collapse (e.g., *Cynoscion guatucupa*, a migratory species) at Bahía Blanca from the increasing fishing pressure exerted by the industrial fishing fleet operating in open waters (López Cazorla et al., 2014). Information on the status of the exploited species can be found in www.inidep.edu.ar/pesquerias/ppales-pesquerias.

Global climate change affects fish and fisheries. The effects range from increased oxygen consumption rates in fishes, to changes in foraging and migrational patterns in polar seas, to fish-community changes in bleached tropical coral reefs. Projections of future conditions portend further impacts on the distribution and abundance of fishes associated with relatively small temperature changes (Roessig et al., 2004). The information on the effects of climate change and long-term studies to assess those effects in the Southwest Atlantic are scarce or non-existent. Schroeder and Castello (2010) modelled effects of climate change scenarios on Patos Lagoon estuarine-dependent resources, notably pink shrimp, white-mouth croaker and grey mullet. ENSO cycles and climate changes may increase the limnic and decrease the saline influence in the estuary. This scenario may affect the biology and dynamics of estuarine-dependent species and their fisheries, because temperature influences metabolism, which affects the growth of individuals. The natural mortality of larvae may increase due to metabolic stress, although increased growth rates may also reduce the period during which the young are vulnerable to predation. A decrease in the maximum size of the species is also expected, as well as a shift in biomass peaks and the effect of fisheries. West Africa is considered one of the regions most vulnerable to the impact of climate change on fisheries because of the threats to livelihoods and well-being of communities depending on fisheries. The model's estimates indicate a 21 per cent drop in landed value and a 50 per cent loss in fisheries-related jobs (Lam et al., 2012).

5. Marine Mammals

5.1 Status

Marine mammals comprise a diverse group of taxonomically and ecologically distinct aquatic vertebrates that inhabit pelagic to coastal and estuarine waters, from the photic zone to deep ocean canyons (Berta et al., 2006). Most marine mammals are top predators that have spatial and temporal separation of feeding and nursing areas; they must maximize the energy obtained during foraging events and thus are considered good indicators of environmental conditions and health because they depend on the ocean for food and survival (Block et al., 2002; Hooker and Boyd, 2003; Fedak, 2013). Along the coast of South America, several species of marine mammals are found at different (partial or full) stages of their life cycles (Miloslavich et al., 2011 and references herein).

Worldwide, 129 species of marine mammals are described, of which 60 have also been reported for the South Atlantic Ocean (Perrin et al., 2009). Among resident, frequent and occasional visitors, the South Atlantic Ocean is home to approximately 20 species of the Order Carnivora (Suborder Pinnipeda and Family Mustelidae), and ~45 species of the Order Cetacea. Three Mysticete families (seven species of baleen whales), five Odontocete families (27 species of toothed whales), two Pinniped families (10 species), two Mustelidae species and one Sirenid family (a manatee) were reported for Patagonian and Brazilian coastal waters. Throughout South America, we find marine mammals that are endemic or limited in distribution (La Plata River dolphin, Austral dolphin, Commerson dolphin and manatees), and others with wider distribution that depend on coastal areas of the region for important stages of their life cycles.

Some baleen whales, such as the southern right whale and the humpback whale, breed in waters off Santa Catarina, Brazil (28°S), the north Patagonian gulfs (34°S), or in the Abrolhos Bank (17°S), Northeast Brazil, and on the coast of Southwest Africa. The only representative of the manatees in the SAO, *Trichechus manatus*, occurs discontinuously along coastal waters of Northeast Brazil (Alagoas -9°S to Amapá 0°) where it is under serious threat (Luna et al., 2010). Manatees (*Trichechus* spp.), that are commonly found in mangrove areas in the North and Northeast regions and along the Amazon River Basin, were hunted in the past for their meat and skin and were at risk of extinction, but they are currently protected by the Brazilian Government. Humpback whales (*Megaptera novaengliae*) frequent the southern tip of South America, the Beagle Channel and South Africa. Blue whales (*Balaenoptera musculus*) are only seen sporadically along northern Argentine and South African coasts. Southern right whales, *Eubalaena asutralis*, inhabit the north Patagonian gulfs, one of the most important breeding grounds for the species, and are also regularly seen along the coasts of Uruguay and Brazil. Three coastal dolphins are endemic to the region: Peale's dolphin *Lagenorhynchus australis*, Commerson's dolphin *Cephalorhynchus commersonii* and the La Plata or Franciscana dolphin *Pontoporia blainvillei* (Bastida and Rodriguez, 2010). The orca *Orcinus orca* presents smaller populations with a characteristic predatory behaviour in north Patagonia (Lewis and Campagna, 2008) and Isla de los Estados (Raya Rey, pers. obs.). Given advances in technology, the at-sea movements of several species have been revealed, from the pelagic southern elephant seals (Campagna et al., 1999; Campagna et al., 2006) and the more coastal South American sea lion (Campagna et al., 2001) to the endemic and coastal La Plata River dolphin (Bordino et al., 2008) and breeding and post-breeding humpback whales (Horton et al., 2011).

Resident species also include the South American sea lion *Otaria flavescens*, widely distributed all along the southern coast of South America, including Isla de los Estados and Falkland Islands (Malvinas), South American fur seals *Arctocephalus australis* and southern elephant seals *Mirounga leonina*, with the only land-breeding colony along the coasts of Península Valdés and Punta Ninfa (Chubut, Argentina) believed to be the same stock as the seals breeding at the Falkland Islands (Malvinas) (Lewis and Campagna, 2008). On the African coast between the resident species are found the Cape fur seal *Arctocephalus pusillus pusillus*.

Among the cetaceans that visit and live within the Southwest Atlantic Ocean, five species are considered "vulnerable" or "endangered" worldwide. Among these are the blue whale, the humpback whale, the sperm whale *Physeter macrocephalus*, the La Plata River dolphin *Pontoporia blainvillei* and the manatee *Trichechus manatus*. Most of the Odontoceti species are considered to be data-deficient (Lewis and Campagna, 2008). Two of the three mustelid species, *Lontra provocax* and *L. felina*, that inhabit the southern region, are considered endangered.

5.2 Pressures

Some coastal species are threatened by anthropogenic activities, such as pollution, fishing and fisheries by-catch, tourism activities, coastal development and habitat destruction. Pelagic species are also threatened by increasing traffic of ocean vessels (boats and ships), seismic prospection, fishing, and oil and gas activities.

The indirect effects of fisheries have also been observed in seal populations. For the South American sea lion it has been shown that the level of harvested squid and hake could have a negative impact on seal populations (Koen Alonso and Yodzis, 2005). In the Benguela ecosystem, the interaction of seals (Cape fur seal *Arctocephalus pusillus pusillus*) and fisheries have been also described (Yodzis, 1998).

Artisanal fisheries and entanglement pose a major threat for small cetacean populations, in particular the endangered La Plata dolphin (Praderi et al., 1989; Pérez Macri and Crespo, 1989; Secchi et al., 1997). Although not in big numbers and without a clear impact on the population, some other species caught in fishing nets are the Commerson's dolphin (Crespo et al., 1994; Crespo et al., 1997; Crespo et al., 2000; Schiavini and Raya Rey, 2001; Dans et al., 2003), dusky dolphin, common dolphin and seals (Dans et al., 1997; Crespo et al., 2000; Dans et al., 2003). Elephant seals are also known to become entangled in squid fishing gear (Campagna et al., 2007), as well as many sea lions dying every year with plastic rings around their necks, although this fact has not been quantified and therefore its effect on the population is not known.

Recently the Southern right whale populations have suffered from kelp gull (*Larus dominicanus*) attacks. This problem started during the 1970s as a consequence of gull population growth due to an increase in food supply of human origin (fisheries and home garbage). Although wounds inflicted by kelp gulls do not pose a real threat for the population, gull attacks impose a change in behaviour by the target whale as it increases its attention to the source of the attacks in 24 per cent of cases, to the detriment of other "natural" forms of behaviour (Rowntree et al., 1998; Rowntree et al., 2001; Bertellotti and Perez Martinez, 2008). On average, 27 southern right whales, mostly pups, die annually in Península Valdés; saw a record of 83 dead whales from unknown causes. Although pathogens are not believed to be a major threat to biodiversity, the growth of human activities and climate change could promote their expansion (Uhart et al., 2008).

5.3 Trends

Recent studies have provided insights into marine biodiversity in South America, specifically regarding the Patagonian Shelf (Uruguay and Argentina) and the Brazilian Continental Shelf (Miloslavich et al., 2011). Even though Miloslavich and colleagues' assessment represented a major breakthrough in our knowledge of marine biodiversity in South America, their focus was on macroalgae, cnidarians, molluscs, crustaceans, echinoderms, and fish. The assessment represented an initiative by the Census of Marine Life (CoML) to promote a thorough background check into the information on marine biodiversity produced and accessed only locally in South America and to make it available worldwide via a marine diversity database (OBIS). The knowledge generated by marine research in South America has been limited, given the poor access to oceanographic vessels, isolation between researchers, and the lack of coordination between scientific programmes (Ogden et al., 2004). The lack of dedicated efforts to examine the trends in biodiversity and species richness for the region has represented a major bottleneck for the development of efficient conservation and management measures. Whereas governmental agencies (e.g., the National Oceanic and Atmospheric Administration (NOAA) and the National Marine Fisheries Service (NMFS) of the United States and the Department of Fisheries and Oceans of Canada (DFO)) in the North Atlantic are focused on performing marine mammal assessments to help establish their status and improve their conservation, south of the Equator most assessments are a result of isolated research initiatives with local or regional scope, given the costs associated with this type of assessment.

The South American sea lion is the most abundant marine mammal in the region, with several breeding grounds along the coast from Uruguay to Tierra del Fuego, Staten Island and Falkland Islands (Malvinas) (Reyes et al., 1999; Dans et al., 2004; Schiavini et al., 2004). Most of its populations have been recovering over the last decades from the devastating exploitation suffered between the 17th and 20th centuries (Bastida and Rodriguez, 2010). Nevertheless, whereas colonies in north Patagonia are growing at a 5.4 per cent (Dans et al., 2004) annual rate, the Uruguay populations are decreasing by 4 per cent annually (Páez, 2005). The South American fur seal, with smaller populations, is also recovering, with a 1-2 per cent annual increase rate in the Uruguay populations (Bastida and Rodriguez, 2010). Southern elephant seal populations also increased at an annual rate of 3 per cent from the 1980s to 2000, and have remained stable in numbers since then (Lewis and Campagna, 2002; Lewis and Campagna, 2008).

Data on cetacean population numbers and trends are scarce for the region. Southern right whales show a 7 per cent annual increase rate in Península Valdés (Cooke et al., 2001). Population numbers are known for some of the coastal species (Brownell et al., 1998; Lescrauwaet, 1997; Schiavini et al., 1999; Pedraza, 2008) with no trends available, although given the mortality rate and the narrow distributional range, the La Plata dolphin populations are thought to be decreasing (see threats). No population estimates are known for the Falkland Islands' (Malvinas') resident populations (Otley et al., 2008).

The Brazilian Ministry of Environment has established MPAs and implemented action plans for wildlife, particularly marine mammals (Barreto et al., 2010; Di Benedetto et al., 2010; Luna et al., 2010; Campos et al., 2011). In Uruguay and Argentina, MPAs are increasing, but the implementation of specific action plans for marine mammals has not yet been achieved. In Argentina, marine and coastal resources (Yorio et al., 1998; Sapoznikow et al., 2008), have been under protection in about 59 coastal and marine protected areas, which include marine organisms, such as seabirds and marine mammals, among their main conservation targets (GEF, 2013). In Uruguay, the process of establishing MPAs is incipient, but a National System of Protected Areas is responsible for this process, and three coastal areas are currently being considered (Santa Lucía, Cabo Polonio, and Cerro Verde), as well as a proposal for a network of MPAs (Defeo et al., 2009). Recently, ecosystem-based fishery management and MPAs are emerging as promising tools to conserve marine environments, in view of declining fisheries indicators in the South Western Atlantic Ocean (Mugetti et al., 2004; Milessi et al., 2005; Defeo et al., 2009). The overall aim is to ensure ecosystem resilience and adaptation to a changing environment while maintaining ecosystem processes and a sustainable use of marine resources. Thus it is important to focus not only on vulnerable species, such as the coastal manatees, sea lions or breeding baleen whales, but also on vulnerable areas, or areas of ecological significance for many species of marine mammals as well as also other groups, such as birds, turtles and fish (Mittermeier et al., 2011).

6. Seabirds

6.1 Status

Tropical waters are relatively poor in seabirds as a result of low productivity. About 130 coastal and marine species are found north of the Río de la Plata. The larger part of these birds comes from the northern hemisphere between September and May and from the southern seas between May and August to reproduce in areas such as Atol das Rocas, which are crucial for the maintenance of their populations (Miloslavich et al. 2011).

South of the Río de la Plata, shelves are high-productivity areas which maintain a great diversity of seabirds. This ecosystem not only harbours many birds that come each summer to breed, but also thousands of seabirds forage within its waters (Yorio et al., 1999; Croxall and Wood, 2002; Favero and Silva, 2005). Pelagic and coastal waters are home to about 50 species that belong to the orders Procellariiformes, Sphenisciformes, and the families Stercorariidae, Sturniidae, Lariidae and Phalacrocoraciidae.

The main breeding sites in the South West for these populations are concentrated in three areas: (a) Península Valdés and adjacent coasts; (b) Tierra del Fuego and adjoining areas; and (c) the Falkland Islands (Malvinas) (Croxall et al., 1984; Strange, 1992; Woods and Woods, 1997; Yorio et al., 1999). Three species (Magellanic penguin *Spheniscus*

magellanicus, southern rockhopper penguin *Eudyptes chrysocome* and black-browed albatross *Thalassarche melanophris*) have over half their world population in the area (Boersma et al., 2013; Pütz et al., 2013) and two others (gentoo penguin *Pygoscelis papua* and thin-billed prion *Pachyptila belcheri*) probably have more than one-quarter of their world population in the region (Croxall and Wood, 2002).

Seabird diversity and abundance have long been studied by ship surveys (e.g., Cooke and Mills, 1972; Jehl, 1974; Veit, 1995; Orgeira, 2001a; Orgeira, 2001b). With advances in technology (satellite tracks, global positioning system devices and geolocators), the origin, sex, age and status of birds using the area can be established and quantified (Falabella et al., 2009). Therefore, it is known that the area is intensively used by a wide range of species: from pelagic flying birds (e.g., Jouventin and Weimerskirch, 1990; Weimerskirch et al., 1997; Prince et al., 1998; Berrow et al., 2000; González-Solís et al., 2002; Quintana and Dell’Arciprete, 2002; Trathan and Croxall, 2004; Masello et al., 2010) to penguins (Stokes et al., 1998; Stokes and Boersma, 1999; Pütz et al., 2002; Pütz et al., 2007; Wilson et al., 2007; Raya Rey et al., 2007; Sala et al., 2014; Rattcliffe et al., 2014) and coastal birds (Suárez and Yorío, 2005; Suárez et al., 2012). The waters are not only used by resident species but also by seabirds that breed in distant colonies: wandering albatrosses *Diomedea exulans* from the South Georgias Islands extensively use the Patagonian shelf, two fulmarine petrels, cape petrel *Daption capense* and Antarctic fulmar *Fulmarus glacialoides*, which breed on the Antarctic Peninsula and Continent, are very common visitors over the Patagonian shelf (Orgeira, 2001a). Wilson’s storm petrel *Oceanites oceanicus*, a trans-equatorial migrant, with a large Antarctic but small Falkland Islands (Malvinas) breeding population is also common in the region (Orgeira, 2001a). Although only present in small numbers, seabirds breeding at Tristan da Cunha and Gough (mainly soft-plumaged petrel *Pterodroma mollis*, Atlantic petrel *P. incerta*, Kerguelen petrel *Lugensa brevirostris* and great shearwater *Puffinus gravis*) visit the southern part of the Patagonian Shelf (Orgeira, 2001a). In addition, substantial numbers of Tristan albatross *Diomedea dabbenena*, Atlantic yellow-nosed albatross *Thalassarche chlororhynchos* and spectacled petrel occur in similar areas of northern Argentina, Uruguay and southern Brazil (Olmos et al., 2000). Finally, northern royal albatross *Diomedea sanfordi*, endemic to New Zealand, is known to forage along the Patagonian Shelf (Nicholls et al., 2005).

Of the seabirds which breed in the region, two species (southern rockhopper penguin and white-chinned petrel *Procellaria aequinoctialis*), qualify under the IUCN criteria for globally threatened status; magellanic penguin, black-browed albatross and gentoo penguin are regarded as Near Threatened. Also seven of the non-resident visitor species qualify for the globally threatened status (BirdLife International, 2014). Seabirds in the region are considered in the International Plans of Action presented by Argentina, Brazil, Chile, South Africa and Uruguay.

South African waters are of prime importance for conserving seabirds because the Benguela upwelling system and the Agulhas Bank provide rich foraging opportunities for a wide diversity of seabirds (Petersen et al., 2009). The Benguela Ecosystem harbours 15 seabird species, of which 10 are endemic to South Africa. Species belong to the families

Spheniscidae, Hydrobatidae, Pelecanidae, Sulidae and Haemotopodidae with one species each, three species of the Laridae family and four species in the Phalacrocoracidae and Sternidae families (Kemper et al., 2007). Seabirds from the Benguela Ecosystem are highly threatened; in particular, the African Penguin *Spheniscus demersus* and Cape Cormorant *Phalacrocorax capensis* are now considered endangered following ongoing decreases (Birdlife, 2014). The Southeast Atlantic Ocean also has numerous islands (Ascension, St. Helena, Inaccessible, Tristan and Nightingale) rich in seabird species (Cuthbert 2004; Birdlife, 2014). Most of these islands are home to the endangered northern rockhopper penguin *Eudyptes moseleyi* (Birdlife, 2014), and 15 albatrosses and petrels foraging within these waters qualify under the IUCN criteria for globally threatened status, such as the Tristan albatross which is critically endangered (Abrams, 1983; Abrams, 1985; Ryan and Moloney, 1988; Nel and Taylor, 2002; Wanless et al., 2009; Petersen et al., 2009; Birdlife, 2014).

6.2 Trends

Population trends of resident and non-resident seabirds that forage in the Southwest Atlantic Ocean present different trajectories over the years, with some species showing opposite trends at different locations. Some of the large Procellariiformes species have declined over the past decades (i.e., wandering albatross) and this trend continues (Poncet et al., 2006), but others, such as the southern giant petrel, are recovering at least at some colonies (Reid and Huin, 2005; Quintana et al., 2006; Wolvaardt, 2012). Small petrels' trends are not well known in the area (Otley et al., 2008). Among penguins, southern rockhopper penguins have experienced dramatic declines between 1930 and 2005 (Pütz et al., 2003), although this trend seems to have reverted within the Falkland Islands (Malvinas) (Baylis et al., 2013), whereas the population at Staten Island has reduced its numbers during the last decade (Raya Rey et al., 2014). Gentoo and Magellanic penguins present different trends, depending on the colony. Gentoos in the Falkland Islands (Malvinas) presented a 42 per cent decrease, which was attributed to a paralytic shellfish poisoning in 2002, with a later increase of 95 per cent since 2005 (Pistorius et al., 2010); a recent study showed interannual fluctuations without a clear trend (Baylis et al., 2012), but in the meantime the small population of Tierra del Fuego has increased (Raya Rey et al., 2014). Magellanic penguin population trends are variable: some of the bigger colonies are decreasing, but at the same time new colonies are being established in northern Patagonia (Boersma, 2008; Boersma et al., 2013); the population in the Falkland Islands (Malvinas) does not present a clear trend, whereas populations in Tierra del Fuego are increasing (Raya Rey et al., 2014).

Long-term population trends for coastal birds, such as gulls, cormorants, skuas and terns, are scarce and limited for certain regions. Cormorants present opposite trends depending on the species and site, but in general numbers have been stable with some populations slightly increasing or decreasing (Frere et al., 2005; Raya Rey et al., 2014). Kelp gulls take advantage of human garbage, and their populations are increasing all along the Patagonian coast (Lisnizer et al., 2011; Raya Rey et al., 2014). Terns and skuas

are the least studied of the species, with small populations and frequent variations in colony locations with unknown trends (Yorio, 2005; Otley et al., 2008).

Southeast Atlantic seabird population trends contrast between species, but several have experienced severe decreases during the last decades, such as the African penguin, the Cape Gannet *Morus capensis* and Cape cormorant (Kemper et al., 2007). Some gull populations are increasing, which is largely attributable to the provision of additional food sources from human activities (Crawford, 1997) and the cessation of population control measures (mainly the destruction of eggs and chicks) at most breeding localities (Hockey et al., 2005). The decrease in Northern rockhopper penguins is evident from population estimates in the Tristan da Cunha group and Gough Island, which indicate a decline of more than 50 per cent (Cuthbert et al., 2009). The Tristan albatross also decreased severely at 3 per cent per year, and the sooty albatross *Phoebastria fusca*, Atlantic yellow-nosed albatross *Thalassarche chlororhynchos* and southern giant petrels *Macronectes giganteus* remained stable during the last decade (Cuthbert et al., 2014).

6.3 Pressures

Direct and indirect discharge of chemical pollutants, industrial and expanded city pollution, bycatch, entanglement, climate change and alien species pose severe threats for seabird populations both at sea and at their colonies in the Southwest Atlantic Ocean. Oil pollution in Argentine inshore waters is of major concern and kills thousands of Magellanic penguins annually (Gandini et al., 1994; Garcia-Borboroglu et al., 2006; Garcia-Borboroglu et al., 2010). Negative consequences of garbage disposal have also been documented in the region (Copello and Quintana, 2003; Otley and Ingham, 2003).

Bycatch (incidental mortality) of seabirds in fishing gear has been a foremost conservation issue, due to the large number of albatrosses and petrels killed by longline fishing vessels (Croxall, 1998; Neves and Olmos, 1998; Olmos et al., 2000; Prince et al., 1998; Schiavini et al., 1998; Stagi et al., 1998). Seabird mortalities decreased by one order of magnitude towards the end of the decade (2001-2010), not due to lower bycatch rates but rather to a drop in the number of hooks set per year (Favero et al., 2013). Black-browed albatrosses, white-chinned petrels, southern giant petrels and southern royal albatrosses are the most common species interacting with trawlers. The total annual mortality of these birds associated with the trawl fleet under investigation was roughly estimated to be from several hundred to over a thousand albatrosses (Favero et al., 2011). Entanglement of penguins in trawl nets is considerable, and other inshore feeding species are doubtless at risk (although this risk is in some cases minor) in various other net fisheries (Gandini et al., 1999; González-Zevallos et al., 2007; González-Zevallos and Yorio, 2011; Seco Pon et al., 2012; Seco Pon et al., 2013).

Seabirds foraging and breeding in the Southeast Atlantic are subject to many threats, such as: human disturbance of breeding colonies; destruction of breeding habitats by development (du Toit et al., 2003); predation by domestic cats and mice (Wanless et al., 2009); egg and chick predation by Kelp Gulls and Great White Pelicans (Crawford, 1997;

du Toit et al., 2003); competition with commercial fisheries for food (du Toit et al., 2003). Longline fisheries pose a serious threat in particular for the Tristan albatross, and also for albatrosses and petrels in general (Baker et al., 2007). Introduced mice species at Gough Island are known to affect albatrosses and petrels (Cuthbert et al., 2013). Food supplies for northern rockhopper penguin may be affected by squid fisheries, climate change and shifts in marine food webs (Cunningham and Moors 1994; Guinard et al., 1998; Hilton et al., 2006). African penguins have dramatically decreased during the last decade, which is related to prey abundance (Crawford et al., 2011).

Chapter 36C. North Pacific Ocean

Contributors: Thomas Therriault (Convenor), Chul Park and Jake Rice (Co-Lead members and editors for Part VI Biodiversity)

1. Introduction

The Pacific is the largest division of the World Ocean, at over 165 million km², extending from the Arctic Ocean in the north to the Southern Ocean in the south (Figure 1). Along the western margin are several seas. The Strait of Malacca joins the Pacific and the Indian Oceans to the west, and the Drake Passage and the Strait of Magellan link the Pacific with the Atlantic Ocean to the east. To the north, the Bering Strait connects the Pacific with the Arctic Ocean (International Hydrographic Organization, 1953). The Pacific Ocean is further subdivided into the North Pacific and South Pacific; the equator represents the dividing line. The North Pacific includes the deepest (and, until recently, the least explored) place on Earth, the Mariana Trench, which extends to almost 11 km below the ocean's surface, although the average depth of the North Pacific is much less, at approximately 4.3 km. Thus, the North Pacific encompasses a wide variety of ecosystems, ranging from tropical to arctic/sub-arctic with a wide diversity of species and habitats. Further, the volcanism that creates the "rim of fire" around the Pacific has resulted in unique undersea features, such as hydrothermal vents (including the Endeavor Hydrothermal Vents) and seamount chains (including the Hawaiian-Emperor Seamount Chain). Both create unique habitats that further enhance biodiversity in the North Pacific. The continental shelves around the North Pacific tend to be very narrow with highly variable productivity, with the exception of the continental shelf of the Bering Sea, which is one of the largest and most productive in the World Ocean (Miles et al., 1982). Further influencing productivity and biological diversity in the North Pacific is a series of large-scale oceanic currents on both sides of the basin, especially the Kuroshio and Oyashio Currents on the western side and the Alaska and California Currents on the eastern side. Also, the North Pacific Transition Zone (NPTZ) is an oceanographic feature of special importance to the biology of many species in the North Pacific Ocean. This 9,000 km wide upper water column oceanographic feature is bounded by thermohaline fronts thereby establishing a highly productive habitat that aggregates prey resources, attracts a number of pelagic predators, and serves as a migratory corridor. Ocean climate indices, such as the Pacific Decadal Oscillation (PDO), reflect spatial and temporal variability observed in the North Pacific (Mantua and Hare, 2002). For example, the PDO tends to indicate that a cool eastern North Pacific is associated with a warmer central and western North Pacific and *vice versa*, thereby contributing to spatial and temporal variability in ecosystem productivity and shifting patterns of biological diversity. The density of human habitation around the North Pacific is more concentrated in southern latitudes and on the western side of the basin.

This in turn influences the anthropogenic stressors affecting biodiversity and productivity.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

2. Coastal Areas of the North Pacific

Like other oceanic basins, the coastal areas of the North Pacific encompass a wide variety of complex habitat patches, each with different levels and types of biological diversity. Spalding et al. (2007) identify at least 50 ecoregions around the North Pacific, based in part on their relatively homogenized biological diversity and differentiation from adjacent areas, but status and trend information for biodiversity is not available even at this intermediate spatial scale. Limited information is derived from localized, smaller-scale studies conducted for specific habitat patches (e.g., coral reefs, estuaries, etc.) or fish stocks, but synthesis at the basin scale remains a critical gap for coastal

areas of the North Pacific. For example, Japan has established a programme to track community-structure changes at 1,000 monitoring sites (both terrestrial and marine) and many countries around the North Pacific conduct stock assessments for major commercial species, but higher-level synthesis remains a gap. Furthermore, coastal systems are under different pressures in different parts of the basin, which will only complicate higher-level synthesis of status and trends.

2.1 Biodiversity status and trends

2.1.1 Primary producers

Climatic variability continues to increase in the North Pacific Ocean, especially in the eastern part of the basin, where both extreme warm and cool events have occurred in the Gulf of Alaska, the California Current and equatorial waters in recent years (Sydeman et al., 2013). At finer spatial scales, eddies and current meanders are important determinants of ecosystem productivity. For example, in the Gulf of Alaska region, eddies influence nutrients, phytoplankton, and even higher trophic levels (Ream et al., 2005). In the California Current, chlorophyll concentrations have increased (Kahru et al., 2009), but this has resulted in a shift to a community more dominated by dinoflagellates, at least in Monterey Bay, that has resulted in significant ecosystem changes, including impacts at higher trophic levels. In the Kuroshio Current region, the species-composition time-series is limited, hence it is not possible to identify trends in biomass, but the dominant taxa have been highly variable with an obvious diatom spike in 2004, possibly due to the meandering of this current (Sugisaki et al., 2010; Figure 2). In general, large-scale, taxonomically diverse time series for phytoplankton are lacking.

Figure 2. Composition of diatoms in the euphotic zone at Station B03 (34°N 138°E) in May (from Sugisaki et al., 2010).

2.1.2 Zooplankton communities

One of the most significant biological changes in the North Pacific is the explosion of gelatinous macrozooplankton in the western portion of the basin, especially the Yellow Sea, where medium to large jellyfish have become overly abundant in recent years and have resulted in increased reports of impacts (Purcell et al., 2007; Figure 3). This increase in jellyfish has had unforeseen biological (e.g., effects on productivity and diversity) and economic consequences (e.g., effects on fisheries, industry, and tourism) with resulting impacts to ecosystem and human services.

Figure 3. Percentage of years in each decade with reports of human problems with jellyfish in Japan (from Purcell et al., 2007).

Studying the California Current system Chelton et al. (1982) showed a strong correlation between zooplankton biomass anomalies and temperature anomalies. Thus, it is not surprising that recent changes between warm and cool periods in the eastern North Pacific coincided with large-scale changes in zooplankton community composition and abundance. Cool periods favour northern copepod species that tend to be larger and energy rich, making them good prey items while warm periods favour southern copepod species that tend to be smaller and energy poor making them less suitable prey (McKinnell et al., 2010; Figure 4). Anomalously strong upwelling further influences the zooplankton community composition and abundance in the California Current system. On the western side of the North Pacific, the hydrography of the Kuroshio Current acts to differentiate zooplankton biomass and diversity between the onshore and offshore sides and main stream of this current. Further, copepod biomass varies interannually with different seasonal peaks but the overall trend remains relatively constant (Sugisaki et al., 2010). Large-scale, taxonomically diverse time series are lacking for other important zooplankton species (e.g., arrow worms, pteropods, salps, krill).

Figure 4. Northeast Pacific anomaly time series for upper ocean temperature, biomass of “Northern” and “Southern” copepods, and marine survival of coho salmon relative to ocean entry year (from McKinnell et al., 2010).

2.1.3 Benthic communities

Although cold, deep-water corals and sponges have received some attention in recent years (and some have been afforded special protection at regional or local scales), our understanding of the diversity and distribution of these organisms at larger spatial scales is very incomplete, making inferences about status of and trends in diversity impossible. Given their very slow growth rates and long regeneration times, they are particularly sensitive to disturbances, such as bottom-contact fishing gear, harvesting, natural resource exploration and extraction, submarine cable/pipelines, climate change, ocean acidification, and invasive species (Hourigan et al., 2007). Corals and sponges are not the only benthic taxa but no large-scale synoptic information was identified on status and trends in the diversity of other benthic communities in the coastal areas of the North Pacific. However, Kodama et al. (2010) and Kodama and Horiguchi (2011) document periods of defaunation in Tokyo Bay for macrobenthic and megabenthic communities, suggesting there have been decreases in benthic community diversity at least at local scales around the North Pacific (beyond the scope of this Assessment).

2.1.4 Higher trophic levels

McKinnell et al. (2010) provide the only intra-basin comparison of changes in key fish and invertebrate stocks between 1990-2002 and 2003-2008. In this study many taxa in the Sea of Okhotsk and Oyashio regions increased and many taxa in the California Current, Yellow Sea, and East China Sea decreased (Table 1). In addition to changes in abundance, distributional shifts occurred, related at least in part to changing ocean conditions; these shifts can have ecological and economic consequences on ocean services (e.g., Mueter and Litzow, 2008).

In the eastern North Pacific, a mid-water trawl survey for the California Current system provides evidence that the forage fish community of this ecosystem tends to alternate between a less productive warm community and a more productive cool community in response to widely recognized regime shifts in oceanic conditions (NOAA's Southwest Fisheries Science Center (SWFSC) in Bograd et al., 2010). Similarly, on the western side of the basin in the Kuroshio-Oyashio system, where a strong latitudinal gradient in annual productivity (Pope et al., 1994) exists, evidence of decadal-scale changes in fish communities or "species replacements" linked to regime shifts have been observed (Chiba et al., 2010; Figure 5).

Figure 5. Biomass of sardine, anchovy, chub mackerel, Pacific saury and common squid (winter spawning stock) along the Pacific coast of Japan (from Chiba et al., 2010).

Pacific salmon are an economically and culturally important species in the North Pacific. Marine survival for over 40 coho salmon stocks has decreased substantially in the California Current system since the early 1970s, due at least in part to poor marine survival (Bograd et al., 2010; Figure 6); extremely low survival corresponds to the 2005 smolt entry year; this trend is also detected in marine birds (see 2a (v) below). Similarly, masu salmon (*Oncorhynchus masou*) in Japan have experienced significant declines in returns over the same period (Chiba et al., 2010). Additional higher trophic level species in the North Pacific include a variety of fish and invertebrate species, including: small pelagic species (e.g., anchovy, sardine, saury, mackerel, squid); large pelagic species (e.g., tuna, shark, billfish, ray); benthopelagic species (e.g., rockfish, croaker, cod); and

demersal species (e.g., pollock, flatfish, crab), some of which may have experienced population declines at regional or sub-regional scales.

Figure 6. Average marine survival of up to 45 coho salmon (*O. kisutch*) stocks in the northern California Current region by year of ocean entry (from Bograd et al., 2010).

For Pacific salmon spawning in Canadian waters, the Canadian Department of Fisheries and Oceans has provided outlooks since 2002. In the most recent iteration, 91 stocks were assessed and an outlook provided for 84, of which 28 were linked to a conservation concern, despite 21 units showing improvement, compared to 9 that have worsened since the previous period (DFO, 2014). In the United States, the National Oceanic and Atmospheric Administration (NOAA) reports on the status of 480 managed stocks and stock complexes, including rockfishes, flatfishes, and gadoids, relative to fishing mortality and biomass reference points. Several of these stocks from the Pacific Ocean have been identified as overfished, but all domestic stocks are rebuilding and one stock (Sacramento River Fall Chinook) was recently removed from this list (NOAA, 2013). No domestic stocks in the Pacific currently are experiencing overfishing, although several stocks of highly migratory species are under international management and two species (Pacific bluefin tuna and striped marlin) were added to the list of overfished stocks in 2013 (NOAA, 2013).

2.1.5 Other biota

At least eleven species of marine birds and nine species of marine mammals designated as being at risk by the IUCN are found in the North Pacific; overall, it does appear that populations are either stable or increasing. Only planktivorous auklets in the Sea of Okhotsk appear to be the exception for marine birds (McKinnell et al., 2010; Table 3); Steller sea lions and harbour seals in the central and western Aleutian Islands, northern fur seals from the Pribilof Islands, and potentially harbour seals in Prince William Sound, Alaska, are the exceptions for marine mammals (McKinnell et al., 2010; Table 4) have experienced population declines. Additional species that are critically endangered in the North Pacific include the vaquita (*Phocoena sinus*) which is on the verge of extinction: only 241 animals were estimated in 2008 (Gerrodette et al., 2011) and Hawaiian monk seals (*Monachus schauinslandi*). Additional marine birds and mammals may be

considered at-risk at regional or sub-regional scales that are beyond the scope of this Assessment.

In the California Current, increased variability has resulted in significant responses at higher trophic levels, including marine birds and mammals, and the cumulative effects of human-mediated stressors on marine predators can be difficult to unravel (Maxwell et al., 2013). For example, Cassin's auklets experienced an almost complete breeding failure in 2005-2006, due to changes in upwelling phenology that affected euphausiid prey populations (Sydeman and Thompson, 2010). Also, the California sea lion (*Zalophus californianus*), where the number of pups produced at the Channel Island reference site has shown a quadratic increase since the mid-1970s (Bograd et al., 2010), has experienced a recent decline in abundance and poor pup health. The spotted seals of the Yellow Sea also have decreased precipitously since the 1960s, due to overharvesting and habitat destruction; this has resulted in local extirpation and some rookeries support fewer than 150 individuals.

2.2 *Major pressures in the coastal area and major groups affected by the pressures*

In addition to global climate change impacts, including ocean acidification, there are a large number of coastal pressures affecting the North Pacific, similar to other coastal marine ecosystems, due largely to the diverse human-mediated activities in these environments. These include, but are not limited to: habitat loss; over-exploitation and fishing impacts; shipping; energy development/exploration; aquaculture; pollution (both direct and indirect), eutrophication and resulting impacts (pathogenic bacteria, harmful algal blooms; hyp/anoxia); species introductions/invasions; watershed alteration and physical alterations of coasts; tourism; and marine litter. None have been quantified at the scale of the North Pacific, but some regional patterns can be highlighted. Studies such as by Halpern et al. (2008) demonstrate that coastal area can be severely affected by human activities, including those in the western North Pacific. Furthermore, the Yellow and East China Seas area is one of the most densely populated areas of the world; approximately 600 million people inhabit this area, resulting in immense anthropogenic stressors on this coastal system. Urbanization in Asia is not unique and other coastal areas of the North Pacific also have experienced increased urbanization and an increase in a wide variety of ecosystem stressors.

Runoff from the Fraser and Columbia Rivers in the California Current region, the Amur River in the Sea of Okhotsk, the Changjiang River in the East China Sea, and the Pearl River and Mekong River in the South China Sea all play important roles in driving coastal processes and resulting ecosystem services. The Changjiang River is the world's third-longest river; its watershed of approximately 1.8 million km² encompasses about one-third of China's population and 70 per cent of its agricultural production. The widespread use of fertilizers for agricultural production has resulted in increased nutrient discharge to the coastal environment, causing increased eutrophication since the early 1970s. As a result, in the Yellow Sea, nitrogen:phosphorus and nitrogen:silicon ratios have been increasing basin-wide for decades (Yoo et al., 2010; Figure 7). This in

turn has resulted in an increase in the frequency and intensity of harmful algal bloom events and a shift in the phytoplankton community from diatoms to dinoflagellates that have affected ecosystem services and increased the severity of hypoxic events in the estuary (Yoo et al., 2010). A related anthropogenic activity that could significantly alter riverine discharges is large-scale water diversion projects that would result in less discharge to coastal environments around the North Pacific. For example, much of the flow of the Columbia and Fraser Rivers is used for agricultural production that can result in less discharge reaching ocean in some years. This can result in reduced nutrient inputs, which in turn lowers productivity, and that reduction adversely affects the diversity that depends on it. As increased climate variability intersects with growing human populations and increased irrigation demands in coastal environments, reduced river discharges could have profound impacts on coastal productivity and biodiversity.

Figure 7. Long-term trend in the nutrients along a transect across 36°N in the Yellow Sea. (a) Dissolved Inorganic Nitrate (DIN), (b) phosphates, (c) silicates, (d) N:P ratio (from Yoo et al., 2010, and modified from Lin et al., 2005).

The introduction of non-indigenous species continues to result in economic and ecological consequences, including negative impacts on native biodiversity (Sala et al., 2000). In the first synoptic study of non-indigenous species in the North Pacific, Lee II and Reusser (2012) identified 746 species that were present in, but not native to, at least one ecoregion in the North Pacific. Of these, 32 per cent were native elsewhere in the North Pacific, 48 per cent were native to regions outside the North Pacific, and 20 per cent were cryptogenic (of unknown origin). Furthermore, the Hawaiian and Northeastern Pacific regions had considerably more introduced species than the Northwestern Pacific (Lee II and Reusser, 2012; Figure 8). Given the continued increase in global trade, it is expected that the number of species that will be introduced to new environments also will increase. Combined with the high species richness and density of non-indigenous species already reported for many regions that have significantly altered

population, community, and ecosystem processes (Ruiz et al., 1997), additional, cumulative consequences of these invasions should be expected.

Figure 8. Number of non-indigenous species in central/northern North Pacific marine ecoregions (from Lee II and Reusser, 2012).

Other major stressors in the North Pacific include hypoxia, habitat destruction, pollution, and overfishing. However, none of these have been quantified at the scale of the North Pacific. Ocean acidification has dramatically impacted some calcifying organisms such as pteropods (Orr et al., 2005). Hypoxia has not only increased in the Yellow Sea, but continues to be a major pressure on coastal ecosystems in the eastern North Pacific, including off Oregon, with lethal consequences for benthic species (Grantham et al., 2004) and the western North Pacific, including Tokyo Bay where there has been a reduction in nutrient recycling (Kodama and Horiguchi, 2011). Further, the shoaling of this continental hypoxic zone has reduced habitat for several species, including some commercially important ones, which could alter ecosystem services. Habitat destruction is the leading cause of biodiversity loss (Sala et al., 2000). Many forms of habitat destruction and/or degradation are occurring around the North Pacific, including shoreline hardening/development and land creation, but quantifying the amount of habitat lost or impaired at the scale of the North Pacific remains a gap. Overfishing continues to be a major pressure in some coastal areas of the North Pacific. For example, in the Yellow Sea, overfishing has contributed to trophic cascades, resulting in

fishing down the food chain. In addition, Hutchings (2000) has shown that most stocks are very slow to recover from overfishing; this has consequences for ecosystem services and can adversely affect biodiversity. However, it should be noted that some managed fisheries systems in the North Pacific are doing well (Hilborn et al., 2005).

2.3 Major ecosystem services being affected by the pressures

2.3.1 Ecosystem services being lost

Although it is expected that ecosystem services being lost in coastal areas of the North Pacific would be consistent with those affected by these pressures globally, these data are lacking at the scale of the North Pacific. Worm et al. (2006) showed that reduced biodiversity increased the rate of resource collapse and decreased recovery potential, stability, and water quality; in contrast, restoration of biodiversity increased productivity and decreased variability. Furthermore, Francis et al. (1998) document the ecological consequences of major species re-distribution in the northeast Pacific following the major regime shift in 1977. Species invasions (and extinctions) also reorganize coastal ecosystems; Hooper et al. (2005) show that this has altered ecosystem goods and services in many well-documented cases and that most are difficult, expensive, or impossible to reverse.

The Pacific Ocean has the largest pool of low-oxygen water in the global ocean and in recent decades this pool has been expanding, with reduced oxygen concentrations observed both on the western and eastern sides of the basin (Ono et al., 2001; Emerson et al., 2004; Bograd et al., 2008). Generally, global climate models predict that global warming will lead to deoxygenation of the deep ocean because warmer surface waters will hold less oxygen and will be more stratified, resulting in less ventilation of the deep ocean (Sarmiento et al., 1998; Keeling et al., 2010). This will adversely affect benthic and pelagic ecosystems (Levin et al., 2009; Stramma et al., 2010; Koslow et al. 2011). Koslow et al. (2011) showed decreased mid-water oxygen concentrations were correlated with the decline of 24 mid-water fish taxa from eight families. Extended to larger scales, this could have significant adverse ecological and biogeochemical effects.

2.3.2 Human services being lost

Changes to marine biodiversity in coastal systems, and hence in ecosystem structure and function, can result from both direct impacts (e.g., exploitation, pollution, species invasion, and habitat destruction), or indirect impacts, via climate change and related perturbations of ocean biogeochemistry (e.g., acidification, hypoxia); these can have severe consequences on human services. Although no basin-scale studies quantifying these impacts were found, smaller-scale examples can highlight what might be expected. Myers and Worm (2003) demonstrated a dramatic decline in large predatory fish globally while Ovetz (2007) showed how industrial longline fishing has extensive negative economic and social consequences for coastal communities, especially those heavily reliant on fish protein, as biomass/species changes resulted in cascading effects, some of which were not predicted.

Also, Schroeder and Love (2002), who compared rockfish assemblages among three differently fished areas, showed large differences in fish density, size structure, and species composition. Only the protected area had both higher density and larger fish and greater species composition. Finally, Jackson et al. (2001) highlight how overfishing that precedes other forms of human disturbance to coastal ecosystems (pollution, degradation of water quality, and anthropogenic climate change) has resulted in ecological extinctions, especially of large vertebrate predators, with significant ecological and economic consequences.

In the western North Pacific, increased jellyfish blooms have had both direct and indirect negative impacts on human services. These blooms have reduced tourism, affected fishing and aquaculture and increased industrial costs, by, e.g., clogging the cooling-water intake screens of power plants (e.g., Purcell et al., 2007). Furthermore, blooms of gelatinous zooplankton have indirect effects on fisheries by feeding on zooplankton and ichthyoplankton; thus they are predators on and potential competitors with fish. Similarly, Cooley et al. (2009) showed that ocean acidification could affect a range of ecosystem services, such as fishery/aquaculture harvests, coastal protection, tourism, cultural identity, and ecosystem support, by adversely affecting calcifying marine organisms; they also showed that these impacts are expected to be greater in developing countries. Thus, more research is needed to understand how pressures are affecting services at the basin scale.

Coastal eutrophication is a growing concern, especially in the western North Pacific, where increases in nutrient loading have been linked with the development of large biomass blooms and harmful algal blooms, resulting in anoxia and toxic/harmful impacts on fisheries, aquaculture, ecosystems, human health and recreation (see Anderson et al., 2002; McKinnell and Dagg, 2010).

3. Oceanic Areas of the North Pacific

Unlike the coastal realm, where Spalding et al. (2007) proposed marine ecoregions, the oceanic realm of the North Pacific does not have a similar delineation scheme. Longhurst (2007) identifies zones in the North Pacific, but these are delineated more on the basis of oceanographic conditions and have relatively little weighting based on differences in biological diversity, species composition and productivity. It is probable that biological diversity in the oceanic North Pacific is also patchy, but the nature and scale of this patchiness needs to be determined.

3.1 Biodiversity Status and Trends

3.1.1 Primary producers

Using SeaWiFS satellite data, it is possible to detect large-scale changes in chlorophyll concentrations between 1998-2002 and 2003-2007. During this period, average

chlorophyll decreased in parts of the eastern North Pacific (with the exception of the California Current region) and increased in the western North Pacific (McKinnell et al., 2010; Figure 9). Also of note is the significant decline in average chlorophyll across the entire tropical/subtropical zone from Indonesia to Baja California, Mexico. However, at finer spatial and temporal scales, interannual variations in the location, timing, and magnitude of surface chlorophyll levels can be considerable around the North Pacific (Yoo et al., 2008). The general trend towards increased sea surface temperatures has resulted in an expansion of the low surface-chlorophyll extent in the subtropical North Pacific (Polovina et al., 2008). The areal increase in these low-chlorophyll waters of the central North Pacific from 1998 to 2006 is about 2 per cent per year (Batten et al., 2010); much of this expansion is eastward. The expansion of low surface-chlorophyll waters is consistent with increased vertical stratification due to ocean warming; this situation also has been identified in the South Pacific, North Atlantic, and South Atlantic (Polovina et al., 2008). Two satellite-derived time series exist for chlorophyll estimates (SeaWiFS and MODIS) for three major domains in the North Pacific (Batten et al., 2010; Figure 10). Both the central subarctic Pacific (CSP) and eastern subarctic Pacific (ESP) are completely oceanic; the western subarctic Pacific (WSP) does infringe upon the coastal environment and thus is subject to potential biases in spring-bloom characteristics (both concentration and seasonal variability were greatest for this domain). The spike in 2008 is obvious in both the ESP and CSP series. As noted above, the NPTZ is a key feature of the oceanic realm of the North Pacific and the transition-zone chlorophyll front (TZCF), which indicates a strong meridional gradient in surface chlorophyll at the boundary of the subarctic and subtropical gyre, migrates from south to north over 1,000 km annually (Polovina et al., 2001). Ocean productivity estimates derived from models and satellite observations (Behrenfeld and Falkowski, 1997) indicate high annual average phytoplankton production throughout the NPTZ, in particular in the west, related to the Kuroshio Extension region. Surface chlorophyll concentrations in the subtropical gyre are usually $<0.15 \text{ mg/m}^3$, whereas in the subarctic gyre and NPTZ they can be $>0.25 \text{ mg/m}^3$. Further, the expansion of the subtropical central gyre appears to have resulted in a change in primary productivity from a nitrate-limited, diatom-dominated phytoplankton community to one that is dominated by the N_2 -fixing *Prochlorococcus* (Karl, 1999; Karl et al., 2001).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 9. Ratio of mean chlorophyll a between 1998-2002 (denominator) and 2003-2007 periods. White colour indicates minimal change between the two periods (ratios = 0.9-1.1) (from McKinnell et al., 2010).

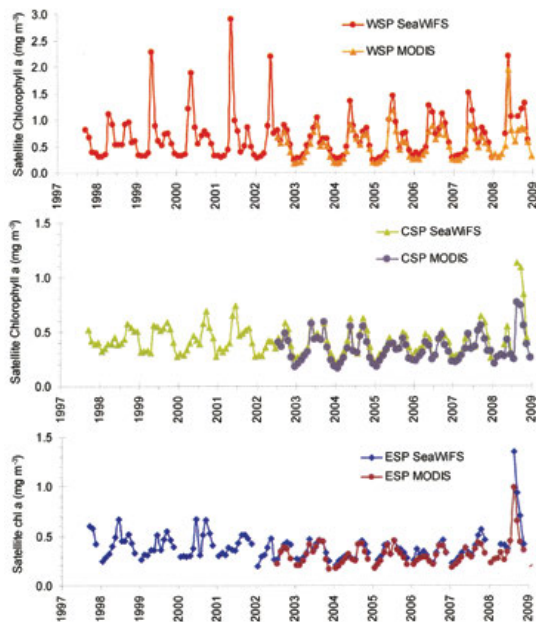

Figure 10. Chlorophyll a concentration for three regions (western subarctic Pacific (WSP), 155-172°E, 45-53°N; eastern subarctic Pacific (ESP), 140-155°W, 49.5-57°N; and central subarctic Pacific (CSP), 45-51°N 160-180°W) estimated from ocean colour-sensing satellites (from Batten et al., 2010).

3.1.2 Zooplankton communities

The NPTZ supports higher secondary productivity with respect to zooplankton biomass (McKinnell and Dagg, 2010) relative to other areas of the North Pacific, but no single comprehensive index exists for mesozooplankton time-series trends in the North Pacific.

Efforts at sub-basin scales are focused on the Alaska Gyre (Continuous Plankton Recorder (CPR) Survey, Line P), near Hawaii (Hawaii Ocean Time Series), and in the western Pacific along 155°E (Hokkaido University T/S *Oshoro Maru*). The Weathership surveys provided a zooplankton time series within the Alaska Gyre along Line P off the West Coast of Vancouver Island from 1956-1980 (see Fulton, 1983) but only intermittent sampling was conducted opportunistically, until more regular surveys were initiated in 1997 (Mackas and Galbraith, 2002). In addition, a CPR survey has provided additional zooplankton productivity and diversity measures since 2000 (Batten et al., 2010). Although zooplankton taxa are similar between nearshore and offshore stations, the dominance hierarchies differ between the shelf margin (Mackas et al., 2001) and the oceanic zone, (Mackas and Galbraith, 2002) where “subarctic oceanic” copepod species dominate. These species have distributions that span the Pacific basin north of the subarctic front and their interannual variability has been attributed both to temperature variability and increased transport by the North Pacific Current; this could result in redistribution of other marine species (Batten et al., 2010; Figure 11). Zooplankton time-series information also exists for station ALOHA, due to survey efforts by the Hawaii Ocean Time Series programme showed an increase in biomass between 1994 and 2004, after which it either stabilized or decreased slightly (Sheridan and Landry, 2004; Batten et al., 2010). The sampling along the 155°E transect provides an opportunity to look at productivity and diversity along a north:south gradient that encompasses the subarctic front, transition domain, subarctic boundary and subtropical current system. Batten et al. (2010) demonstrate that zooplankton biomass tends to be higher in the transition domain, and during the unprecedented warm year of 2008, this transition domain extended north into the historical zone of the subarctic front. Furthermore, taxonomic composition differs along this latitudinal gradient, with small and large copepods most prevalent at the subarctic front and transition domain; amphipods, euphausiids, chaetognaths, and copepods are represented in the subarctic boundary and subtropical current system.

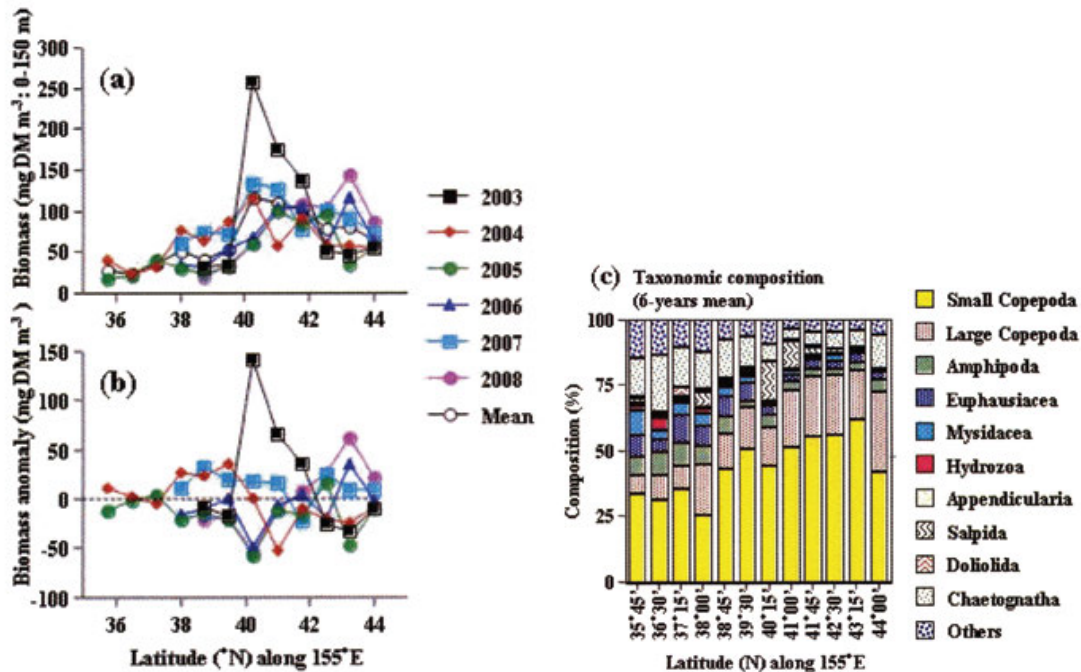

Figure 11. (a) Zooplankton dry biomass at 35°45'N-44°00'N along 155°E in the western North Pacific between 10-20 May, 2003-2008. (b) biomass anomalies compared to a 6-year mean, (c) and the taxonomic composition (from Batten et al., 2010).

3.1.3 Benthic communities

Perhaps with the exception of the limited snap-shot surveys of hydrothermal vent and seamount chain communities, no large-scale synoptic information is available on status of and trends in the diversity of benthic communities in the oceanic realm of the North Pacific. Much of this area is extremely deep, making survey efforts virtually impossible until recently, leaving much to be explored and characterized. The limited studies of vent communities in the North Pacific suggest high levels of endemism and diversity, especially within microbial communities that have different physiologies/metabolisms and thermal and salinity tolerances (e.g., Hedrick et al., 1992; Tunnicliffe et al., 1993). Furthermore, for these unique systems, the chemosynthesis that forms the basis of these deep-water food webs is critically important (Zhou et al., 2009). Stone and Shotwell (2007) have identified at least 140 coral species associated with seamounts in Alaska, representing at least six major taxonomic groups.

3.1.4 Higher trophic levels

Taxonomic diversity in both the eastern and western divisions of the North Pacific contains a mix of subtropical, temperate, subarctic and arctic species. The eastern North Pacific shows a gradient in diversity from east to west (Mueter and Norcross, 2002), with most fish biomass (and exploited stocks) on the continental shelf or coastal nearshore areas. Relatively little is known about the demersal species in the oceanic

realm due to the great depths. Some exploitation of species associated with seamounts occurs in the Gulf of Alaska and along the west coast of North America, for species such as sablefish (*Anaplopoma fimbria*), but within exclusive economic zones (EEZs), most seamounts have some level of protection due to restrictions on bottom-contact fishing gear and seamounts have been identified as Ecologically and Biologically Significant Areas (CBD, 2014). Furthermore, limited surveys/data mean that no time series are available.

The NPTZ once supported large-scale squid (*Ommastrephes bartrami*) driftnet fisheries, until a United Nations General Assembly ban on this gear was imposed in 1992 (see resolution 46/215) (PICES, 2004). Now the NPTZ supports the pelagic longline fishery based in Hawaii, with many vessels targeting tunas (including albacore, *Thunnus alalunga*), billfish, and squid. Albacore tuna is an economically important and widely distributed species in the North Pacific. Reported catches for albacore have been variable over time, but peaked in 1976 and 1997, and were rather depressed until the early 1990s, in part due to overfishing and below average recruitment (Cox et al., 2002; Batten et al., 2010; Figure 12). The catch of other tuna species, especially skipjack and yellowfin, has increased substantially since the 1950s (Sibert et al., 2006). However, Sibert et al. (2006) found that, although biomass was lower than that predicted in the absence of fishing (and perhaps higher than management targets), a reduction in the proportion of large fish, and the decreased trophic level of the catch suggest fisheries impacts on these top-level predators.

Figure 12. Total annual catch (tons reported) of North Pacific albacore tuna by all nations, 1966-2007 (from Batten et al., 2010, with data taken from ISC, 2008).

3.1.5 Other biota

As noted in 2(a) above, at least eleven species of marine birds and nine species of marine mammals designated as being at risk by the IUCN are found in the North Pacific. Although it appears that some populations are either stable or increasing, significant

threats remain. No additional entirely oceanic organisms are known to be designated as being at risk for the North Pacific.

3.2 Major pressures in the oceanic area and major groups affected by the pressures

It appears that the open oceanic area of the North Pacific is significantly less affected than coastal areas, where multiple point-source stressors are routinely encountered. However, the large-scale stressors that are affecting this oceanic area will require substantial international efforts to mitigate: specifically the climate impacts that have resulted in changes to both the physical and biogeochemical properties of the ocean. For example, global climate change is altering temperature, salinity, mixed-layer depth, and pCO₂ (acidification) in the open ocean. It has been demonstrated that marine organisms have shifted their distributions in response to changing marine conditions and this can result in local extinctions or incursions (Cheung et al., 2009). Furthermore, Cheung et al. (2009) suggest that under certain climate change scenarios up to 60 per cent of current biomass could be affected, and disrupt existing ecosystem services.

In addition to climate change, overfishing, illegal, unreported and unregulated fishing, and commercial shipping are major pressures in the oceanic North Pacific. Other major pressures in the oceanic areas of the North Pacific include ocean dumping and increased UV-B radiation (Gray, 1997). However, time series are unavailable for these oceanic stressors at the scale of the North Pacific and require more study.

A rather unique but more localized feature of the North Pacific that could be affecting the open-ocean environment is the Pacific garbage patch. Day and Shaw (1987) have shown that the amount of plastic material in the oceans has increased over historical levels, and as oceanic eddies represent favourable locations for accumulation of floating debris like plastic, it should not be surprising that Moore et al. (2001) found the highest concentrations of plastic recorded in the Pacific within the North Pacific Subtropical Gyre. Also, mesopelagic fish species such as myctophids, have been shown to ingest microplastics in both the eastern (Davison and Asch, 2011) and western (Van Noord, 2013) parts of the basin. Thus, there are potential implications of this microplastic on a variety of organisms and on ecosystem structure and function although the specific effects are less clear.

3.3 Major ecosystem services being affected by the pressures

3.3.1 Ecosystem services being lost

It has been shown that zooplankton on both sides of the North Pacific respond strongly to regime shifts and hence should be expected to respond similarly to climate change. Thus, if the results of the study by Beaugrand et al. (2010) for the North Atlantic translate to the reorganization of the planktonic ecosystem towards smaller organism dominance that affects carbon flows, there could be adverse effects. As in coastal ecosystems, oceanic fishing operations can cause different types of ecological impacts,

including bycatch of non-target species, habitat damage, mortality caused by lost or discarded gear, pollution, generation of marine debris, etc. Understanding the specific ecosystem services lost due to these activities will require more study.

3.3.2 Human services being lost

As in the coastal areas, changes to marine biodiversity (and hence to ecosystem structure and function) in oceanic systems also can result from direct impacts (e.g., fishing, pollution, and habitat destruction), and indirect impacts via climate change and related perturbations of ocean biogeochemistry (e.g., acidification) and these can have severe consequences on human services. As with the coastal areas, no basin-scale studies quantifying these impacts have been found and the lack of smaller-scale examples from oceanic areas of the North Pacific suggest that significant gaps exist. Although some studies have suggested fisheries targeting top predators have resulted in fewer large fish available for fishermen (Myers and Worm, 2003), other impacts on human services are less clear, suggesting that additional research is needed.

Historically, plastic debris was seen as a major concern for organisms that became entangled in or were ingesting it, especially marine mammals, seabirds, turtles, and fish (Laist, 1987). More recently, Boerger et al. (2010) showed that 35 per cent of the planktivorous fish sampled in the North Pacific Gyre (Garbage Patch) had ingested plastics; with this increased recognition of microplastics in the marine environment, the potential services being lost could be greater than initially thought, suggesting that more research is warranted.

4. Specific Areas of the North Pacific

The Bering Sea is a semi-enclosed subarctic sea that connects the North Pacific and Arctic Oceans and is bounded to the north by the Bering Strait and to the south by the Aleutian Archipelago. The deep central basin of this sea is bordered by a western shelf that extends from the Gulf of Anadyr along the Kamchatka Peninsula and a very broad eastern shelf extending from Alaska to the Russian Federation. Sea ice is important for determining the extent of the cold pool and regulates the timing of the spring bloom that has important cascading effects on ecosystem productivity and biological diversity (Stabeno and Hunt, 2002; Stabeno et al., 2007). Similarly, sea ice is a critical component of the structure and function of the Sea of Okhotsk. As with the Bering Sea, the Sea of Okhotsk has a relatively large shelf zone covering approximately 40 per cent of the basin (Udintsev, 1957). Predictions of potential impacts of global climate change are expected to be more severe at higher latitudes, suggesting native biodiversity could be adversely affected.

The South China Sea is a tropical system that includes diverse habitats such as mangrove forests, seagrass beds, and coral reefs. It lies within the Tropic of Cancer and has an area of 3.5 million km², of which 30 per cent is relatively deep sea with an average depth of

about 1,400 m. The unique feature of this sea includes the effect of a monsoonal climate and complex surface-current patterns (Huang et al., 2010 and references therein). The complex surface-current system greatly influences the structure of the marine ecosystem, which is a mixture of tropical and subtropical communities. In addition, the Pearl and Mekong rivers discharge a huge amount of nutrients into the South China Sea. These characteristics support very diverse fauna and flora, with over 2,300 fish species (Caihua et al., 2008), 58 cephalopod species, and many other invertebrates (Jia et al., 2004). However, the dramatic expansion of fishing effort and improved fishing technology (Pang and Pauly, 2001) resulted in over-exploitation of fisheries resources here (Cheung and Sadovy, 2004).

Two additional semi-enclosed seas around the North Pacific deserve attention, due to increased human population growth and anthropogenic stress (e.g., urbanization, pollution, fisheries, and invasive species). On the eastern side of the basin is the Salish Sea; this relatively large estuarine system extends from the Strait of Georgia/Desolation Sound in the north to Puget Sound in the south and the Strait of Juan de Fuca to the west. With over seven million people living in the basin, the number of anthropogenic stressors is large with many having the potential to adversely affect biodiversity and ecosystem structure and function. Similarly, on the western side of the basin is the Seto Inland Sea, which serves as an important transportation link between the Pacific Ocean and the adjacent sea and between industrial centres around Japan. Many unique species call the Seto Inland Sea home, but anthropogenic impacts have been severe. For example, increased frequency of red tide (HAB) events and jellyfish blooms, possibly due to changes in nutrients in recent years, have resulted in significant losses to fisheries and aquaculture production.

A number of major rivers terminate in the North Pacific, but the ones that empty into semi-enclosed basins can result in unique attributes there. For example, the Colorado River, that discharges into the upper portion of the Gulf of California, results in biophysical features and oceanographic characteristics (strong tidal mixing, significant freshwater influx) that has resulted in a high level of endemism, such as the vaquita (a critically endangered porpoise; Gerrodette et al., 2011). In addition, other marine megafauna, such as the totoaba (*Totoaba mcdonaldi*) and the curvina golfin (*Cynoscion othonopterus*) have disjointed distributions in the upper Gulf of California.

The Emperor Seamount Chain and Hawaiian Ridge extends over 3,000 km from the Aleutian Trench to the Hawaiian Islands and seamounts outside of the United States EEZ were identified as meeting the criteria for Ecologically and Biologically Significant Areas (CBD, 2014). Hart and Pearson (2011) identified 49 fish species associated with this seamount chain and commercial fisheries targeting North Pacific armorhead (*Pseudopentaceros wheeleri*) and Splendid alfonsin (*Beryx splendens*) have operated since the late 1960s. Further, Japanese surveys have identified a variety of coral species inhabiting this chain including; Gorgonaceans (8 families, 24 genera), Alcyonaceans (6 families, 7 genera), Antipatharians (4 families, 5 genera) and Scleractinians (6 families, 16 genera). Also, the more productive surface waters provide good foraging environments for a variety of seabird species, including albatrosses.

Other specific areas in the North Pacific include the Mariana Trench and deep-sea hydrothermal vents. The Mariana Trench is unique in being the deepest location known on Earth. Relatively few studies exist; most characterize or describe the unique bacterial communities inhabiting this environment. Globally, hydrothermal vents are relatively rare and a unique geological feature associated with the spreading of tectonic plates. These sites support chemosynthetically driven ecosystems that support a diverse array of unique organisms (see Chapter 45).

5. Special conservation status issues

5.1 Taxonomic groups

Corals are often identified as a taxonomic group requiring special conservation consideration. In the North Pacific, approximately 30 per cent of the world's coral reefs are located in Southeast Asia; Wilkinson et al. (1993) suggest that more than half are already destroyed and being destroyed by sedimentation, overexploitation (including by dynamite and chemicals), and pollution. In addition to these warm-water corals, a growing number of cold-water corals and sponges also should be considered (e.g., Stone and Shotwell, 2007). Both warm- and cold-water corals are covered in more detail in Chapters 43 and 42, respectively.

Pacific salmon (*Oncorhynchus* species) are ecologically, commercially, and culturally important around the North Pacific. As anadromous species they require both freshwater and marine habitats for their continued survival and productivity but increased human activities have reduced productive habitat (in both freshwater and marine environments) and resulted in a number of additional stressors. The unique homing nature of salmon has resulted in a high degree of stock differentiation. For example, Slaney et al. (1996) identified 9,662 anadromous salmon stocks in British Columbia and the Yukon, including 866 Chinook, 1,625 Chum, 2,594 Coho, 2,169 Pink, 917 Sockeye, 867 Steelhead and 612 sea-run Cutthroat trout stocks. Maintaining genetic diversity will be important for maintaining productive Pacific salmon stocks; a goal of Canada's Wild Salmon Policy (DFO, 2005).

Other taxonomic groups often identified for special conservation status include many large or apex predators, such as tunas, sharks, billfish, and sea turtles, including Loggerhead (*Caretta caretta*) and Olive Ridley (*Lepidochelys olivacea*) sea turtles often found associated with the NPTZ (Polovina et al., 2004), because of their vulnerability to overexploitation and their role in ecosystem structure and function. Each of these is considered in more detail in Chapters 37-41.

5.2 Habitats

Much remains to be discovered with respect to biodiversity in the North Pacific, but additional conservation measures could be considered for several habitats, including

hydrothermal vents, seamounts, large river deltas, kelp forests, mangroves, and coastal lagoons. In general, seamounts are often highly productive ecosystems that can support high biodiversity (Pitcher et al., 2007; Chapter 51), especially where their summit reaches into the euphotic zone and can be utilized by pelagic species, including marine birds and mammals. However, they can be susceptible to overfishing (see Douglas, 2011). Closer to the equator, coastal habitats, such as mangroves and coastal lagoons, are important habitats supporting relatively higher levels of biodiversity where degradation and/or complete destruction are significant concerns (see Chapters 48 and 49).

6. Factors for sustainability

It is clear that the maintenance of biodiversity contributes to ecosystem stability and sustainability and, like the other world oceans, the North Pacific is not unique in being under a barrage of anthropogenic stressors, that threaten the biodiversity and the sustainability it provides both for ecosystem services and human well-being. However, these stressors are not uniformly distributed across the North Pacific, with many more stressors noted for coastal ecosystems relative to the oceanic North Pacific. Furthermore, as research expands into the realm of how multiple stressors interact to affect biodiversity and ecosystem structure, function, and productivity, evidence is mounting that ecosystems are responding in complex, non-linear, non-additive - but cumulative - ways. Understanding and managing human activities to maintain or enhance biodiversity will make a substantial contribution to ecosystem sustainability globally (e.g., Hughes et al., 2005) and in the North Pacific specifically. However, as human populations, many of which are dependent on coastal or oceanic ecosystems for their existence, continue to expand around the North Pacific, there will be challenges.

Table 1. Interregional comparison of levels in biomass or abundance indices of fishes and invertebrates since 2003 compared to 1990-2002. Colour codes are: blue (increase), red (decrease), orange (change <|10%|), grey (not relevant to the region), and white (no data). The symbol © indicates that the evaluation for that taxon/region is based on catch data. In some regions, flatfish data were not reported by species, so any trends that are indicated apply only to the aggregate of flatfish species caught in that region, and not necessarily to the individual species listed in the column headers (from McKinnell et al., 2010).

Koniuji Is., C. Aleutian Islands	Unidentified murre	Population trend	2001 - 2007	No trend	Dragoo, pers. comm.
Ulak Is., C. Aleutians	Unidentified murre	Population trend	1998 - 2008	Up 6.2% y ⁻¹	Dragoo, pers. comm.
C. Aleutian Islands	Harbour seal	Population trend	1977 - 82 vs. 1999	Down 66%	Allen & Angliss 2009
Buldir Is., W. Aleutians	Black-legged kittiwake	Population trend	1998 - 2007	No trend	Dragoo, pers. comm.
Bering Sea Stock	Harbour seal	Population trend	1980s - 1990s	Probably down	Allen & Angliss 2009
Western Aleutian Islands	Harbour seal	Population trend	1977 - 82 vs. 1999	Down 86%	Allen & Angliss 2009
Aleutian Islands	Steller sea lion	Pup count	1994 - 2009	Down 1.6% y ⁻¹	DeMaster 2009
Western Aleutian Islands	Steller sea lion	Pup count	1997 - 2008	Down 10.4% y ⁻¹	DeMaster 2009

Table 4c. Piscivorous species in the western Pacific, including western Bering Sea, Sea of Okhotsk, Oyashio, and Yellow Sea (from McKinnell et al., 2010).

Location	Species	Metric	Dates Used	Trend	Reference
E. Kamchatka	Steller sea lion	Non-pup count	2001 – 2008	No trend	Burkanov et al. 2009
Commander Islands	Steller sea lion	Non-pup count	2000 - 2008	No trend	Burkanov et al. 2009
Commander Islands	Northern fur seal	Pup production	1972 - 76 vs. 2002 - 06	No trend	Olesiuk 2009
Kuril Islands	Northern fur seal	Pup production	1972 - 76 vs. 2002 - 06	Up, 3% y ⁻¹	Olesiuk 2009
Robben Is., Okhotsk	Northern fur seal	Pup production	1972 - 76 vs. 2002 - 06	No trend	Olesiuk 2009
Kuril Islands	Steller sea lion	Non-pup count	2000 – 2007	Up	Burkanov et al. 2009
N. Okhotsk	Steller sea lion	Non-pup count	1996 – 2006	Up	Burkanov et al. 2009
Sakhalin Island, Okhotsk	Steller sea lion	Non-pup count	2000 – 2009	Up	Burkanov et al. 2009
Talan Is., Okhotsk	Horned puffin	Population count	1989 vs 2008	Up	Andreev et al., In Press
Talan Is., Okhotsk	Black-legged kittiwake	Population count	1989 vs 2008	Up	Andreev et al., In Press
Talan Is., Okhotsk	Unidentified murre	Population count	1989 vs 2008	No trend	Andreev et al., In Press
Teuri Is., W. Hokkaido	Japanese cormorant	Nest count	2007 - 2008	No trend	Watanuki, pers. comm.
Teuri Is., W. Hokkaido	Rhinoceros auklet	Population count	1985 -1997	Up	Watanuki, pers. comm.

Chapter 36D. South Pacific Ocean

Contributors: Karen Evans (lead author), Nic Bax (convener), Patricio Bernal (Lead member), Marilú Bouchon Corrales, Martin Cryer, Günter Försterra, Carlos F. Gaymer, Vreni Häussermann, and Jake Rice (Co-Lead member and Editor Part VI Biodiversity)

1. Introduction

The Pacific Ocean is the Earth's largest ocean, covering one-third of the world's surface. This huge expanse of ocean supports the most extensive and diverse coral reefs in the world (Burke et al., 2011), the largest commercial fishery (FAO, 2014), the most and deepest oceanic trenches (General Bathymetric Chart of the Oceans, available at www.gebco.net), the largest upwelling system (Spalding et al., 2012), the healthiest and, in some cases, largest remaining populations of many globally rare and threatened species, including marine mammals, seabirds and marine reptiles (Tittensor et al., 2010).

The South Pacific Ocean surrounds and is bordered by 23 countries and territories (for the purpose of this chapter, countries west of Papua New Guinea are not considered to be part of the South Pacific), which range in size from small atolls (e.g., Nauru) to continents (South America, Australia). Associated populations of each of the countries and territories range from less than 10,000 (Tokelau, Nauru, Tuvalu) to nearly 30.5 million (Peru; Population Estimates and Projections, World Bank Group, accessed at <http://data.worldbank.org/data-catalog/population-projection-tables>, August 2014). Most of the tropical and sub-tropical western and central South Pacific Ocean is contained within exclusive economic zones (EEZs), whereas vast expanses of temperate waters are associated with high seas areas (Figure 1). The eastern and western extremes of the ocean basin contain two major boundary currents: the poleward-flowing East Australian Current (EAC), which runs along Australia's North-West shelf in the west (Ridgway and Dunn, 2003) and the northward-flowing Humboldt Current, which runs along South America's continental shelf in the east (Montecino and Lange, 2009). The dominant shallow water ecosystems of the region are tropical coral reef and lagoon systems and mangrove communities in the sub-tropics and tropics and temperate rocky reefs and kelp beds in temperate zones. Other marine communities across tropical, sub-tropical and temperate zones include rocky intertidals, mudflats, seagrass beds, estuaries and salt marshes in inshore areas and seamount, hydrothermal vents and trenches in offshore zones. Five Large Marine Ecosystems (www.lme.edc.uri.edu) have been defined across the South Pacific Ocean, including the Humboldt Current, the northeast Australian shelf, east-central Australian shelf, southeast Australian shelf and New Zealand shelf.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

With the kind assistance of the FAO.

Physical processes of the basin play an important role in driving shelf and coastal marine processes and climate across the region. Northern parts of the South Pacific Ocean are dominated by a basin-scale sub-tropical gyre, whose northern branch forms the South Equatorial Current (SEC; Figure 2; Reid, 1997). The SEC is predominantly driven by prevailing easterly trade winds and as water moves from the east to the west, a thick layer of warm water ($>29^{\circ}\text{C}$), the Western Warm Pool (WWP) is formed west of $\sim 170^{\circ}\text{E}$ (Picaut et al., 1996). As the westward-flowing SEC encounters islands and land masses, it splits into several currents and jets, some of which, particularly the New Guinea Coastal Under-current (NGCU), contribute to the Equatorial Under-Current (EUC; Figure 2). The EUC contributes significantly to equatorial thermocline waters and is thought to modulate the El Niño-Southern Oscillation (ENSO; Grenier et al., 2011). The EUC is also the primary source of iron in the photic layer of the region, and variability in the EUC drives regional biological productivity (Ryan et al., 2006). Once the jets meet the land mass of Australia, they

form the poleward-flowing western boundary current, the East Australian Current (EAC).

As the EAC flows south along the Australia's North-West shelf, eddies separate from the main body of the EAC, forming a region of upwelling and downwelling. Outflow from the EAC forms a band of zonal eastward flow, the Tasman Front. The band of zonal eastward flow associated with the Tasman Front contributes to the East Auckland Current and eventually to the subtropical gyre moving northward and contributing to the SEC.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Major currents of the South Pacific Ocean. NECC: North Equatorial Counter-Current; NGCU: New Guinea Coastal Under-current; EUC: Equatorial Under-Current; SEC: South Equatorial Current; SECC: South Equatorial Counter-Current; ITF: Indonesian Through-Flow; QC: Queensland Current; EAC: East Australian Current; LC: Leeuwin Current; ACC: Antarctic Circumpolar Current.

The eastern boundary of the gyre combines waters from the trans-Pacific West Wind Drift (WWD) with a northward-flowing arm of the Antarctic Circumpolar Current. At its arrival on the South American coast, the WWD diverges into the poleward-flowing Cape Horn Current and the northward-flowing Humboldt or Peru-Chile Current (PCC) which flows along western South America (Strub et al., 1998). Similarly to the EAC, the PCC is characterized by significant mesoscale variability in the form of fronts, eddies and filaments (Hill et al., 1998; Montecino and Lange, 2009), which intensify closer to the coast. The Humboldt Current system is highly productive due to the combined effect of advection of nutrient-rich waters from the south and upwelling. Cool, nutrient-rich waters are brought to the surface north of ~40°S as a result of coastal upwelling driven by winds and the impingement of the subtropical gyre along the coast (Morales et al., 1996; Montecino and Lange, 2009). Upwelling occurs seasonally across the ~30°S-40°S region (Strub et al., 1998; Shaffer et al., 1999), whereas in Northern Chile and off the Peruvian coast, upwelling is permanent (Hill et al., 1998; Vasquez et al., 1998). As the EUC encounters the Galápagos Islands it splits: one arm forms an under-current that reaches South America near the equator and becomes the poleward-flowing Gunther or Peru-Chile Under-Current, which flows

beneath the PCC across the slope and outer shelf. The other arm flows to the southeast of the Galápagos Islands and forms the poleward-flowing Peru-Chile Counter-Current which divides the PCC into two branches: a coastal and an oceanic branch (Strub et al., 1998).

The physical dynamics of the region vary markedly with ENSO: during La Niña, stronger trade winds increase the intensity of the SEC, pushing the WWP west, and upwelling and productivity in the Pacific Equatorial Divergence (PEQD) increase. During El Niño, trade winds weaken, the SEC weakens, allowing the WWP to extend east and upwelling and productivity in the PEQD decrease (Ganachaud et al., 2011). Shifts in the intensity of the SEC have flow-on effects for both basin-scale circulation and shelf systems at the basin edges where shifts result in weakening/strengthening of the boundary currents.

Interaction of the easterly trade winds and ocean currents with island topography modifies the flow of water downwind of the islands, creating counter-currents, eddies and upwelling. This results in enhanced mixing of deeper nutrient-rich waters with surface waters, increasing biological production and enriching coastal waters (Ganachaud et al., 2011). For many South Pacific islands, these processes support rich coastal ecosystems in regions which would otherwise be regarded as oligotrophic.

Coordinated assessments of the state of the environment (including the marine environment) have been undertaken by several countries over the last decade, including: Australia (State of the Environment Committee, 2011), French Polynesia (Gabrie et al., 2007), Kiribati (Ministry of Environment Lands and Agricultural Development, 2004), New Zealand (Ministry for the Environment, 2007), Palau (Sakuma, 2004), Peru (World Bank, 2006), Samoa (Ministry of Natural Resources and Environment, 2013), the Solomon Islands (Ministry of Environment Conservation and Meteorology, 2008) and Vanuatu (Mourgues, 2005). A number of regional assessments have also been undertaken: The State of the Environment in Asia and Pacific 2005 (UNESCAP, 2005), the Pacific Environment Outlook (McIntyre, 2005), the Global International Waters Assessment (UNEP, 2006a), including the Global Assessment and Synthesis Reports from the Millennium Ecosystem Assessment (www.unep.org/maweb/en/Global; UNEP 2006b), the Pacific Ocean Synthesis (Center for Ocean Solutions, 2009), the UNEP Large Marine Ecosystems Report (Sherman and Hempel, 2009), the Global Biodiversity Outlook (Secretariat of the Convention on Biological Diversity, 2010), the Global Environment Outlook (UNEP, 2012) and the Pacific Environment and Climate Change Outlook (SPREP, 2012). This chapter summarizes the available assessments and current knowledge from peer-reviewed literature on the status of, immediate and long-term concerns for, and threats to the coastal and shelf marine ecosystems of the South Pacific Ocean.

2. Status and trends of biodiversity

Across the South Pacific Ocean, the most reliable time-series of the status of biodiversity across the region from which trends can be derived are largely limited to

high-level indicators, including some oceanographic parameters (e.g., sea-surface temperatures, sea level) and industrial commercial fisheries (e.g., tuna, anchoveta). Indicators of pressures and impacts are similarly limited to high-level indicators of population and socio-economic measures. Long-term monitoring initiatives (e.g., those spanning multiple decades) are sparse and are largely limited to within-country monitoring of a few indicators associated with specific objectives. The TAO/TRITON array, which consists of approximately 70 moorings deployed across the tropical Pacific Ocean to collect primarily physical and meteorological data, can be considered the most extensive ocean observation system currently functional in the South Pacific Ocean. For a short period in the late 1990s, biological and chemical sensors (i.e., continuous pCO₂ analyzers, three biospherical irradiance meters, nitrate analyzers, and PAR sensors) were added to several buoys. This enabled continuous monitoring of biological productivity during deployment, improving understanding of biophysical coupling from inter-annual (ENSO events) to intra-seasonal (tropical instability waves) time scales (e.g., Chavez et al., 1998; Chavez et al., 1999; Strutton et al., 2001). More recently, several regional alliances and programmes under the Global Ocean Observing System (GOOS), including the Australian Integrated Marine Observing System (www.imos.org.au; see Lynch et al., 2014), Pacific Islands Global Ocean Observing System (PI-GOOS) and GOOS Regional Alliance for the South-East Pacific region (GRASP) are expanding physical and biological monitoring of ecosystems across the South Pacific Ocean.

2.1 Primary producers

High inter-annual variability in surface chlorophyll concentrations throughout the South Pacific Ocean tends to be associated with the eastern boundary upwelling of the Humboldt Current system, restricted regions east of New Zealand, around islands and in coastal margins where variability in local dynamics is high (Dandonneau et al., 2004). Although information on the assemblages of plankton is available for most coastal and shelf regions across the South Pacific Ocean, data on seasonal and inter-annual variability or longer-term trends are sparse.

In the western equatorial region, during the northwest monsoon, an area of upwelling develops along the coast of Papua New Guinea (Ueki et al., 2003), bringing nutrient-rich waters to the surface and resulting in increased concentrations of surface chlorophyll which are evident in satellite imagery (Messié and Radenac, 2006). This pool of nutrient- and chlorophyll-rich waters advects eastward during westerly wind events with concentrations of phytoplankton rapidly declining as the oligotrophic waters of the WWP are reached. This decline in concentration is thought to be associated with low nitrate concentrations in surface waters resulting from a stratified salinity layer at the base of the WWP that creates a barrier layer to nutrients (Messié and Radenac, 2006). Shifts in the nitrocline depth, which allow mixing of surface waters with deep nutrient-rich waters associated with eastward expansion of the WWP during La Niña events, contribute to positive primary production anomalies observed in the western equatorial Pacific Ocean (Radenac et al., 2001; Turk et al., 2001; Messié et al., 2006). This is further enhanced by changes in NGCU circulation which enhances iron transport from the shelf and upper slope of Papua New Guinea to the EUC (Ryan et al., 2006). Diatoms in the region have been

observed to increase their concentration fourfold as a result of this increased nutrient input (Rousseaux and Gregg, 2012).

In situ sampling across the shelf region of north-eastern Papua New Guinea has recorded a phytoplankton community during the austral summer dominated by nanoeucaryotes and *Prochlorococcus* (Everitt et al., 1990; Higgins et al., 2006). Variability in phytoplankton community assemblages has been observed to be high with a gradient in concentrations from the coast (high) to waters further offshore (low). High nitrogen-fixation rates have also been observed in coastal regions of north-east Papua New Guinea, associated with nanoplankton cyanobacteria and *Trichodesmium* spp. (Bonnet et al., 2009). Across the western equatorial region, nitrogen fixation is dominated by fractions of less than 10 mm associated with unicellular photosynthetic diazotrophs.

Further to the south in the western Pacific Ocean (south of ~23°S) and in the region of New Caledonia, seasonal enrichment of surface chlorophyll concentrations during the austral winter months has been observed and is associated with surface cooling and vertical mixing (Dandonneau and Gohin, 1984; Menkes et al., 2015). Assemblages are dominated by the cyanobacteria *Prochlorococcus*, with lower concentrations of *Synechococcus* and picoeukaryotes (Dandonneau et al., 2004; Menkes et al., 2015). Around the New Caledonian and Vanuatu archipelagos, blooms of *Trichodesmium* spp. are often reported during the austral summer months and have been associated with increased nutrient inputs from islands as a result of seasonal patterns in rainfall (Rodier and Le Borgne, 2008; Le Borgne et al., 2011), although direct linkages between *Trichodesmium* blooms and seasonal land-based nutrient input are not clear (Peter Thompson, CSIRO, pers. comm., 21 August 2014). In contrast to the productivity observed around high islands, such as Papua New Guinea, New Caledonia and Vanuatu, productivity around low islands and coral atolls is rarely enhanced. This is because in general these islands and atolls release very few sediments and nutrients into coastal and shelf regions (Le Borgne et al., 2011).

Overall, a distinct latitudinal gradient in phytoplankton is observed in eastern Australian coastal and shelf waters: higher concentrations of the picoplankton *Prochlorococcus* and *Synechococcus* are found in the north, which gradually decline to the south (Thompson et al., 2011). Tropical shelf waters are typified by phytoplankton communities similar to those observed in the oligotrophic waters of the northern Coral Sea and those around New Caledonia and southern parts of the Coral Sea. The Great Barrier Reef lagoon supports a high diversity of nanoplankton and picoplankton species, which demonstrate a seasonal progression in community structure and biomass across the austral summer months (chlorophyll *a* concentrations have been observed to increase by up to 50 per cent). In outer regions of the lagoon this is associated with intrusion of nutrient-enriched Coral Sea water (Furnas and Mitchell, 1986; Brodie et al., 2007) and in inner regions associated with sediment-laden river plumes (Revelante et al., 1982). Surface chlorophyll concentrations are frequently, although not always, higher in lagoon regions of the Great Barrier Reef than in adjacent shelf regions (Furnas et al., 1990). Assessments of surface chlorophyll *a* concentrations throughout the Great Barrier Reef lagoon suggest that relatively short (5 – 8 years) time-series may provide spurious estimates

of longer-term trends, given the high variability in multi-year patterns (Brodie et al., 2007).

In general, phytoplankton assemblages in the EAC are diatom-dominated in inshore regions; flagellates dominate offshore regions (Young et al., 2011). Assemblages associated with the mesoscale features of the EAC are highly variable with distinct spatial separation of phytoplankton species observed across individual eddy systems (Jeffrey and Hallegraeff, 1980; Jeffrey and Hallegraeff, 1987). Further south, across the temperate neritic province, episodic phytoplankton blooms driven by seasonal intrusions of nitrate-rich water into the euphotic zone occur (Hallegraeff and Jeffrey, 1993; Bax et al., 2001). These seasonal blooms can include diatoms such as *Pseudonitzschia*, which is responsible for amnesic shellfish poisoning (Hallegraeff, 1994), *Thalassiosira partheneia* (Bax et al., 2001), and also coccolithophorids (e.g., Figure 3).

Waters around the north of New Zealand typically demonstrate similar seasonal patterns in chlorophyll concentrations to those observed in the broader Tasman Sea: higher concentrations in the austral spring and autumn and lowest in the winter. Phytoplankton maximas in north-eastern New Zealand shelf regions have been associated with diatom blooms with community succession to dinoflagellates, nanoflagellates and picophytoplankton as blooms decline (Chang et al., 2003). Along the west coast, diatoms are most abundant close to shore, phytoflagellates most abundant seaward of shore areas and dinoflagellates most abundant in areas further offshore (Chang, 1983). In the High-Nitrate-Low-Chlorophyll (HNLC) subantarctic waters southeast of New Zealand, episodic elevated chlorophyll events have been observed (Boyd et al., 2004) with phytoplankton assemblages dominated by cyanobacteria (Bradford-Grieve et al., 1997) and diatoms (Boyd et al., 1999).

Figure 3. A coccolithophorid bloom in the coastal waters of north-east Tasmania, Australia. Photo taken in October 2004. Image courtesy of CSIRO, Australia.

Declines in austral spring bloom biomass and growth rates of chlorophyll *a* along the south-eastern Australian region have been suggested to be associated with a long-term decrease in dissolved silicate concentrations. This decrease is thought to be driven by increased intensity in the EAC (Thompson et al., 2009) associated with decadal climate variability (see Section 3). Range expansion of some species has also been reported (Hallegraeff, 2010). The drivers of these expansions have not been established and may be associated with eutrophication, ballast water translocation or oceanographic changes associated with a changing climate (see also Section 3).

Further east in the waters of the PCC, marine ecosystem dynamics are driven by intra-seasonal, annual and inter-annual changes in the upwelling systems that typify the region (Alheit and Niquen, 2004; Montecino and Lange, 2009). Productivity is highest in inshore areas of high upwelling. Coastal upwelling regions off Peru are mainly composed of early successional stages of small diatoms (5-30 nm) with high re-production rates, whereas in later successional stages, they are characterized by larger species (Tarazona et al., 2003). Small phytoplankton, including nano- and picoplankton, have been reported to account for a large proportion (> 60 per cent) of the primary production and chlorophyll *a* concentration in the coastal waters between 18°S and 30°S. (Escribano et al., 2003).

South of ~30°S, where upwelling is seasonal, coastal surface chlorophyll *a* concentrations demonstrate a maximum in the austral summer. Further offshore, concentrations are out of phase with upwelling events, demonstrating a winter maximum potentially associated with offshore advection of productivity away from coastal regions by eddy systems (Morales et al., 2007). Assemblages are diatom- and silico-flagellate-dominated; similar assemblages are observed offshore associated with coastally derived filaments and eddy systems. Assemblages demonstrate little variability throughout the year. The northern Coquimbo upwelling system, despite being an area of persistent upwelling, demonstrates lower production than the more southern Antofagasta and Concepción Shelf areas where production values have been reported to be some of the highest in the ocean (Daneri et al., 2000). Abundances vary considerably, both temporally and spatially, in response to high variability in upwelling systems and associated coastally derived filaments and eddy systems (Daneri et al., 2000; Morales et al., 2007). Such variability makes describing trends in productivity associated with climate variability (such as ENSO) difficult over shorter time scales (Daneri et al., 2000).

2.2 *Zooplankton communities*

Within coastal mangrove and seagrass systems in the tropics and sub-tropics, the composition of zooplankton communities is principally controlled by diel changes in tidal flows and seasonal changes in salinities, influenced by the seasonal outflow of freshwater from estuaries or seasonal changes in rainfall in coastal lagoon systems (Grindley, 1984; Duggan et al., 2008). Estimates of the biomass of zooplankton in inshore and estuarine systems tend to be much higher than adjacent coastal regions – tropical Australian mangrove and seagrass habitats have been recorded as having a zooplankton biomass an order of magnitude higher than adjacent embayments (Robertson et al., 1988). Similar spatial gradients in abundance have been recorded

elsewhere in the subtropical western Pacific Ocean (Kluge, 1992; Champalbert, 1993; Le Borgne et al., 1997; Carassou et al., 2010).

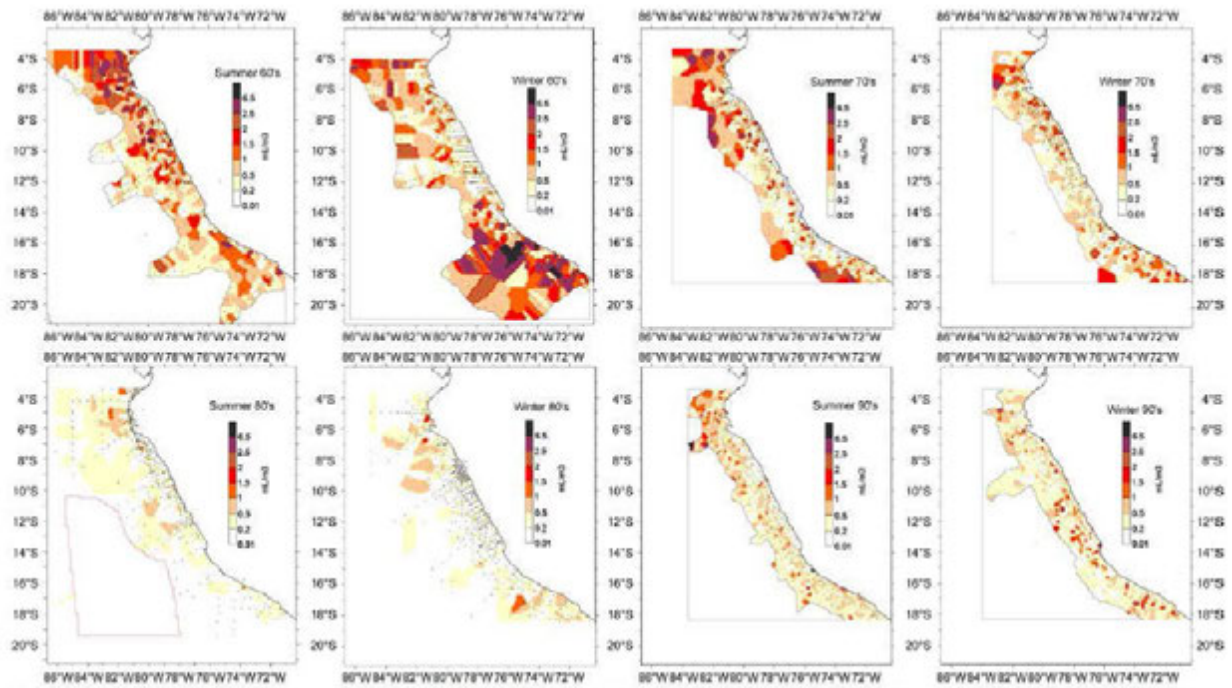

Within coral reef systems, abundances of zooplankton can vary in relation to the structure of reef/lagoon systems. Enclosed and semi-enclosed atolls (e.g., the Tuamotu archipelago in French Polynesia) have higher densities of zooplankton species than lagoon systems that are more open and have regular exchange of waters with adjacent open oceans (e.g., Uvea lagoon in New Caledonia and the Great Barrier Reef lagoon in Australia; Le Borgne et al., 1997; Niquil et al., 1998).

Composition of zooplankton in tropical and subtropical coastal regions can vary on scales of metres; assemblages in mangrove forests, mangrove streams, coral mounds and sandy floor areas vary distinctly (Jacoby and Greenwood, 1988; Robertson et al., 1988). Mangrove systems have been observed to contain higher amounts of meroplankton species than seagrass habitats, which are more similar to habitats further offshore in bay and lagoon areas (Robertson et al., 1988). Reef systems have been observed to comprise a mix of resident, swarming and demersal species, most of which associate with benthic communities during the day, ascending into the water column during the night. The resident demersal component of zooplankton communities on reef systems can be 5-20 times more abundant than pelagic communities (Alldredge and King, 1977; Roman et al., 1990). In the western Pacific Ocean, cyclopoid copepods, such as *Oithona* spp., and calanoid copepods, such as *Parvocalanus* spp., have been recorded as being numerically the most abundant taxa across all habitats (Robertson and Howard, 1978; Saisho, 1985; Jacoby and Greenwood, 1988; Robertson et al., 1988; Roman et al., 1990; Kluge, 1992; Robertson and Blaber, 1993; Le Borgne et al., 1997; McKinnon and Klumpp, 1998; Duggan et al., 2008). Abundances of zooplankton in the tropical coastal waters of northern Peru are some of the highest recorded in the eastern Pacific Ocean and are associated with high primary production resulting from coastal upwelling across the region (Fernández-Álamo and Färber-Lorda, 2006).

Zooplankton communities in tropical and subtropical habitats demonstrate high variability across tidal to seasonal time scales (Jacoby and Greenwood, 1988; Hamner et al., 2007). The biomass of most communities tends to be highest in the austral summer in the western Pacific Ocean and is associated with peaks in primary productivity (see Section 2.1) and seasonal spawning of invertebrate and vertebrate plankton predators. Not all species demonstrate peaks in abundance during the austral summer; some species demonstrate a peak in the austral winter (Jacoby and Greenwood, 1988). In the eastern Pacific Ocean, increased zooplankton in coastal upwelling regions occurs after winter wind-driven production with peaks in October–December (Fernández-Álamo and Färber-Lorda, 2006).

Inter-annually, zooplankton community structure and abundances in tropical and sub-tropical habitats vary in association with rainfall, associated terrestrial run-off and turbulence, water temperatures, adjacent offshore upwelling in the western Pacific Ocean (Robertson et al., 1988; McKinnon and Thorrold, 1993) and inter-annual variability in upwelling in the eastern Pacific Ocean associated with ENSO. Although clear patterns associated with ENSO cycles are not yet established (Alamo and Bouchon, 1987; Fernández-Álamo and Färber-Lorda, 2006), zooplankton abundances have been observed to be higher during “cold” decades, particularly in

the 1960s, than more recent “warm” decades and have been associated with regime shifts in fish communities in the region (see Section 2.4; Figure 4; Ayón et al., 2004). Similar shifts in the size distribution of zooplankton have also been observed in the eastern Pacific Ocean with smaller zooplankton dominating during warmer, lower upwelling conditions (Ayón et al., 2011).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 4. Spatial and temporal variability in zooplankton biomass in the tropical and subtropical coastal waters of the eastern South Pacific Ocean. Reproduced from Ayón et al., 2004.

Zooplankton communities in temperate waters of the South Pacific Ocean, similarly to those in the tropics and sub-tropics, are dominated by copepod species (Tranter, 1962; Bradford, 1972; Escribano et al., 2007). Swarming gelatinous species, such as salps, can also dominate; increased abundance of salps is associated with declines in copepod abundances (Tranter, 1962). In the western South Pacific Ocean, assemblages and abundances are spatially and temporally highly variable, reflecting high variability in the physical features and primary productivity of the EAC. Eddy systems associated with the EAC can contain distinct abundances and assemblages of taxa in comparison to adjacent waters and other eddies, which evolve, becoming less distinct as the eddy ages (Griffiths and Brandt, 1983; McWilliam and Phillips, 1983; Tranter et al., 1983; Young, 1989). Further south, the shelf waters off south-eastern Australia are dominated by the euphausiid *Nyctiphanes australis*; peaks in abundance occur in the austral autumn months in association with seasonal upwelling onto shelf regions and resulting peaks in primary production (Young et al., 1996). The temperate zooplankton communities of east New Zealand waters are also typified by *N. australis*, gelatinous zooplankton and copepod species (Jillet, 1971; Jillet, 1976; Bradford, 1972). Peaks in abundance vary between species, but most species have been observed to demonstrate peaks in abundance in the late austral

winter/early spring (Bradford, 1972). Shifts in the composition of zooplankton communities from predominantly cold water species to more warm water species have been reported from the shelf waters off south-eastern Australia and have been associated with large shifts in regional oceanography (Johnson et al., 2011).

In the eastern South Pacific Ocean, temperate zooplankton communities are dominated by copepods, euphausiids and gelatinous zooplankton (Escribano et al., 2007). Community composition in coastal and shelf regions off Peru tends to correspond with large oceanographic features throughout the region; coastal upwelled waters are comprised of copepod species and meroplanktonic larvae. Waters further offshore are largely comprised of large holoplankters, such as euphausiids, copepods, siphonophores and chaetognaths (Tarazona et al., 2003; Fernández-Álamo and Färber-Lorda, 2006; Ayón et al., 2011). In the coastal regions of central Chile, where assemblages are influenced by subantarctic waters, copepods dominate offshore shelf regions, whereas euphausiids dominate the fjord region (Escribano et al., 2003). Abundances of zooplankton in the region are both strongly and positively associated with the vertical distribution of the oxygen minima zone. Abundances of gelatinous zooplankton have been observed to peak in the austral winter and spring; copepods demonstrate a peak in the austral spring and summer in association with seasonal upwelling conditions. Euphausiids, dominated by the endemic *Euphausia mucronata*, demonstrate little seasonal variability in abundances (Gonzalez and Marin, 1998; Escribano et al., 2007). Little inter-annual variability in species assemblages and abundances has been observed in the region, although shifts in species assemblages of zooplankton in coastal Chilean waters have been associated with ENSO phase. Species alternate between copepods and euphausiids during upwelling events associated with La Niña and cyclopoid copepods during warmer events associated with El Niño (Hidalgo and Escribano, 2001).

2.3 Benthic communities

Benthic communities across the South Pacific Ocean occupy a diverse range of habitats, including estuaries, mangroves, rocky intertidals, seagrass beds, kelp forests, soft bottoms (ranging from sandy to muddy), coral reefs and rocky reefs, and form one of the richest assemblages of species in the marine environment (Snelgrove, 1999). Many species are subject to recreational, artisanal and commercial fisheries. These include bivalves (e.g., giant clams, scallops) echinoderms (e.g., sea cucumbers, sea urchins) and gastropods (e.g., *Trochus*, abalone). Benthic fish and macro-invertebrates are discussed in Section 2.4.

Given the diversity of benthic community habitats across the South Pacific Ocean, few have been sampled comprehensively. Most assessments have focused on classification and documentation of the sediments or plants forming the basis of a habitat type or on individual species, rather than on benthic community assemblages (e.g., Kennelly, 1987; Heap et al., 2005; Fisher et al., 2011; Waycott et al., 2009). Because of a lack of assessments, surveys often discover previously undescribed species that may only be documented once in a survey (Snelgrove, 1999; Williams et al., 2010). Establishing trends in benthic communities in most regions is at present difficult, in large part due to the sparse data available across all habitat types and the

high variability in faunal assemblages associated with each habitat (e.g., Waycott et al., 2005).

Coral reef communities are one of the better documented benthic communities throughout the South Pacific Ocean. Although 75 per cent of the world's coral reefs are found in the Indo-Pacific region, few long-term trends have been documented for these communities (Bruno and Selig, 2007). Densities of species in coral reef communities exhibit considerable variability spatially across multiple scales and reflect larval dispersion, recruitment success, competition for substrate and local environmental conditions. Community structure within reef communities tends to follow a nutrient gradient and is also associated with proximity to inner lagoon or outer open-ocean regions.

Coral reef assemblages attenuate gradually in diversity with increasing distance from the Coral Triangle; 60 genera of reef-building (hermatypic) corals have been reported at 9°S in comparison to 18 genera at 30°S (Wells, 1955; Veron, et al. 1974; Bellwood and Hughes, 2001). Eastern South Pacific coral reefs are low in diversity; however, most species within these communities are unique (Glynn and Ault, 2000). In areas where water temperatures seasonally drop to below 18°C, hermatypic corals become sparse: coral reef communities give way to rocky reef and soft substrate communities (Veron, 1974). Factors suggested to be associated with attenuation of coral reef communities include water temperature, aragonite saturation, light availability, larval dispersal and recruitment, and competition with other species, including macroalgae (Harriott and Banks, 2002).

Overall, coral communities across the South Pacific Ocean are considered to be generally healthy (Burke et al., 2011), although coral cover is gradually declining (Bruno and Selig, 2007). Exposure and resilience to disturbance vary depending on reef type and location; major drivers of changes in species densities, assemblages and spatial distributions are associated with natural phenomena such as storms and cyclones, outbreaks of natural predators (e.g., crown-of-thorns starfish) and seasonal local coral bleaching events (Chin et al., 2011; Hoegh-Guldberg et al., 2011). Coral reef communities in the eastern South Pacific Ocean recorded the earliest mass bleaching and mortality of any region; widespread losses are linked to high ocean temperature anomalies that occur during El Niño events (Glynn and Ault, 2000; Burke et al., 2011).

Coral cover from reefs in the Indo-Pacific region has been declining relatively uniformly since records began in the 1960s and 1970s; yearly estimates of loss average 1 – 2 per cent over the last 20 years (Bruno and Selig, 2007). Hard coral cover on the Great Barrier Reef has declined from 28.0 per cent in 1985 to 13.8 per cent in 2012; the rate of decline is increasing in recent years (De'ath et al., 2012; Figure 5). Declines have been most severe on reefs south of 20°S, particularly since 2006, and on areas of inshore reefs which have been documented to have declined by 34 per cent since 2005 (GBRMPA, 2014). Tropical cyclones, coral predation by the crown-of-thorns starfish and coral bleaching have accounted for 48 per cent, 42 per cent and 10 per cent, respectively, of declines observed; elevated loads of nutrients, sediments and pollutants via terrestrial run-off affect reef resilience and the potential for recovery (De'ath et al., 2012; Wiedenmann et al., 2013).

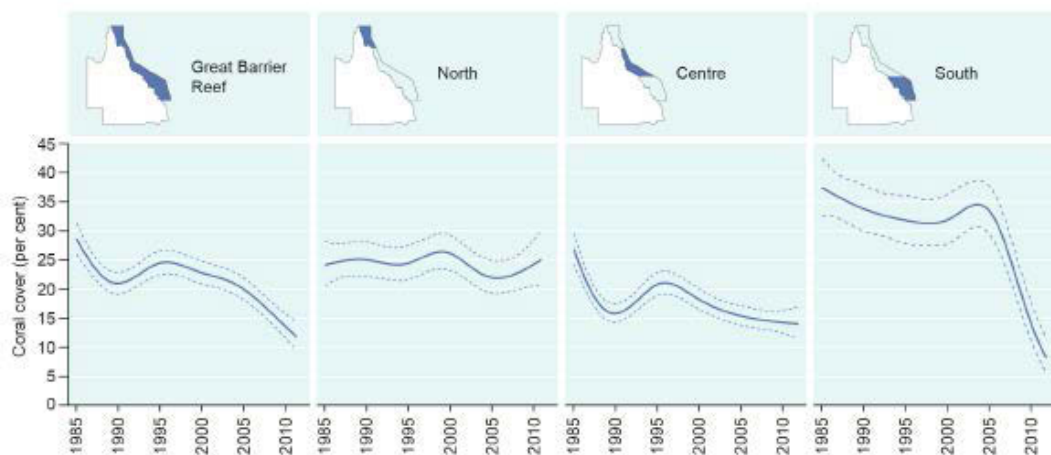

Figure 5. Estimates of hard coral cover across the Great Barrier Reef 1986 – 2012, based on data collected from 214 reefs. Dashed lines represent the standard error. Taken from Great Barrier Reef Marine Park Authority (2014) (modified from De’ath et al. (2012).

Local declines in species densities, assemblages and spatial distributions are increasingly being observed, particularly in areas close to population centres where over-fishing, pollution from terrestrial run-off and sewage, and damage from coastal developments are occurring (see Section 3). Bleaching events are becoming more widespread, increasing in intensity and frequency as surface waters of the South Pacific Ocean warm with long-term climate change (Burke et al., 2011; Chin et al., 2011; Hoegh-Guldberg et al., 2011). Recovery from bleaching events is possible if local factors which affect reef systems, such as coastal runoff and overfishing, are minimized (Figure 6); however, as marine conditions alter with climate change, the ability of coral reefs to recover from bleaching events is expected to decline (see section 3.1; De’ath et al., 2012).

Monitoring of approximately 30 intertidal seagrass meadows along the central and southern coast of the Great Barrier Reef suggests that their overall abundance, reproductive effort and nutrient status have all declined. Although shallow subtidal seagrass meadows are less extensively monitored, many sites also show signs of declines in abundance. Causes for these declines include cyclones and poor water quality (GBRMPA, 2014).

Figure 6. Variation in coral, turf and macroalgal cover at the Tiahura outer reef sector, French Polynesia, 1991 – 2006, in relation to coral bleaching and cyclone events. Dotted lines indicate the standard deviation. Taken from Adjerdoud et al., 2009; with permission of Springer.

Across temperate regions, benthic communities of rocky intertidal and rocky reef habitats are reasonably well documented, although studies are often local and only include assessments of a few sites. In the western South Pacific Ocean, subtidal coastlines are typified by patches of common kelp, ascidians and crustose coralline algae barrens, which are often associated with the sea urchin *Centrostephanus rodgersii* (Connell and Irving, 2008). Other herbivores common in these habitats include limpets and topshells (Underwood et al., 1991). Community assemblages vary with depth; sponges, ascidians and red algae are more abundant in deeper sheltered areas (Underwood et al., 1991). In protected areas where removal of urchin predators is restricted and predator populations are provided with the opportunity to increase, sea urchin barrens demonstrate a decline and macroalgal forests are more extensive (Babcock et al., 1999; Shears and Babcock, 2003; Barrett et al., 2009). This suggests that removal of urchin predators (e.g., via fishing) can have widespread effects on community structure in subtidal habitats (Connell and Irving, 2008). Declines in the density of giant kelp beds and increased densities of sea urchins and urchin barrens have also been associated with increased southward larval advection of urchin larvae following shifts in large oceanographic features throughout the south-eastern Australian region (Johnson et al., 2011). Commercial and recreational fishing practices have been associated with declines in benthic communities. Oyster reef communities in south-eastern Australia have been largely destroyed by fishing and mining practices: over 60 per cent are considered

functionally extinct, and of the remaining, 90 per cent of the original area of the reef is lost (Beck et al., 2011). The flow-on impacts of such reductions include reduced habitat and food sources for other species and reduced water-filtering capacity, resulting in a reduction in overall water quality (Beck et al., 2011).

Estuarine and coastal soft-sediment benthic communities have been routinely monitored, mostly by councils and unitary authorities, at over 70 sites in New Zealand for up to 25 years (see http://geodata.govt.nz/geonetwork_memp). Time series established demonstrate a wide variety of trends and cycles, and it is difficult to draw overall conclusions. For example, Mahurangi Harbour, which has a predominantly rural catchment, has demonstrated a declining trend in species sensitive to increased sediment loading (Halliday et al., 2013), whereas Manukau Harbour, adjacent to New Zealand's largest city, has demonstrated no declining trends that might indicate that the habitat is becoming degraded (Greenfield et al., 2013). New Zealand is developing a Marine Environmental Monitoring Programme to coordinate and report on the diverse monitoring being conducted.

In temperate regions of the eastern South Pacific Ocean, rocky intertidal communities are dominated by mussel beds, corticated algae and herbivorous gastropods in shallow regions and kelps, crustose algae, chitons and fissurellids in deeper regions (Broitman et al., 2001). Carnivorous gastropods and crustaceans also dominate communities. Latitudinal gradients occur in some species; mussel and crustose algae densities decrease with decreasing latitudes, whereas ephemeral algae increase with decreasing latitudes (Broitman et al., 2001). Further south, recent inventory studies conducted in the relatively easily accessible areas of the Chilean fjord region have documented that over 30 per cent of the sampled specimens represent new species; 10 per cent of these are in benthic communities (Häussermann and Försterra, 2009). Many of the species documented exhibited unexpected distribution patterns: for example, species thought to be limited to the Peruvian faunal province were discovered far to the south; others, presumed to be subantarctic, were present in northern Chilean fjords, and deep water species were found in shallow depths of the fjords (e.g., Försterra et al., 2005). The species richness of several benthic taxa has been observed to decrease with increasing latitude and then increase again south of 40-45°S. This is possibly associated either with an increase in the presence of Antarctic fauna or an increase in habitat with the broadening of the continental shelf south of 40°S (Escribano et al., 2003).

Temporal changes in the density and assemblage of benthic communities have been observed at two long-term sites in the Chilean fjord region. Within the Comau Fjord, mussel banks, meadows of sea whips, sea anemones, large calcified bryozoans and the rare gorgonian *Swiftia* n. sp. have reduced by at least 50 per cent and in some cases, completely disappeared. Associated decapod species have also experienced declines in abundance (Häussermann et al., 2013). Declines in biodiversity in this fjord are thought to be associated with increased mussel harvesting in the area, eutrophication, increased organic sedimentation and the extensive use of chemicals in aquaculture operations (Häussermann et al., 2013; Försterra et al., 2014; Mayr et al., 2014).

Further detail on estuaries, mangroves, kelp forests, seagrass and corals can be found respectively, in chapters 44, 48, 47 and 42-43.

2.4 Fish and macro-invertebrates

Fish and macro-invertebrates occurring in coastal and shelf regions of the South Pacific Ocean range from highly resident species (e.g., cardinal fishes, Apogonidae; wrasses, Labridae), species that move relatively small distances, but utilize multiple habitats during their lifespan (e.g., penaeid prawns; yellowfin bream, *Acanthopagrus australis*), pelagic species that roam shelf waters extensively (e.g., Australian salmon or kahawai *Arripis* spp., white sharks, *Carcharodon carcharias*), to highly migratory pelagic species that utilize shelf regions periodically or seasonally (bigeye tuna, *Thunnus obesus*; southern bluefin tuna, *T. maccoyii*). A few species are anadromous (e.g., shorthead and pouch lampreys, Mordaciidae) and some are catadromous (e.g., barramundi, *Lates calcarifer*; short-finned eel, *Anguilla australis*).

Time series of indicators of populations are largely limited to species that are the focus of recreational/sport, subsistence and commercial fisheries and are subject to varying degrees of management (Bates et al., 2014). Subsistence fishing tends to be more important in rural areas throughout the South Pacific Ocean and is much larger than commercial fishing in these areas (Dalzell et al., 1996; Kulbicki et al., 1997). In the Pacific Islands region, where fish consumption in some countries is at least twice the level needed to supply 50 per cent of the recommended protein requirements, 60 – 90 per cent of fish consumed is caught by subsistence fishers (Bell et al., 2009). Across much of the rest of the South Pacific Ocean, and in the shelf areas of the Pacific Island region, commercial fishing is much larger than subsistence or recreational fishing.

Small-scale subsistence and commercial reef fisheries across the Pacific Island region and coastal commercial fisheries in Ecuador and northern Peru can catch up to 200 – 300 species (Dalzell et al., 1996; Heileman et al., 2009; FAO, 2010). The primary fish families important to Pacific Island communities are the Acanthuridae (surgeonfish), Scaridae (parrot fish), Lutjanidae (snapper), Lethrinidae (emperor fish) and Balistidae (triggerfish; Dalzell et al., 1996; Pratchett et al., 2011). A number of fish species are also commercially fished for the live reef food and the aquarium trade. Macroinvertebrates of importance include sea cucumbers (22 species are commercially caught across the region for the production of bêche-de-mer), trochus (*Trochus* spp.), green snail (*Turbo marmoratus*), giant clams (*Tridacna* spp.), cephalopods (primarily cuttlefish and octopus) and crustaceans (penaeid prawns, crabs, lobsters). Commercial pearl oyster aquaculture operations occur in the eastern (Melanesian) part of the Pacific Islands region; two-thirds of all production occurs in French Polynesia (Dalzell et al., 1996). Species of importance in the eastern South Pacific include silverside (*Odontesthes regia*), flathead grey mullet (*Mugil cephalus*), lorna drum (*Sciaena deliciosa*), Peruvian scallop (*Argopecten purpuratus*), and the cephalopods *Loligo gahi* and *Dosidicus gigas* (FAO, 2010).

Reef fish abundances are influenced by the extent and condition of coral cover, and can vary two- to ten-fold over time, largely in association with loss and subsequent recovery of coral reef habitat following storm events (Halford et al., 2004; Kulbicki et al., 2007; Wilson et al., 2008; Brewer et al., 2009). Macro-carnivores, micro-herbivores and plankton feeders show some of the highest variability (Kulbicki, 1997).

A large-scale assessment of coral reef fish and invertebrate communities in 17 Pacific Island countries and territories found that across 63 sites, less than one-third of the sites had resources that were in good condition; most were in average/low or poor condition (Pinca et al., 2009). Herbivores and smaller fish were more abundant in reefs of below average condition, whereas reefs in good condition had higher biomasses of carnivores and greater numbers of larger fish (Pinca et al., 2009). More recently an assessment of the status of reef fish assemblages on fished reefs estimated that reef fish assemblages around Papua New Guinea were at a point indicating fisheries collapse (Mac Neil et al., 2015). Declines have also been observed in sea cucumber species, giant clam and *Trochus* spp. Sea cucumber fisheries in Palau, Papua New Guinea, Samoa, Solomon Islands, Tonga and Vanuatu have been closed due to overfishing (Purcell et al., 2013). Some species of giant clam have been declared extinct in a number of countries and all giant clam species are now listed under Appendix II of the Convention of International Trade in Endangered Species¹ (CITES), which covers species that may become threatened if their trade is not effectively regulated (Pinca et al., 2009). Formal monitoring and regulation of coastal fishery resources is largely lacking throughout the region, particularly for subsistence fisheries resources (Dalzell et al., 1996; Gillett, 2010). Landings that are reported are considered to be underestimates; reconstructed catches from coral fisheries in American Samoa have been estimated to be 17-fold greater than those officially reported (Zeller et al., 2006).

Large components of tropical reef systems along eastern Australia are managed as part of the multiple use Great Barrier Reef Marine Park, some of which is open to commercial, recreational and traditional fishing for a range of fish (for food and the live aquarium trade), crustaceans (penaeid prawns, crabs, lobsters), sea cucumbers, trochus, beach or sand worms and live coral. Monitoring of 214 fish populations in the Great Barrier Reef Marine Park since the 1990s indicate high inter-annual variability (Figure 7); population declines are associated with a declining coral cover, particularly in southern parts of the park, where coastal development is greatest (GBRMPA, 2014). Overall abundance and size of commercially caught species have declined when compared to historical abundance and size; the fishery for black teatfish sea cucumber (*Holothuria whitmaei*) was closed in 1999 (GBRMPA, 2014). Illegal fishing is known to occur in areas closed to fishing and is likely to have contributed to overall declines in fish populations. Recreational fishing catches throughout the marine park are largely unmonitored; however, in 2010 an estimated 700,000 recreational fishers throughout Queensland caught over 13 million fish, approximately half of which were returned to the water (Taylor et al., 2012). Recreational catches appear to have been declining over the last decade.

Temperate fish and macro-invertebrates are also affected by the physical and biological attributes of temperate habitats (De Martini and Roberts, 1990; Curley et al., 2003; Anderson and Millar, 2004). Spatial variability in assemblages has been associated with type of reef habitat (e.g., urchin barren, kelp forest, sponge habitat), benthic topography and depth (Williams and Bax, 2001; Curley et al., 2003; Hill et al., 2014). Long-term changes in temperate fish assemblages have been observed in

¹ United Nations, *Treaty Series*, vol. 993, No. 14537.

eastern Australia, associated with fishing, introduced alien species and ongoing changes to the marine environment as a result of climate change and coastal development (Last et al., 2011; State of the Environment Committee, 2011; Bates et al., 2014).

Coastal waters of the tropical eastern Pacific are some of the least explored in the region (Cruz et al., 2003; Zapata and Robertson, 2007); approximately 70 per cent of fish are endemic to the region. The unique oceanographic conditions and heterogeneity of the coastal regions of Chile have resulted in high levels of endemism in many invertebrate groups (Griffiths et al., 2009; Miloslavich et al., 2011). Endemism is also high in the waters of small oceanic islands in the eastern South Pacific Ocean; approximately 77 per cent of the fish at Easter Island, 73 per cent at Salas y Gómez, 72 per cent at Desventuradas and 99 per cent at the Juan Fernández Archipelago are endemic (National Geographic/Oceana/Armada de Chile, 2011, Friedlander et al., 2013; National Geographic/Oceana, 2013). Most of the oceanic islands of the eastern South Pacific are thought to have relatively healthy biomasses of fish and macro-invertebrates, with the exception of Easter Island, where fisheries have been operating for over 800 years (Hunt and Lipo 2011). Within the last three decades, a dramatic decrease in the marine resources of Easter Island has been observed; this is largely associated with overexploitation, increasing tourist numbers with associated increases in demand for resources, illegal industrial fishing and lack of surveillance and enforcement procedures (Gaymer et al., 2013).

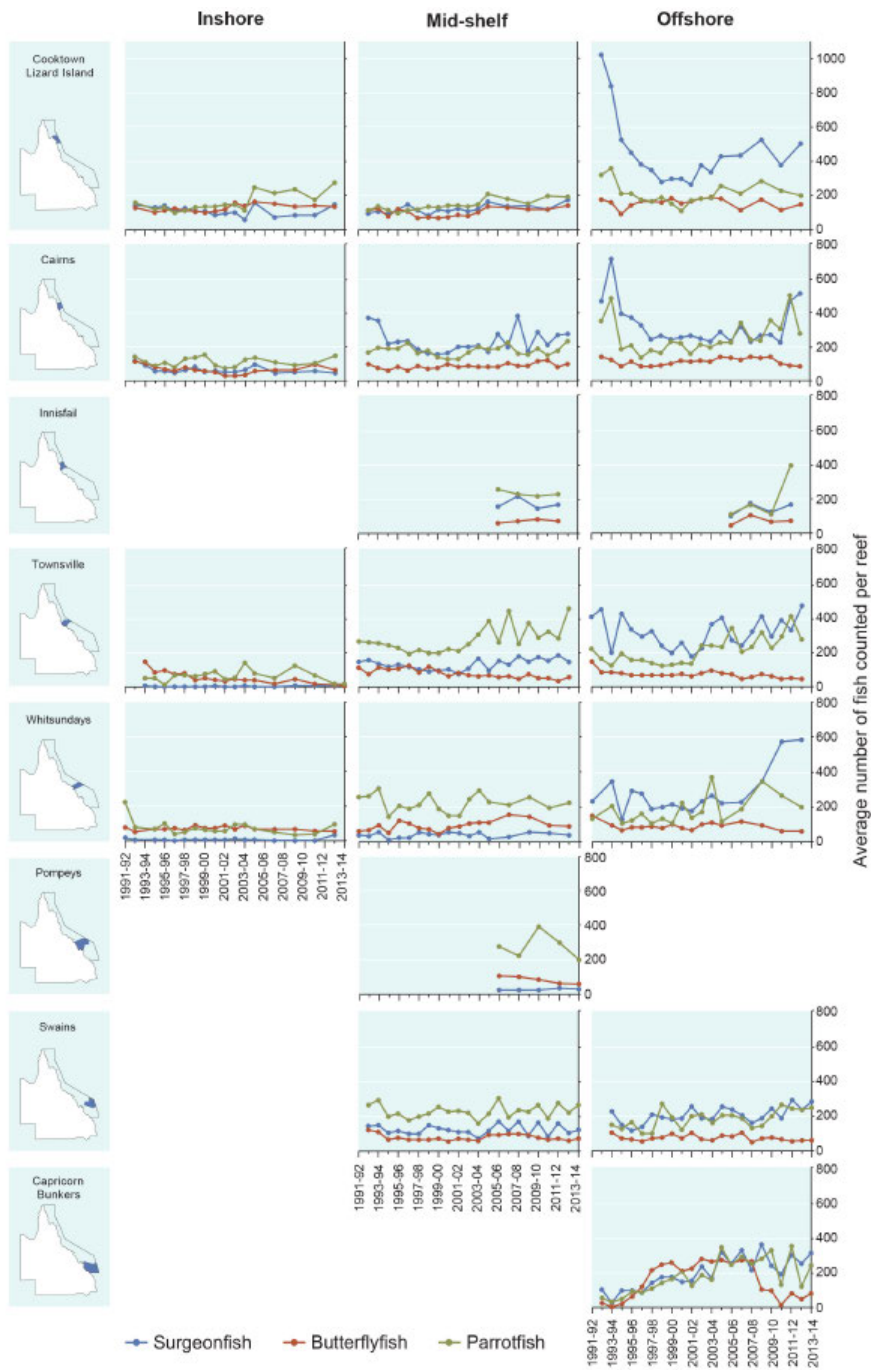

Figure 7. Time series of the abundance of some coral reef fish species in the Great Barrier Reef Marine Park 1991 – 2003. Taken from Great Barrier Reef Marine Park Authority (2014) and adapted from Australian Institute of Marine Science Long-term Monitoring Program (2008 and 2014).

Shallow reef habitats of the Galápagos archipelago are reported to have undergone major transformation as a result of the severe 1982/1983 El Niño warming event, resulting in local and regional decline in biodiversity, including a number of identified extinctions (Edgar et al., 2010). Artisanal fishing for lobster and fish species is thought to have magnified the impacts of the El Niño event; the grouper *Mycteroperca olfax* is characterized as functionally extinct in the central Galápagos region (Ruttenberg, 2001; Okey et al., 2004). Commercial fishing within the Galápagos Islands reserve has been largely banned from the area, except for artisanal fishing, which has been allowed in the reserve since 1994. The region has been subject to extensive illegal fishing for sharks, sea cucumber and a range of fish in the region and a lack of controls on or enforcement of management measures for artisanal fishing and a lack of credible assessment of stocks have resulted in over-exploitation (Hearn, 2008; Castrejón et al., 2013).

Coastal regions of Ecuador and northern Peru have been the site of extensive shrimp (penaeid prawn) mariculture operations since the 1960s. The establishment of these operations has been responsible for extensive reduction in mangrove forests and associated fish and invertebrate populations (Bailey, 1988; Primavera, 1997).

A diverse range of fish and macro-invertebrate species are targeted by fisheries in the coastal waters of Chile, including molluscs, gastropods, echinoderms, cephalopods and fish. Fisheries catches in general were low prior to the 1980s, reflecting low levels of effort and predominantly local consumption of catches. During the 1980s, export markets grew and catches increased substantially. Catches of many invertebrate species subsequently declined and have remained at low levels since (Thiel et al., 2007). Many species targeted by coastal fisheries demonstrate fluctuations in abundances linked to El Niño/Southern Oscillation (ENSO) (e.g., Wolff, 1987).

A wide range of fish and macro-invertebrate species are the focus of commercial and recreational fisheries in Australia and New Zealand; most coastal and shelf stocks are considered to be sustainably fished (e.g., MPI, 2013; Andre et al., 2014). For example, of 93 stocks managed at the national level in Australia, 77 (83 per cent) were considered as not subject to overfishing, four were considered to be subject to overfishing and 12 were considered as uncertain (Woodhams et al., 2013). In New Zealand, 99 of 114 (87 per cent) were considered as not subject to overfishing. The proportion of assessed stocks experiencing overfishing declined from 25 per cent in 2009 to 13 per cent in 2013 (MPI, 2013). Inshore stocks are the least assessed in New Zealand waters, particularly inshore fish species. Species of ongoing concern tend to be long-lived, slow-maturing species which have been subject to a number of decades of fishing, such as southern bluefin tuna, orange roughy (*Hoplostethus atlanticus*) and school shark (*Galeorhinus galeus*). Species that are caught in lesser amounts and non-targeted species are not routinely assessed and as a result the status of populations is largely unknown (Woodhams et al., 2013; MPI, 2013). In Australian waters, the grey nurse shark (*Carcharias taurus*) is listed as critically endangered, the white shark (*Carcharodon carcharias*), black rockcod (*Epinephelus daemeli*), and the whale shark (*Rhincodon typus*) are listed as vulnerable, and orange roughy, gemfish (*Rexea solandri*), southern bluefin tuna and several shark

species, including school shark, have been listed as conservation-dependent under the Environment Protection and Biodiversity Conservation Act 1999.

Recreational fisheries are subject to variable levels of assessment and monitoring and most are regulated only via size and bag limits. In some areas (e.g., New South Wales, Australia) and for some species recreational fishing licenses are required. In Australia, recreational catches of many highly sought-after species are thought to be larger than commercial catches (State of the Environment Committee, 2011). Catches of snapper (*Chrysophrys auratus*), which comprise New Zealand's largest recreational fishery from the north-east coast of the North Island, were 3,750 t in 2011/12, similar to commercial landings (Hartill et al., 2013). The first reliable and comprehensive assessment of recreational harvest across all stocks in New Zealand was completed in 2013 (Hartill et al., 2013). Populations of commercially exploited fish and macro-invertebrates in the temperate coastal regions of New Zealand are considered mainly to be in good condition (Mace et al., 2014).

Offshore fisheries resources in tropical, sub-tropical and temperate shelf regions of the western and central South Pacific Ocean largely consist of commercial operations targeting tuna and billfish species, as well as a number of other large pelagic species, such as mahi mahi (*Coryphaena hippurus*), rainbow runner (*Elegatis bipinnulata*), wahoo (*Acanthocybium solandri*) and Spanish mackerel (*Scomberomorus commerson*), and small pelagic species, such as flying fish, pilchards and sardines. Several shark species are either directly targeted or caught as by-catch. Across the Pacific Island region, pelagic fish species are estimated to contribute on average up to 28 per cent of coastal fisheries production (range 10 – 70 per cent; Pratchett et al., 2011). This proportion is likely to increase as increasing populations lead to further exploitation of pelagic species by coastal populations (Bell et al., 2009).

All of the tuna and billfish species, that comprise the majority of commercial catches in the Western and Central Pacific Fisheries Commission (WCPFC) area, except bigeye tuna, are not considered to be in an overfished state, although recent catches of skipjack tuna (*Katsuwonus pelamis*) and yellowfin tuna (*T. albacares*) are at levels that marginally exceed maximum sustainable yield and catches of swordfish (*Xiphias gladius*) are at levels that exceed maximum sustainable yield (Hoyle et al., 2012; Davies et al., 2013; Davies et al., 2014; Rice et al., 2014). In the Inter-American Tropical Tuna Commission (IATTC) area in the eastern Pacific Ocean, all of the main tuna and billfish species are not considered to be in an overfished state, although some uncertainty exists as to whether current catches of skipjack tuna are at levels that exceed maximum sustainable yield (IATTC, 2012; IATTC, 2014). Catches of species other than the main tuna and billfish species that comprise the majority of commercial catches are largely unmonitored and so the status of populations and ongoing sustainability of resources is unknown. Recent assessments of shark species caught in substantial numbers throughout the WCPFC and IATTC areas have indicated that fishing mortalities are well above those considered to be sustainable (e.g., Rice and Harley, 2013; IATTC, 2013). Current catches of most small pelagic species throughout the Pacific Island region are considered to be sustainable (Blaber, 1990; Pratchett et al., 2011).

Pelagic fisheries in the eastern South Pacific have been responsible for approximately 10 – 20 per cent of the world landings over the last 50 years (Chavez,

2008; Fréon et al., 2008) and are dominated by the anchoveta fishery, which primarily targets anchovy (*Engraulis ringens*) and sardine (*Sardinops sagax*). Jack mackerel (*Trachurus murphy*), chub mackerel (*Scomber japonicus*) and, in the southern Peru-Chile region, a herring-like sardine (*Strangomera bentincki*) also sustain important pelagic fisheries. Fisheries across the region also target the common hake (*Merluccius gayi*), swordfish, tunas, cephalopods, primarily *D. gigas*, and a number of crustaceans. The Chilean fjord region is an important region for catches of gadiform fishes, such as Patagonian grenadier (*Macruronus magellanicus*) and the southern hake (*Merluccius australis*; FAO, 2011). Variability in the population size and distributions of anchovies and sardines in the waters of the eastern South Pacific Ocean and linkages with environmental variability have been well documented (e.g., Arntz and Tarazona, 1990; Ayón et al., 2004; Bertrand et al., 2004; Cubillos et al., 2007) and are now recognised to be associated with short-term dynamics associated with ENSO and longer-term dynamics associated with decadal climate variability (Alheit and Nuiquen, 2004; Fréon et al., 2008). The two northern anchovy stocks appear to not be overfished, whereas the southern stock is considered to be depleted and estimated to be at around 8 per cent of virgin stock biomass (Fish Source, www.fishsource.com, accessed 17 August 2014). Currently no recovery plan is in place for this fishery. Fisheries for sardine are based on four stocks: northern, central and southern Peru and northern Chile. Stocks between Peru and Chile are assessed independently and management measures are not co-ordinated between the two countries.

For many other species subject to commercial catches, information on important biological parameters (larval ecology, spawning, movements) is lacking and consequently, little is known about the effects of inter-annual variability in oceanographic conditions on their population dynamics (Thiel et al., 2007). Artisanal fishing, which comprises a significant proportion of the total fishing effort in the region, is largely unreported and is unregulated across the region. Most fisheries throughout the region, other than those mentioned above, are considered to be over-exploited (De Young, 2007).

Further detail on sharks and other elasmobranchs and tuna and billfish can be found in chapters 40 and 41.

2.5 Other Biota

The South Pacific Ocean contains a diverse assemblage of marine mammals, seabirds and marine reptiles, most of which have been subject to some level of direct and indirect harvesting (SPREP, 2012). The region contains the northernmost populations of penguins and fur seals, both of which breed on the Galápagos Islands, breeding populations of six of the seven species of sea turtles and populations of the only sirenian in the family Dugonidae. Although harvesting of many of these species has been either banned or limited in many countries across the region and protection measures have been put in place for some species in some countries, many species interact with commercial fishing operations (e.g., Table 1) and for some, this is a substantial source of mortality (Waugh et al., 2012; Reeves et al., 2013; Richard and

Abraham, 2013; Wallace et al., 2013; Lewison et al., 2014). Populations of species throughout the region demonstrate varying trends as a result.

Overall, global populations of sea turtles are considered to have declined (Wallace et al., 2011) with those that occur in the South Pacific Ocean demonstrating varying trends. Two distinct genetic stocks of green turtles (*Chelonia mydas*) occur within the Great Barrier Reef Marine Park which experience different pressures and demonstrate differing population trajectories. The southern stock has demonstrated a consistent increase in population size, whereas the northern stock may be in the early stage of decline (GRMPA, 2014). The loggerhead turtle (*Caretta caretta*) population is increasing after substantial decline, whereas the hawksbill turtle (*Eretmochelys imbricata*) population has declined and the flatback turtle (*Natator depressus*) population has remained stable (GRMPA, 2014). Little is known of the current population status of leatherback turtles (*Dermochelys coriacea*), which are known to nest in Papua New Guinea, the Solomon Islands and Vanuatu in the western South Pacific Ocean, but regionally they are considered to be in decline (Dutton et al., 2007). In the eastern Pacific Ocean, leatherback, green and hawksbill turtles nest along the coast in Ecuador, with vagrant nesting sites occurring in Peru. Large numbers are caught in small-scale fisheries off the coasts of Ecuador and Peru (Alfaro-Shigueto et al., 2011).

Table 1. Fisheries interactions with species of conservation concern 2006 – 2012. Reproduced from Great Barrier Reef Marine Park Authority (2014) using data from Queensland Department of Agriculture, Fisheries and Forestry (2013).

Humpback whale		•	•	
Minke whale			•	

International protection and management of saltwater crocodile populations in Australia and Papua New Guinea after periods of commercial harvesting have resulted in increases in populations to pre-exploitation levels (Thorbjarnarson, 1999; Tisdell and Swarna Nantha, 2005). Few data on the population abundances of sea snake species are available, despite substantial numbers being caught in fishing operations (e.g., Milton 2001; Wassenberg et al., 2001). What data have been collected indicate population declines (Goiran and Shine, 2013).

Most large cetaceans occurring in coastal and shelf regions throughout the South Pacific Ocean are seasonal visitors, spending large periods of time in offshore regions (e.g., Birtles et al., 2002; Hucke-Gaete et al., 2004; Olavarría et al., 2007). Of those species that historically have been subject to widespread commercial harvesting, some populations have been documented to be increasing, while the status of others in the South Pacific Ocean region is still uncertain (e.g., Baker and Clapham, 2004; Branch et al., 2007; Magera et al., 2013). Smaller coastal cetacean species, although largely lacking in population data, are considered to demonstrate varying trends: some are relatively stable and others are decreasing (e.g., Gerrodette and Forcada, 2005; Parra et al., 2006; Currey et al., 2009). Dugong (*Dugong dugon*) populations across the western South Pacific are considered to be declining, although estimates of abundance are lacking for most countries (Marsh et al., 1995; Marsh et al., 1999; Marsh et al., 2002). Fisheries for the species throughout the region are considered to be unsustainable (Marsh et al., 1997; Garrigue et al., 2008). Most pinniped populations, although substantially reduced due to commercial exploitation during the 1800s, are considered in some areas to be increasing at varying rates in temperate regions, whereas in others they may be decreasing (e.g., Kirkwood et al., 2010; Robertson and Chilvers, 2011). Seabirds throughout the region demonstrate varying trends; most species that forage in offshore regions are considered to be decreasing (e.g., Majluf et al. 2002; Baker and Wise, 2005).

Further details on marine mammals, marine reptiles and seabirds can be found in chapters 37-39.

3. Major pressures

3.1 *Climate change and oceanographic drivers*

Changes to ocean environments occurring as a result of long-term changes to the global climate are likely to be highly variable across the South Pacific Ocean. Ocean temperatures have risen across most of the South Pacific Ocean over the last century and are expected to continue to rise into the future (IPCC 2014). Inter-comparison of

climate models used to explore future changes to the global climate under emission scenarios (see Taylor et al., 2012) has identified numerous biases in ocean parameters, both within and across models. These biases are particularly evident in the tropical Pacific Ocean and are associated with difficulties in simulating sea-surface temperatures, precipitation and salinity (Sen Gupta et al., 2009; Ganachaud et al., 2011). Use of a multi-model mean derived from models used in inter-comparisons considerably reduces these biases, although certain regions still retain sizeable biases, indicating systematic biases across models (Sen Gupta et al., 2009). In particular, the eastern tropical Pacific cold tongue is placed too far west and the South Pacific Convergence Zone is too elongated towards the east, resulting in biases in precipitation and ocean surface salinity, which has implications for projections of climate relating to a number of Pacific Islands. Along the Chilean shelf edge, problems with the representation of local atmospheric processes and upwelling lead to biases in cloud formation and radiative heat transfer, with flow-on impacts on ocean salinity (Randall et al., 2007; Sen Gupta et al., 2009; Brown et al., 2013; Ganachaud et al. 2013). The resolution at which most climate models are run does not take into account processes occurring in the near-coastal ocean, so pressures and associated projections derived from climate models are extrapolated from observations made offshore (Rhein et al., 2013). This is particularly problematic for projections relating to islands in the South Pacific Ocean and also for mesoscale and submesoscale processes that are important for delivering nutrients to the photic zone (Ganachaud et al., 2011). Bearing in mind the biases and the resolutions of current models, a summary of observed and projected changes to the South Pacific Ocean are presented here.

Projections of surface temperatures are robust at a large scale and suggest a warming rate of the surface ocean during the 21st century that is approximately seven times that observed in the 20th century (Sen Gupta et al., 2015). Within the South Pacific Ocean, the western tropical Pacific Ocean is projected to warm and the region associated with the EAC and its extensions is projected to undergo enhanced warming (Cravatte et al., 2009; Ganachaud et al. 2013.). Intensification of south-easterly trade winds in the eastern South Pacific Ocean region will result in weakened warming (Sen Gupta et al., 2015).

Observations of surface salinity within the subtropical gyre in the South Pacific Ocean have demonstrated an increasing trend, particularly in the east, whereas in the equatorial WWP, surface waters have freshened (Durak and Wijffels, 2010). Model projections suggest an increase in rainfall across tropical latitudes in association with increased evaporation and enhanced convection, which will have implications for ocean salinity in these regions. The area of the WWP in the tropical western Pacific Ocean is projected to continue to freshen and the area of relatively fresher water is projected to move east (Cravatte et al., 2009; Ganachaud et al. 2013). At mid-latitudes, rainfall is projected to decrease, particularly over the central and eastern Pacific Ocean, which will result in increasing surface salinity (Ganachaud et al., 2011).

Changes in wind stress forcing over the past two decades has resulted in changes in circulation in the South Pacific Ocean (Rhein et al., 2013). The southern limb of the South Pacific subtropical gyre and the subtropical cells have intensified in response

to intensification of Southern Hemisphere westerlies. In addition, the gyre and cells have moved poleward (Roemmich et al., 2007; Rhein et al., 2013). This has also resulted in a southward expansion of the EAC into the Tasman Sea (Ridgway, 2007; Hill et al., 2008). These wind-driven changes are most likely due to inter-annual to decadal variability (i.e., intensification of the Southern Annular Mode); time series are currently not substantial enough to determine longer-term trends (Ganachaud et al., 2011; Rhein et al., 2013). Interactions between large scale oceanographic and atmospheric processes and island topography are expected to have local effects on the waters surrounding islands in the South Pacific Ocean; however, local projections of confidence are scarce (Ganachaud et al., 2011).

The combined effect of changes to surface temperature and salinity will result in changes to the stability of the water column and the level of stratification. The level of stratification of the water column affects the potential for vertical exchange of ocean properties, such as oxygen or nutrients, which has flow-on effects for primary productivity (Ganachaud et al. 2011; 2013). Surface warming of the tropical South Pacific, in combination with freshening in the WWP, have resulted in an increase in stratification over the upper 200 m (Cravatte et al., 2009). Stratification is projected to continue being most pronounced in the WWP and the South Pacific Convergence Zone (Ganachaud et al., 2011; 2013). In conjunction, the annual maximum depth of the mixed layer is projected to shoal across most of the tropical South Pacific Ocean (Ganachaud et al. 2013). Although the mixed layer depth is expected to shoal, in the eastern South Pacific Ocean this is not expected to affect primary production. This is because nitrate concentrations due to upwelling processes are still likely to exceed levels at which the supply of iron currently limits phytoplankton growth (Le Borgne et al., 2011). Within the western South Pacific Ocean, use of high-resolution ocean models has suggested that projected increased mixing due to changes in currents (which are not fully resolved in lower-resolution models), will result in increased subsurface primary production. This is expected to result in close to no change in overall net primary production throughout the region (Matear et al., 2015).

Oxygen concentrations in the tropical South Pacific Ocean thermocline have decreased over the past 50 years in association with changes in oxygen solubility (resulting from warming), ventilation and circulation. This has resulted in a major westward expansion of oxygen minimum waters in the eastern Pacific Ocean (Stramma et al., 2008). Recent observations for the period 1976–2000 have shown that dissolved oxygen concentrations have declined at a faster rate in the coastal ocean than in the open ocean and have also occurred at a faster rate than in the period 1951 – 1975 (Gilbert et al., 2010). Projected changes to surface temperatures and stratification are likely to result in a decreased transfer of oxygen from the atmosphere, resulting in lower concentration of oxygen in waters above the thermocline across the tropics (Ganachaud et al., 2011). Existing oxygen minimum waters in the eastern South Pacific Ocean are projected to intensify (Ganachaud et al., 2011), although uncertainty in model projections limits projections associated with the evolution of oxygen concentrations in and around oxygen minimum zones (Ciais et al., 2013). Outside the tropics, trends in oxygen concentrations are less obvious (Keeling et al., 2010), but it is expected that warming of the ocean will result in declines in dissolved oxygen in the ocean interior (Rhein et al., 2013). In coastal

regions, because hypoxia is largely driven by eutrophication and is therefore controlled by the flow of nutrients from terrestrial origins, any increase in nutrient run-off associated with increasing agriculture or industrialization of coastal regions will also result in increasing coastal water deoxygenation (Rabalais et al., 2010; Ciais et al., 2013; see also section 3.2).

Observations of carbon concentration in the ocean demonstrate considerable variability associated with seasonal, interannual (associated with ENSO) and decadal (associated with the Pacific Decadal Oscillation) changes in wind and circulation (Rhein et al., 2013). Taking into account this variability, trends in surface ocean carbon dioxide have increased, resulting in a decrease in surface pH. This decrease varies regionally: the subtropical South Pacific Ocean demonstrates the smallest reduction in pH (Rhein et al., 2013). Continued increased storage of carbon dioxide in the ocean will result in further decreases in the pH of the ocean; surface ocean pH is projected to decrease by 0.06 – 0.32 depending on the emission scenario used in projections (Ciais et al., 2013). Generally, projected changes to pH are greatest at the ocean surface; surface waters are projected to become seasonally corrosive to aragonite at higher latitudes in one to three decades. In the subtropics, however, the greatest changes to pH are projected to occur at 200 – 300 m where lower carbonate buffering capacity results in lower pH, although carbon dioxide concentration might be similar to that at the surface (Orr, 2011). The horizon separating shallower waters supersaturated with aragonite from deeper undersaturated waters will shoal, resulting in a decline in the global volume of ocean with supersaturated waters (Steinacher et al., 2009). In areas of freshwater input (e.g., around river mouths), reduction in pH and the aragonite saturation state will be exacerbated (Ciais et al., 2013). Overall, projected decreases in pH will be greater at higher latitudes than at lower latitudes (Le Borgne et al., 2011).

Taking into account inter-annual fluctuations associated with ENSO, time series of global sea level measurements demonstrate that mean sea level has risen at a rate of 1.7 mm yr⁻¹ over the last century in association with ocean warming and redistribution of water between continents, ice sheets and the ocean (Church and White, 2011; Church et al., 2013). This rate has increased over the last two decades (to a mean rate of 3.2 mm yr⁻¹), but it is unclear whether or not this reflects decadal variability or an increase in the long-term trend (Church et al., 2013). In the western Pacific Ocean, sea level has risen up to three times the rate of global sea level over the last two decades, largely in association with intensified trade winds which may be related to the Pacific Decadal Oscillation (Merrifield et al., 2012). Increases in mean sea level have resulted in an increase in sea-level extremes. Short-term drivers of sea level (e.g., tides) are not projected to change substantially, whereas longer-term drivers (e.g., ice melt, thermal expansion of the ocean) are projected to continue. Over the next century the rate of global mean sea-level rise is expected to increase to 4.4 – 7.4 mm yr⁻¹ depending on the emission scenario used, noting that the rate of regional sea level rise can differ from the global average by more than 100 per cent as a result of climate variability (Church et al., 2013). In the South Pacific Ocean, coastlines are projected to experience an increase in sea level from approximately 0.3 m to over 0.8 m by 2100 depending on the emission scenario used and noting that projections of land-ice melt have large uncertainties. These

uncertainties result in considerable variability in projected patterns of sea-level change between climate models (Church et al., 2013).

At present little evidence exists of any trend or long-term change in tropical or extra-tropical storm frequency or intensity in the South Pacific Ocean (Rhein et al., 2013). Increases in observed sea-level extremes have primarily been associated with an increase in mean sea level rather than the level of storminess (Church et al., 2013; Rhein et al., 2013). Across the South Pacific Ocean, the monsoon area is projected to expand over the central and eastern tropical Pacific and the strength of monsoon systems is projected to increase. Monsoon seasons are also likely to lengthen and so precipitation throughout tropical regions is projected to increase (Christensen et al., 2013). However, because the South Pacific Convergence Zone is projected to move to the northeast, precipitation over many South Pacific islands is projected to decrease. Projections of tropical cyclones suggest that although the global frequency of cyclones is likely to remain the same, their intensity is likely to increase and a poleward shift in storm tracks is likely, particularly in the Southern Hemisphere. Regional projections are not yet well quantified; many climate models fail to simulate observed temporal and spatial variations in tropical cyclone frequency (Walsh et al., 2012). As a result, projections of the frequency and intensity of cyclones at the level of ocean basins are highly uncertain and confidence in projections is low (Christensen et al., 2013).

The potential impacts of changes to the physical and chemical structure of the South Pacific Ocean and on the biodiversity of the region will depend on the capacity of organisms to adapt to these changes over the time scales at which they are occurring. As waters warm, some species are expected to alter their distribution and already evidence exists that some species have extended their distributions poleward in line with warming trends in the South Pacific Ocean (Sorte et al., 2010; Last et al., 2011). The introduction of new species into regions via expansion of their distribution has the potential to alter marine communities and it is likely that at least some marine communities will undergo major changes to their community structure (Hughes et al., 2003). Conversely, other species may demonstrate range contraction as range edges become thermally unsuitable and the time scales at which changes are occurring exceed the adaptive ability of species (e.g., Smale and Wernberg, 2013). For example, it is likely that the latitudinal and bathymetric range of kelp communities will become restricted. Although other species might replace these climatically sensitive species, reductions in kelp production will have important consequences for the communities that rely on them and other near-shore habitats that depend on the export of kelp detritus (Harley et al., 2006).

Bleaching events as a result of thermal stress induced by higher ocean temperatures, in combination with a reduced ability of corals to calcify due to ocean acidification, are expected to result in steep declines in coral cover across the South Pacific Ocean over the next decades, even under good management (Figure 8; Hughes et al., 2003; Bell et al., 2013). Already evidence exists that corals within the Great Barrier Reef are calcifying at lower rates than those prior to 1990 (De'ath et al., 2009). This will have flow-on effects for benthic organisms and fish and macro-invertebrate populations associated with reef communities. The differing abilities of coral species to migrate in response to climate change and their genetic ability to adapt to warmer waters

will, however, result in changes to community structure beyond the immediate effect of selective mortality caused by severe bleaching (Hughes et al., 2003).

Altered temperatures may decouple population processes of taxonomic groups that are reliant on the population processes of (and) other group(s). For example, the breeding processes of many marine species are timed to coincide with peaks in forage-species populations, whose timing is often driven by temperature. If the timing of the two is altered so that they no longer match, this will likely affect population recruitment (e.g., Philippart et al., 2003).

Figure 8. Projected changes in live coral cover across the Pacific Island region to 2100 based on projected changes in sea-surface temperature and aragonite saturation under the IPCC SRES A2 emissions scenario and current trends in coral decline of 1 – 2 per cent with strong (solid line) and weak (dashed line) management scenarios. Taken from Bell et al. (2013).

Because phytoplankton have differing sensitivities to carbon dioxide concentrations and utilise carbon in differing ways, changes in carbon dioxide concentrations will not only change the activity of individual phytoplankton species, but will also tend to favour some species over others. Increasing ocean carbon dioxide is therefore likely to result in shifts in phytoplankton community structure, which will in turn influence the community structure of higher trophic organisms reliant on phytoplankton for food (Hays et al., 2005). Furthermore, phytoplankton and zooplankton species that depend on current saturation levels of aragonite to build robust shells and skeletons (e.g., coccolithophorids, pteropod molluscs, gastropods) are expected to be most affected by ocean acidification. Reduced capacity to build shells and skeletons will make such organisms more fragile and vulnerable to predation and, in some cases, may result in the disappearance of these organisms from food webs (e.g., Coleman et al., 2014). This is likely to have unpredictable and cascading effects on marine food webs. Higher ocean carbon dioxide concentrations may have physiological impacts on a range of species, altering the metabolism and growth rates of some species and affecting the sensory systems of fish (Poloczanska et al., 2007; Munday et al., 2009; Munday et al., 2010; Appelhans et al., 2014).

Altered precipitation and increased storm intensity will affect the dynamics of coastal marine ecosystems through fluctuations in wave height and intensity, salinity, turbidity and nutrients. In regions where precipitation is expected to decrease, such as many Pacific Islands, these ecosystems will experience higher salinity environments, whereas those in regions where precipitation is expected to increase, such as eastern Australia, will experience fresher environments. Mangrove, seagrass and coral reef communities will be particularly prone to these changes (see Fabricus, 2005; Harley et al., 2006; Polaczanska et al., 2007).

3.2 *Social and economic drivers*

The South Pacific Ocean is a highly diverse region, featuring considerable variation in the social, economic, cultural and infrastructural composition of the countries and territories located within its bounds. Although climate change is considered to be one of the largest threats to marine environments over the long term, management of social and economic stressors on marine environments can be considered to be the most significant challenge over the short term (Bell et al., 2009; Center for Ocean Solutions, 2009; Brander et al., 2010). Coastal habitats have increasingly come under pressure as human populations grow. Pacific Island regions have been increasing at >3 per cent in the last two decades (Figure 9); urban areas are growing at twice the national growth rate (SPREP, 2012). The economic performance by countries throughout the South Pacific Ocean varies, and in some Pacific Island countries poor economic performance has resulted in *per capita* incomes stagnating (McIntyre, 2005). As a result of poor economic performance and growing inequalities, poverty is a growing problem in some countries. The majority of Pacific Island countries have relatively limited opportunities for development and are highly dependent on overseas development assistance (McIntyre 2005). Agriculture and fisheries are the mainstay of many of the economies of South Pacific Ocean countries, and support both subsistence livelihoods and commercial production. Logging and mining are significant in countries such as Australia, Chile, Ecuador, Fiji, Nauru, New Caledonia (France), Papua New Guinea, Peru and the Solomon Islands (Observatory of Economic Complexity, www.atlas.media.mit.edu, accessed 25 August 2014). Tourism is an important economic sector throughout the region and is growing in importance in the Pacific Islands (SPREP, 2012).

Figure 9. Observed and projected increase in Pacific Island populations. Taken from SPREP (2012).

Major pressures on coastal and shelf environments associated with social and economic drivers can be grouped into three broad categories: (i) habitat loss or conversion as a result of coastal development, destructive fisheries, deforestation and extraction of resources; (ii) habitat degradation as a result of various forms of pollution, increased salinization of estuarine areas and introduction of alien species; and (iii) overfishing and exploitation as a result of increasing demand at local, regional and global scales, poor fisheries management and a breakdown of traditional regulation systems (Table 2; UNEP, 2006a; UNEP, 2006b; Center for Ocean Solutions, 2009; UNEP, 2012). Many of these pressures have risen indirectly from larger changes to global populations, economies, industry and technologies.

Nearshore development associated with urbanization, growing populations and tourism replaces vegetated landscapes with hard surfaces and converts marine habitats into new land (e.g., Maragos, 1993; Table 2). Modification of shorelines alters currents and sediment delivery, often inducing erosion and receding beaches. Increased development is often also coupled with increasing land-based pollution (e.g., Ministry of Natural Resources and Environment, 2013; Table 2). The extent of land-use planning varies across the South Pacific Ocean, resulting in varying management of habitat conversion, construction activities and pollution. Many of the Pacific Islands are charting a new path from subsistence and traditional management systems to market-based economies (Center for Ocean Solutions, 2009). In many regions this has led to the slow breakdown of traditional land- and marine tenure systems, resulting in unregulated development and exploitation of coastal regions (Table 2; see also section 2.4 in regard to overexploitation of coastal fisheries). The unique natural environments of many islands in the South Pacific Ocean and the desire to experience these environments can end up contributing to the reason these environments are under threat. Unregulated coastal tourism development can result in the destruction of highly regarded environments (Table 2); the Galápagos Islands World Heritage Site was placed on the List of World

Heritage in Danger in 2007 largely as a result of unregulated tourism development and overexploitation of marine resources (see section 5.1).

Poor management of watersheds often leads to degradation of estuaries and coastal environments (Table 2). Agricultural and grazing practices that destroy natural riparian habitats can result in floods and burial of natural estuarine and coastal habitats under silt and enriched sediment (e.g., Fabricus, 2005). Interruption of natural water flow via extraction for agriculture or power restricts water and nutrient flow into estuarine environments, reducing flushing and dilution of pollution (fertilizers, pesticides, sewage, debris, chemicals, and stormwater run-off), causing siltation and, in extreme cases, closure of estuary mouths, and increasing the salinization and toxicity of estuary areas. Agricultural practices often result in excessive nutrient loading of estuarine and coastal environments, causing these areas to become eutrophied, resulting in algal blooms and dead zones. Land-based sedimentation, combined with nutrient inputs, is a major water-quality threat to many of the coastal environments of the western and central South Pacific (e.g., Maragos and Cook, 1995; Hughes et al., 2003; Orth et al., 2006; Center for Ocean Solutions, 2009; GBRMPA, 2014). Higher nutrient concentrations associated with run-off from coastal urbanized areas have been documented to drive shifts in phytoplankton community composition and abundance (Jacquet et al., 2006).

Port development, such as infilling, dredging, channelling, and installation of harbour works including seawalls and groins, often results in alterations to estuaries and embayments (Table 2). Alterations to soft bottom habitats in these areas often create conditions for new assemblages of species, and facilitate range expansions of invasive species (Ruiz and Crooks, 2001). Furthermore, the movement of ships and other transport vehicles into these areas from around the globe has enabled the spread of many marine species (Table 2). Introduction of invasive species facilitated by shipping (via fouling, boring, nestling into the hull, anchor chain, and ballast water) has been reported extensively across the South Pacific Ocean; alien species are reported from most countries and territories in the region (Carlton, 1987; Bax et al., 2003; Hewitt et al., 2004; Ministry of the Environment, 2004; Sakuma, 2004; Mourgues, 2005; Gabrie et al., 2007; Ministry of Environment Conservation and Meteorology, 2008; Ministry of Natural Resources and Environment, 2013). In the south-east region of Australia, invasive species such as starfish, sea urchins, plankton, algae, molluscs, crustaceans and worms have had major impacts on coastal marine environments. Port Phillip Bay, the site of the Port of Melbourne, has been described as one of the most invaded marine ecosystems in the Southern Hemisphere: more than 150 alien species are reported from the embayment (Bax et al., 2003). Another site of equal note is the Derwent River estuary in Tasmania (State of the Environment Committee, 2011). In New Zealand, invasive species have been detected in virtually all coastal habitat types (Hewitt et al., 2004).

Coastal aquaculture operations, although bringing important socio-economic benefits to countries, can result in modification of coastlines and benthic habitats and pollution of coastal habitats (Table 2). Shrimp and salmonid aquaculture in the coastal regions of Ecuador, Peru and Chile contributes significantly to the economies of each country; Chile is one of the main producers of salmonids in the world (De Young, 2007). After lengthy periods of sustained growth, aquaculture operations in

Ecuador have resulted in the destruction of large tracts of mangrove forest and coastal wetlands (Bailey, 1988; Martinez-Porchas and Martinez-Cordova, 2012). Operations in Chile have caused significant loss of benthic biodiversity and local changes in the physical and chemical properties of sediments have occurred in areas with salmonid farms (Buschmann et al., 2006). Pulses in dinoflagellate densities have increased and it is suggested that escaped farmed fish may have an impact on native species, although their survival in the wild appears low. In addition, the abundance of omnivorous diving and carrion-feeding marine birds in areas of aquaculture operations has increased two - fivefold (Buschmann et al., 2006).

Table 2. Social and economic drivers of change in coastal and shelf ecosystems of the South Pacific Ocean. Modified from UNEP (2006b).

DIRECT DRIVERS	INDIRECT DRIVERS
Habitat loss or conversion	
Coastal development (ports, urbanization, tourism-related development, industrial development, civil engineering works)	Population growth; transport and energy demands; poor urban planning and industrial development policy; tourism demand; environmental refugees and internal migration
Destructive fishing practices (dynamite, cyanide, bottom trawling)	Shift to market economies; on-going demand for live food fish, aquarium species; increasing competition associated with diminishing resources
Coastal deforestation	Lack of alternative materials; increasing competition associated with diminishing resources; global commons perceptions
Mining (coral, sand, minerals, dredging)	Lack of alternative materials; global commons perceptions
Aquaculture-related habitat conversion	International demand for luxury items (including new markets); regional demand for food; demand for fishmeal in aquaculture and agriculture; decline in wild stocks or decreased access to fisheries (or inability to compete with larger-scale fisheries)
Habitat degradation	
Eutrophication from land-based sources (agricultural waste, sewage, fertilizers)	Population growth; urbanization; lack of infrastructure (stormwater, sewage systems); lack of sewage treatment; unregulated agricultural development and management; loss of natural catchments (wetlands, etc.)
Pollution: toxins and pathogens from land-based sources	Increasing pesticide and fertiliser use; lack of regulations associated with use; lack of awareness of impacts; unregulated industries

DIRECT DRIVERS	INDIRECT DRIVERS
Pollution: dumping and dredge spoil	Lack of alternative disposal methods; decreasing terrestrial options; increasing regulation and enforcement of terrestrial disposal; lack of awareness of impacts
Pollution: shipping-related	Increased ship-based trade; substandard shipping, pollution and violation of marine safety regulations; flags of convenience
Increased salinization of estuaries due to reduced freshwater flows	Increased and unregulated agricultural development; increased demand for electricity and water
Introduction of alien species	Lack of regulations on the discharge of ballast; increased aquaculture-related escapes; lack of agreements and policies on deliberate introductions
Overexploitation	
Directed take of low-value species at volumes exceeding sustainable levels	Population growth; demand for subsistence and markets; globalization of trade networks, increased demand for aquaculture feed, industrialization of fisheries; improved fishing technologies; poor management and enforcement; breakdown of traditional regulation systems; introduction/maintenance of subsidies
Directed take of high-value species for luxury markets at volumes exceeding sustainable levels	Demand for speciality foods, medicines, aquarium fish, globalization of trade networks, lack of awareness of or concern about impacts
Directed take of commercial species; decreasing availability for subsistence and artisanal use	Population growth, globalization of trade networks, industrialization of fisheries; improved fishing technologies; poor management and enforcement; breakdown of traditional social systems; introduction/maintenance of subsidies
Incidental take or by-catch	Poor management and enforcement; lack of awareness of or concern about impacts

4. Major ecosystem services

Coastal and shelf ecosystems provide a diverse range of services to marine and terrestrial environments and benefits to human society (Table 4). Globally, coastal

and shelf marine habitats are estimated to provide over 14 trillion United States dollars' worth of ecosystem goods (e.g., food and raw materials) and services (e.g., disturbance regulation and nutrient cycling) per year (Costanza et al., 1997). Valuable natural resources, such as fisheries, oil, deep sea mineral deposits and pharmaceutical constituents, are abundant throughout coastal, shelf and offshore waters of the South Pacific Ocean. Inshore regions provide coastal protection and artisanal fisheries, aquaculture, and tourism provide significant income for local communities (SPREP, 2012). The natural environment of coastal and inshore regions is an integral part of the culture, tradition, history and way of life for many communities. These resources are therefore essential to the livelihoods of communities throughout the South Pacific Ocean, as well as being desirable for the global community. On-going use of coastal ecosystems and associated declines in the health of these ecosystems have flow-on effects on the benefits and ecosystem services these provide to the environment and to the communities that rely on them.

4.1 Services to ecosystem being lost

Loss of coastal ecosystem biodiversity has been identified as affecting three primary ecosystem services: provision of nursery habitats, filtering and detoxification services and maintenance of trophic stability (Worm et al., 2006). Estuaries, salt marshes, mangroves, lagoons, seagrass meadows and kelp forests serve as nurseries for many marine species, provide interconnectivity of habitats for the life stages of some species and provide essential food resources across multiple trophic levels (Figure 10; Robertson and Blaber, 1993; Dayton et al., 1998; Orth et al., 2006; UNEP, 2006b). Mangroves, seagrass meadows and coral reefs provide protective services for the coastline, binding sediments and dissipating wave action (Moberg and Folke, 1999). Mangroves, via their ability to trap water, control the chemistry of estuarine water and the flow rates of mangrove creeks, both of which are important for water-column biota survival and dispersal (Robertson and Blaber, 1993). Mangrove forests and seagrass meadows are both an atmospheric carbon dioxide sink and an essential source of oceanic carbon, providing an essential supply of organic matter in marine environments (Suchanek et al., 1985; Duarte et al., 2005; Duke et al., 2007). Coral reefs are nitrogen fixers in otherwise nutrient-poor environments (Sorokin, 1993) and the release of excess nitrogen by coral reef systems is important for the productivity of adjacent communities (Sorokin, 1990). Reduction of these communities imperils dependent fauna with their complex habitat linkages, and endangers physical benefits like the buffering of seagrass beds and coral reefs by mangroves against the impacts of river-borne siltation (Duke et al., 2007) and protection by coral reefs against the impacts of currents, waves and storms (Moberg and Folke, 1999).

Many coastal marine habitats contain species that regulate ecosystem processes and functions through grazing and predation (Moberg and Folke, 1999). These processes operate across all trophic levels and disruption at any one trophic level can have flow-on effects across other trophic levels. For example, reduction in herbivorous and predatory reef fish in coral reef communities, as a result of overfishing in the South Pacific Ocean, has been found to result in alterations to community structure.

Alterations include increases in coral-eating starfish densities, leading to a decline in reef-building corals and an increase in non-reef-building species, such as filamentous algae (Hughes et al., 2003; Dulvy et al., 2004). Once algae become abundant, coral recovery is suppressed unless herbivores return to reduce algal cover, and corals can then recruit. Recent research on coral communities in Fiji has demonstrated, however, that chemical cues emitted by algae in degraded reefs repulse coral recruits, resulting in coral juveniles actively avoiding recruiting to these areas (Dixson et al., 2014). Declines in coral cover have flow-on effects for ecosystem processes, such as reef building, primary and secondary production, which then in turn affect higher trophic levels, and reduce ecosystem functioning.

4.2 Services to humans being lost

Many of the development goals of Pacific Island countries and territories are intricately linked to marine ecosystems and the benefits provided by them. Nowhere else in the world do so many countries depend on marine resources, and in particular, fishery resources, for economic development, food security, government revenue and livelihoods (Bell et al., 2013). Loss of coral reef habitat will affect coral reef fisheries, the majority of which are already considered to be either fully or overexploited. Anticipated human population growth will place increasing pressures on these resources and it has been estimated that an additional 196,000 km² of coral reef habitat will be required to sustain current levels of fishing (Newton et al., 2007). Projections of further reductions in coral reefs as a result of climate change are more than likely to have flow-on effects on coral reef fisheries and, as a result, reliance on pelagic resources for protein is expected to increase throughout Pacific Island countries and territories (Bell et al., 2009). Increased reliance on pelagic resources will require careful management to ensure that the socio-economic benefits from these resources are maintained sustainably (Bell et al., 2013).

Figure 10. Conceptual depiction of major mechanisms of seagrass and related key ecosystem services loss for (a) tropical and (b) temperate seagrass ecosystems. Taken from Orth et al., 2006.

Many coastal ecosystems provide communities with materials essential for construction and fuel. Mangroves provide timber, fibre and fuel, coral reefs provide lime and other building materials, and sand mining occurs in many coastal regions across the South Pacific Ocean. Shelf regions provide oil and gas and various other minerals. Over-exploitation and reduction of such finite resources will require identification of alternatives and adaptive strategies to ensure transfer to alternative economies. Logging has been identified as the most pressing issue facing the Solomon Islands: current rates are unsustainably high. Maintenance of unsustainably high rates of logging will result in serious impacts on the country's economy when the revenue stream collapses and on the population when building resources are no longer available and watersheds deteriorate (Ministry of Environment Conservation and Meteorology, 2008). Subsequent run-off of sediments from cleared areas will have further impacts on coastal reef environments and associated food resources. Construction of causeways on South Tarawa, Kiribati Islands, which block the migration pathways of several species of fish that are the focus of subsistence fisheries, has been associated with the collapse of their populations. Coastal erosion as a result of infrastructure development, overcrowding and overexploitation of the physical resources of the coastal zone of South Tarawa has resulted in the loss of houses, roads and agricultural land (Ministry of Environment, Lands and Agricultural Development, 2004).

5. Areas of special conservation significance and associated issues of the South Pacific

5.1 World Heritage Sites

Two of the largest World Heritage sites are in the South Pacific Ocean – the Phoenix Islands Protected Area and the Great Barrier Reef. Whereas the Phoenix Islands Protected Area is comprised of largely oceanic, deep water ecosystems, the Great Barrier Reef is entirely shelf-based. Other World Heritage sites located in the South Pacific Ocean with protected marine components include the Lord Howe Island Group in Australia, East Rennell in the Solomon Islands, the lagoons of New Caledonia and the Galápagos Islands in Ecuador.

The Great Barrier Reef is the world's largest coral reef system (34 million hectares), extending 2,000 kilometres along the eastern Australian coast. It comprises over 2,500 individual reefs and 900 islands. Declared in 1981, it was one of the first World Heritage sites. It is home to over 400 types of coral and is one of the richest areas in the world for animal biodiversity. The diversity of species and habitats, and their interconnectivity, make the Great Barrier Reef one of the richest and most complex natural ecosystems on earth. Key threats affecting the site include coastal development, development of ports and liquefied natural gas facilities, extreme weather events, grounding of ships, water quality and oil and gas (UNESCO, 2014a). The 2014 Great Barrier Reef Outlook Report (GBRMPA, 2014) concludes that: "Even with the recent management initiatives to reduce threats and improve resilience, the overall outlook for the Great Barrier Reef is poor, has worsened since 2009 and is expected to further deteriorate in the future." Serious declines in the condition of the Great Barrier Reef, including coral recruitment and reef building across large parts of the reef, have been observed and the report concludes that a 'business as usual' approach to managing the reef is not an option (GBRMPA, 2014; UNESCO 2014a).

The Phoenix Islands Protected Area (PIPA) was declared in 2010; at 40.8 million hectares, it is the world's largest World Heritage Site. It consists of eight oceanic coral atolls, most of which are uninhabited, two submerged reefs and fourteen identified seamounts. Its isolation and low population density have helped the area remain comparatively undisturbed and it provides important habitat for migratory and pelagic/planktonic species. It is an important breeding area for marine and seabird species and is considered a sentinel of the impacts of climate change on coral reef health (Anon., 2009). Key threats affecting the site include illegal fishing and overfishing by licensed and unlicensed vessels and degradation of seamounts. A phased zoning scheme has been proposed to ensure the site's long-term conservation. The first phase has been implemented by designating approximately 3.1 per cent of the total area of the site as a "no take" zone. As of 1 January 2015, the closure of the exclusive economic zone of the PIPA to fishing came into effect. Implementation of the second phase will involve increasing no-take areas to 25 per cent of the site and reducing offshore fishing effort for tunas. However, this implementation relies on the establishment of a trust fund which will only become

operative once its capital reaches a level which will compensate the Kiribati government for losses in distant-water fishing nation license fees associated with the reduction in fishing effort. Currently, no timelines are set for reducing fishing effort (UNESCO, 2012).

The Lord Howe Island Group, declared a World Heritage site in 1982, spans 146,300 hectares and contains the world's most southerly true coral reef. The small land area within the site provides an important breeding ground for many seabirds and its marine system demonstrates a rare example of a transition zone between algal and coral reefs. Marine assemblages consist of cohabiting tropical and temperate species and endemism is high. Key threats affecting the site include invasive plants and animals, climate change, tourism and fishing (Anon., 2003).

The East Rennell World Heritage Site, declared in 1998, comprises the southern third of the world's largest raised coral atoll, Rennell Island, the southernmost island in the Solomon Islands, whose marine area extends three nautical miles to sea. Coastal waters around the island provide important habitat for migratory and pelagic/planktonic species and it is an important site for speciation processes, especially with respect to bird species. Key threats affecting the site include logging, invasive species, overexploitation of marine resources, climate change and management of the site. These threats have resulted in the site being placed on the List of World Heritage in Danger. A state-of-conservation assessment for the removal of the site from the List of World Heritage in Danger is currently underway (UNESCO 2014b).

The lagoons of New Caledonia were declared a World Heritage Site in 2008; at 1.57 million hectares, they comprise the third-largest reef system in the world. Reef systems within the site contain the most diverse concentration of reef structures in the world, ranging from barrier offshore reefs and coral islands to near-shore reticulate reefs. It contains intact ecosystems with top predators and a large diversity and abundance of large fish (Anon., 2008). Key threats affecting the site include mining, fishing and aquaculture, tourism and climate change. One of the main management issues for the site is a lack of capacity and resources for some of the existing co-management committees tasked with managing the site in enforcing fisheries and water-quality regulations and responding to incursions (UNESCO, 2011).

The Galápagos Islands were designated a World Heritage Site in 1978. They are renowned for their unique species and inspiration for the theory of evolution by natural selection proposed by Charles Darwin in the mid-1800s. The archipelago of 19 islands lies at the confluence of three ocean currents and is highly influenced by ENSO, generating one of the richest and most diverse marine ecosystems in the world. The direct dependence on the marine environment by much of the island's wildlife (e.g., seabirds, marine iguanas, sea lions) intricately links terrestrial and marine environments in the site. Lack of management of commercial, sport and illegal fishing, leading to overfishing of the marine environment, a lack of quarantine measures enabling alien species invasions, and unsustainable and uncontrolled tourism development contributed to the islands being placed on the List of World Heritage in Danger in 2007. Following strengthened quarantine, fishing and tourism management and governance of the islands, the site was removed from this list in

2010. Key threats affecting the site include changes in the identity, social cohesion and nature of the local population and community, illegal activities, tourism, visitors and recreation and the related infrastructure and management activities, systems and plans (UNESCO, 2014c).

5.2 Large Marine Ecosystems and Ecologically and Biologically Significant Areas

The South Pacific Ocean contains five Large Marine Ecosystems (LMEs), three along the eastern coastline of Australia (the north-east Australian shelf/Great Barrier Reef, the east-central Australian shelf and the south-east Australian shelf), one on the New Zealand shelf and one incorporating the Humboldt Current. The definition of these areas is based on four ecological criteria: (i) bathymetry; (ii) hydrography; (iii) productivity; and (iv) trophic relationships and definitions. These criteria provide a framework to focus on marine science, policy, law, economics and governance on a common strategy for assessing managing, recovering and sustaining marine resources and their environments (Sherman and Alexander, 1986). The approach uses five modules to measure and provide indicators of changing states within the ecosystem of each LME, including productivity, fish and fisheries, pollution and ecosystem health, socio-economics and governance. Because a lot of these factors have been discussed in previous sections of this chapter, details of each LME will not be provided again here.

The Strategic Plan for Biodiversity 2011-2020 developed under the Convention on Biological Diversity², provides a framework for reducing biodiversity loss and maintaining ecosystem services. It is centred around 20 targets, the Aichi Biodiversity Targets, organized under five strategic goals and the identification of marine areas in need of protection and within which the targets can be best focused known as Ecologically or Biologically Significant Marine Areas (EBSAs). Identification of these areas is based on seven scientific criteria, including (i) uniqueness or rarity; (ii) special importance for life-history stages of species; (iii) importance for threatened, endangered or declining species and/or habitats; (iv) vulnerability, fragility, sensitivity, or slow recovery; (v) biological productivity; (vi) biological diversity; and (vii) naturalness (Secades et al., 2014). To date, 26 EBSAs have been identified from the western South Pacific Ocean and 13 identified from the eastern South Pacific Ocean (Table 3).

6. Factors for sustainability

The conservation and sustainable use of marine ecosystems is a goal articulated under a number of national and international policies and the development plans of countries in the South Pacific Ocean. It is becoming evident that the extent to which marine ecosystems can absorb recurring natural and anthropogenic perturbations and continue to regenerate without continued degradation will require improvements to current resource management (Hughes et al., 2005). Furthermore, current resource management and supporting marine policy will need to incorporate multi-scale ecological and social information in order to sustain delivery of ecosystem services and benefits. With this in mind, coastal and ocean managers confront a growing diversity of challenges in balancing environmental and socio-economic needs throughout the South Pacific Ocean.

6.1 *Ecosystem-based management and integrated coastal zone management*

Ecosystem-based management (EBM) approaches are broadly accepted as cornerstones to effective marine conservation and resource management (Levin et al., 2009). Ideally frameworks for EBM should consider multiple external influences, value ecosystem services, integrate natural and social science into decision-making, be adaptive, identify and strive to balance diverse environmental and socioeconomic objectives, and make trade-offs transparent. Integrated coastal zone management (ICZM) can be used within an EBM framework to address the ecological and human complexity of interconnected systems. Development of ICZM, in principle, should incorporate an integrated, adaptive approach for coastal management that addresses all aspects of the coastal and neighbouring ocean zone, including land–coastal interactions, climate change, geographical and political boundaries, in an effort to achieve long-term sustainable use and reduce conflicts. It requires the careful balancing of a wide range of ecological, social, cultural, governance, and economic concerns. Although some examples exist of the implementation of ICZM throughout the South Pacific Ocean (e.g., see National Resource Management Ministerial Council, 2006; Department of Conservation, 2010; section 6.2), for many countries, comprehensive coastal management remains a challenge.

Within the Pacific Islands region, a Framework for a Pacific Oceanscape has been developed and endorsed by 23 countries and territories within the region. This framework, finalised in 2012, draws on the Pacific Islands Regional Oceans Policy and has been designed to address six strategic priorities associated with marine resource conservation, habitat protection and fisheries management (Pratt and Govan, 2010). These priorities will be met via the development of terrestrial and marine protected areas, identification of risks and mitigation strategies for climate change and the provision of research and leadership capacity development throughout the region (Pratt and Govan, 2010).

Uptake of EBM approaches to resources and, in particular, to commercial fisheries has also been slow and although such an approach may have been adopted at a policy level, practical implementation is largely lacking (Garcia et al., 2003; Smith et

al., 2007). Traditional management of fisheries, which is still conducted by most national and international management agencies throughout the South Pacific Ocean, concentrates on individual fish populations strictly in demographic terms, i.e., accounting for the input of individuals as population growth or immigration and the output in terms of natural and fishing mortality. Fish populations, however, are also affected by variability in external factors, such as predator and prey abundances and variability in their bio-physical environment. At the same time, changes in the abundance of populations will affect all the surrounding ecosystems of which fishes are part. Federal, state and territorial fisheries management agencies in Australia have adopted ecosystem-based fisheries management as the approach to future management (Smith et al., 2007). Tools to facilitate this approach have largely been developed and implemented for most Commonwealth fisheries and are in various stages of development for state and territory fisheries.

6.2 *Marine management areas*

The establishment of representative systems and networks of marine management areas is regarded internationally and nationally as one of the most effective mechanisms for protecting biodiversity and a tool for resource sustainability. Protected areas, including national parks, managed resource protected areas, locally managed marine areas, marine reserves, protected seascapes, and habitat management areas, occur in varying degrees in the coastal and offshore regions of countries and territories throughout the South Pacific Ocean (see also section 5.1). Co-ordinated networks of protected or managed areas providing for protection of ecosystems representative of regions are largely lacking, with the exception of Peru's Guano Islands, Islets and Capes National Reserve System (RNSIIPG), and enforcement is an issue for many marine management areas. Australia's National Representative System of Marine Protected Areas (NRSMPA) has been developed for Australian marine waters, but is currently under review and yet to be implemented. Community-based management areas throughout the Pacific Islands and territories have shown some level of success, largely because those that benefit from sustainable resource use are those directly involved in managing those resources. However, managers of community-based management areas are often not equipped to ensure that management is effective. Across many communities, knowledge about the long-term effects of current use of marine resources, sustainability issues, and the requirements for management, research, and monitoring is poor. The need to strengthen education has been identified by a number of countries. Frameworks for the identification and implementation of marine protected areas at regional scales are also being developed under the Convention on Biological Diversity³ (see section 5.2) and the Framework for a Pacific Oceanscape (see section 6.1). Recent research has demonstrated that in areas where full protection of marine regions is untenable because of dependence of communities on marine resources, even simple forms of fisheries restrictions can have substantive positive effects on functional groups (MacNeil et al. 2015).

³ United Nations, *Treaty Series*, vol. 1760, No. 30619.

6.3 *Integration of climate change adaptation and mitigation into marine policy, planning and management*

Over the long term, one of the largest threats to coastal and marine systems within the South Pacific Ocean is climate change. Responding to the environmental and socio-economic consequences of climate change in order to maintain ecosystem services requires coordinated and integrated efforts in incorporating adaptation and mitigation options into marine policy, planning and management. International efforts at coordinated adaptation and mitigation planning have occurred, largely through the United Nations Framework Convention on Climate Change, either via National Adaptation Programmes of Action (NAPAs) in the case of least developed countries, or National Communications for Annex I countries (see www.unfccc.int). At present, however, examples of the implementation of climate change adaptation actions are limited, even though acceptance is widespread of the need for adaptation and for significant investments in adaptation planning. Factors affecting implementation include local adaptive capacity, inabilities and inefficiencies in the application of existing resources, and limited institutional support and integration, particularly between and across governments (Christensen et al., 2007; Noble et al., 2014). In order to overcome this, adaptation assessments may need to link more directly to particular decisions and tailor information to local contexts to facilitate the decision-making process (Noble et al., 2014). Key components in the integration of adaptation and mitigation options should include (i) stakeholder participation in decision making; (ii) capacity development; (iii) communication, education and public awareness; (iv) development of alternative income-generating activities; (v) monitoring; (vi) addressing uncertainty and (vii) analysis of trade-offs (UNEP, 2006b). Without ensuring that adaptation options are integrated into coastal zone management, it is likely that ecosystem services will not be maintained into the future (Bell et al., 2013).

Chapter 36E. Indian Ocean

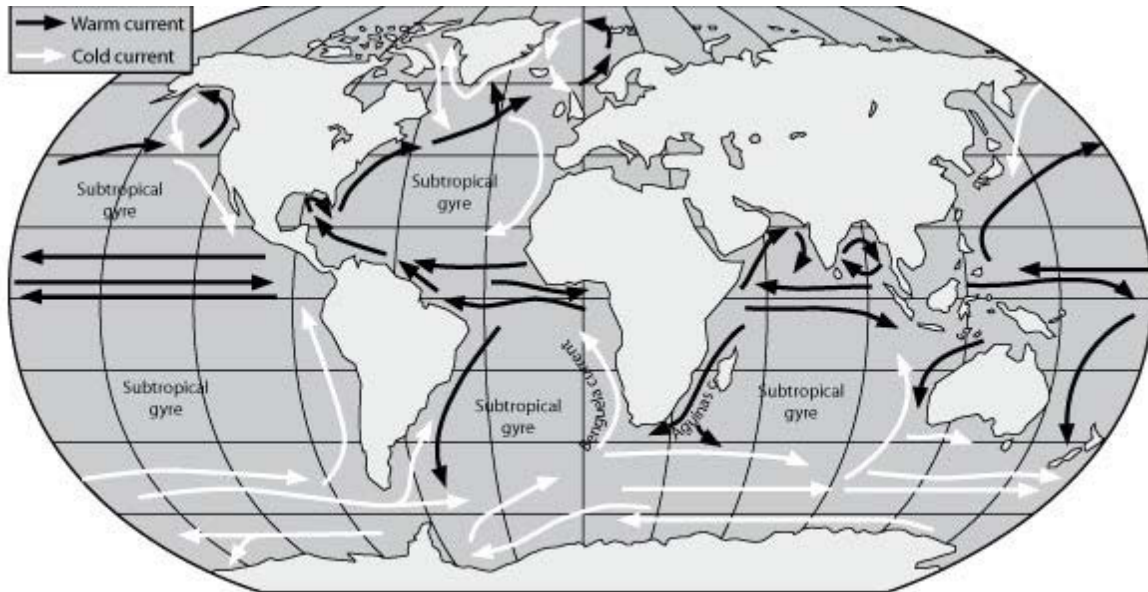

Group of Experts: Renison Ruwa, and Jake Rice¹

1. Introduction

The Indian Ocean is the third largest ocean in the world. It is mostly surrounded by a rim of developing countries and island States, one of which is the fourth largest island in the world, Madagascar. The Indian Ocean is bound by Asia to the north, by Africa to the west, Australia to the east and Antarctica to the south. It has two major seas, the Red Sea between the Arabian Peninsula and Africa, and the Arabian Sea to the west of India; and the largest bay, the Bay of Bengal, to the east of India. Following the FAO statistical fishing areas, the Indian Ocean is divided into two major parts: the Western Indian Ocean (WIO) and Eastern Indian Ocean (EIO) (FAO, 1990-2015).

In terms of the oceanographic physical environment of the Indian Ocean, the major epipelagic atmospheric and ocean currents in relation to other global features are as depicted in Figure 1. The detailed seasonal characteristics of the reversing wind systems of the monsoon are shown in Figure 2. The system is important in the distribution of global heat, salinity and biogeochemical cycling of carbon and inorganic elements (Wajih et al., 2006). There are basically two monsoonal seasons, but it is common to have a third inter-monsoonal season: North East Monsoon (NEM), from February to May; South West Monsoon (SWM) from June to October and an Inter-Monsoon Season (IMS) from November to January.

¹The members of the Group of Experts would like to thank Cosmas Munga, Melchzedek Osore, and Nina Wambiji for their substantive input to this chapter.

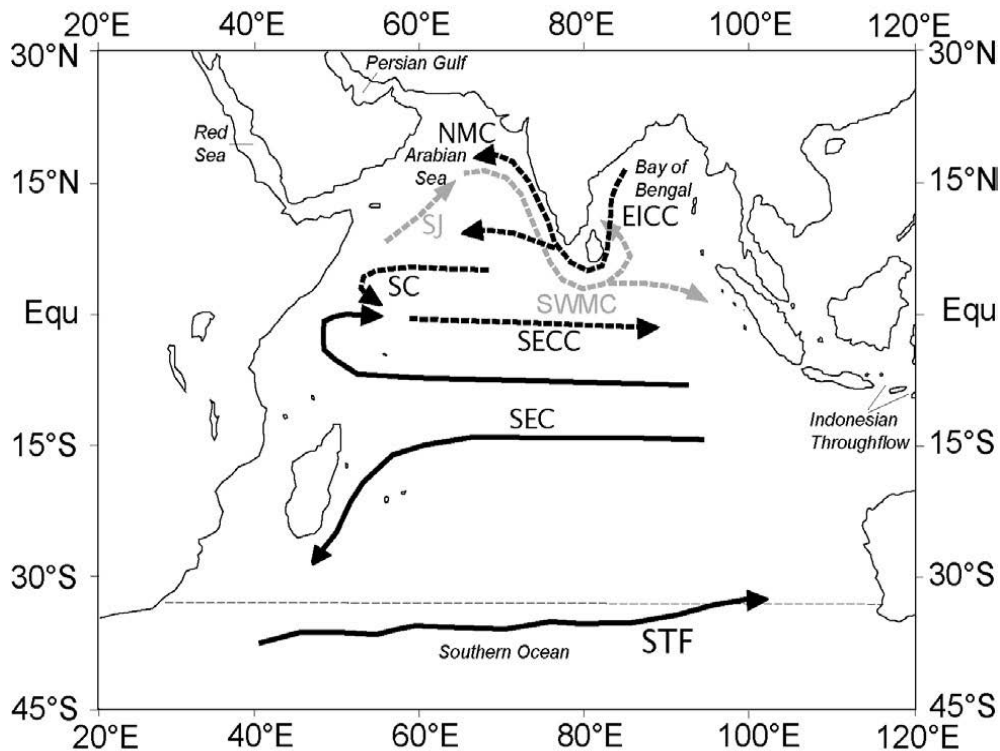

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Map to show the epipelagic water masses and current patterns in the Indian Ocean in relation to other global circulations in the world oceans (Source: Pierrot-Bults and Angel 2013).

It is noted that:

- (a) From a wide geographical perspective, most of the major ocean area is under-sampled with regard to both coastal and oceanic environments. The oceanic areas are particularly unsampled and therefore the biological diversity is still incompletely described for most ecosystems;
- (b) In terms of human scientific capacity, there is an extreme lack of taxonomists and therefore most of the species are still undescribed or are simply unknown;
- (c) Much of the area has largely been studied using satellite technology, so observations are based on remote sensing and therefore driving forces at species and community level are relatively vague or unknown; there is a need to undertake ground truth sampling to support satellite data;
- (d) Most studies are based on isolated collections in localized areas and are not continuous, making it difficult to discern possible trends;
- (e) Coastal and offshore ocean sampling are rarely synchronized in space and time, increasing data gaps in data collection;
- (f) At regional scales most of the sampling methods are not standardized making the data difficult to compare and a weak basis for describing status and trends or creating baselines for benchmarking. There is a need to form regional multidisciplinary research teams to address these needs. Such teams could create the necessary synergy to share research capacity in terms of both human skills and infrastructure, standardize research methodologies, synchronize sampling programmes and plans, establish sampling stations for continuous sampling and data generation for long-term research data requirements, and create databases.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Major features of the surface circulation in the Indian Ocean [after Schott and McCreary, 2001; Wajih et al., 2006]. The SEC (South Equatorial Current), SECC (South Equatorial CounterCurrent), and STF (Subtropical Front) are present throughout the year. Surface currents during the Northeast Monsoon include the NMC (Northeast Monsoon Current), SC (Somali Current), and EICC (East Indian Counter Current). Surface currents during the Southwest Monsoon include the SWMC (Southwest Monsoon Current) and SJ (Somali Jet). (Source: Bates et al., 2006).

2. Indian Ocean Biodiversity

The Indian Ocean covers about 30 per cent of the total global ocean area and being predominantly a tropical ocean, accounts for a significant part of tropical coastal biodiversity and deep-sea oceanic biodiversity in various marine ecosystems. It accounts for 30 per cent of the total global coral reef cover, 40,000km² mangrove cover, besides supporting various types of biodiversity found in its various ecosystems (Table 1). There has been progress in addressing marine and coastal biodiversity since the major surveys undertaken in the first International Indian Ocean Expedition (IIOE) (1960-1965) about 50 years ago (<http://www.incois.gov.in/portal/iioe/aboutus.jsp>). The present review of Indian Ocean biodiversity will address the long-term status, trends and research gaps in relation to:

- (a) Marine fisheries including tuna, focusing on their exploitation and species diversity over wide geographic coverage;

(b) Threatened megafauna species, particularly: marine mammals, marine reptiles and seabirds, focusing on describing the status and trends including their associated drivers and general abundances and what dominant taxa groups exist;

(c) Description of phytoplankton production, zooplankton and benthos structures focusing on their abundance and diversity, including the drivers of change and possible effects of climate change; identifying hot spots for primary production in both coastal and deep sea over various time and geographical scales and major influences of seasonality.

Table 1: Types and area cover of marine ecosystems in the Indian Ocean (Source: Wafar et al., 2011)

ECOSYSTEM	Area (in million km²)
Open ocean	
Oligotrophic	19.6
Transitional	23.8
Equatorial divergence	18.9
Coastal	
Upwelling zones	7.9
Other neritic waters	5.3
Other	
Coral reefs	0.2
Mangroves	0.04
Sandy and rocky beaches	0.004
Estuaries	-
Hypersaline water bodies/lagoons	<0.005

3. Fish Biodiversity

This section mostly presents information on marine capture fisheries, as reported by the FAO and the Indian Ocean Tuna Commission (IOTC).

3.1 Marine Finfish

The contribution of coastal and marine capture fisheries (finfish, shellfish and molluscs) from the Indian Ocean (average of 11.01 million tons annually) to the global landings is third after the Pacific Ocean (average of 48.3 million tons annually) and the Atlantic Ocean (average of 11.03 million tons annually) based on the 2003, 2011 and 2012 FAO estimates (FAO, 2014). This chapter describes the coastal and marine fisheries finfish production excluding tuna in the Indian Ocean, focusing on the status and trends in exploited species, long-term species surveys and different kinds of diversity indices over the FAO statistical areas of the EIO and the WIO. These areas have recorded increasing overall catch trends since 1950 (Figure 3) however, incidences of reduced catches have been reported in inshore areas. This increase in catches may be due to expansion of fishing to new areas or species, and the improved recording of fish landing statistics over time. The EIO and WIO together contributed 28 per cent of the total global marine catches of finfish, shellfish and molluscs in 2011 (FAO, 2014).

Figure 3. Long term trends in total finfish landings excluding tuna in the EIO, WIO and overall Indian Ocean (data source: FishstatJ – FAO Fishery and Aquaculture Global Statistics).

The EIO total finfish catches except tuna (Figure 3) are based on fish statistics from Australia and India. On the other hand, catches from the WIO are based on statistics from Kenya, Madagascar, Mauritius, Mayotte (France), Mozambique, Seychelles, South Africa and the United Republic of Tanzania. Although finfish total catches seem to be higher in the WIO, the EIO has recorded a higher growth rate in the overall catches (finfish, shellfish and molluscs), with a 17 per cent increase from 2007 to 2011, now totalling 7.2 million tons (FAO, 2014). The Bay of Bengal and Andaman Sea regions have seen total catches increase steadily with no signs of the catch levelling off. The highest catches both in the EIO and WIO are made up of the category "marine fishes nei", that is, "marine fish that are not identified" (Figure 4). This is a cause for concern as regards

the need for monitoring stock status and trends. In the EIO alone, this category “marine fishes nei” makes up about 42 per cent of the catches (FAO, 2014). A group of small pelagic fish categorized as “clupeoids nei” also support high landings, as do sharks, rays and skates in the EIO. The decline in fish catches in the EIO, especially within Australia’s exclusive economic zone, can be partly explained by a reduction in effort and catches following structural adjustment to reduce overcapacity and a ministerial direction in 2005 aimed at ceasing overfishing and allowing overfished stocks to rebuild (FAO, 2014).

Figure 4. Top twenty highest landed finfish species except tuna from the Eastern Indian Ocean based on total catches from 1950-2010 data in Australia and India (data source: FishstatJ – FAO Fishery and Aquaculture Global Statistics).

The WIO shows a similar scenario, in which the largest catches are made up of the category “marine fishes nei” followed by the small pelagic “Indian oil sardine”, ponyfishes, and sharks, rays and skates. Total landings in the WIO reached a peak of 4.5 million tons in 2006, but then declined slightly, with 4.2 million tons in 2011 (FAO, 2014). A recent assessment has shown that the narrow-barred Spanish mackerel (*Scomberomorus commerson*) is overfished, and this species is among the 20 most highly landed (FAO, 2014; Figure. 6) in the WIO. Long term catch data in the Indian Ocean, especially the WIO, are often not detailed enough for stock assessment and

species composition purposes, a situation aggravated by the lack of adequate resources to conduct scientific studies, monitoring and enforcement (McClanahan and Mangi, 2004). However, the Southwest Indian Ocean Fisheries Commission (SWIOFC) conducted stock assessments for 140 species in 2010 based on best available data and information (FAO, 2014). Overall, 75 per cent of fish stocks were estimated to be fully fished or under-fished, and 25 per cent fished at unsustainable levels. There are many other species in the Indian Ocean where the level of exploitation is unknown or is extremely difficult to determine. Long-term trend analysis by individual fish taxa indicates that catches of sharks, rays and skates together started to decline or level off from the mid-1990s in both the EIO and WIO (Figure 5a). In the late 1990s, a similar trend is observed with the narrow-barred Spanish mackerel in the WIO (Figure 5b).

Figure 5. Long-term trends in total landings of (a) sharks, rays and skates in EIO and WIO, and (b) narrow-barred Spanish mackerel in the WIO.

Fish species diversity studies in the Indian Ocean, especially in the WIO are biased to coral reef areas. Fish diversity in relation to coral reefs in the region covering about 200 sites situated in Kenya, Madagascar, Maldives, Mauritius, Mayotte (France), Mozambique, Reunion (France), Seychelles, South Africa and the United Republic of Tanzania was studied (McClanahan et al., 2011). This study found that the region from

southern Kenya to northern Mozambique across to northern eastern Madagascar and the Mascarene Islands and the Mozambique-South Africa border are areas with moderate to high fish diversity. The WIO fish fauna is one of the richest marine fish faunas in the world, with some 3,200 species or about 20 per cent of the world marine fish fauna. Despite considerable effort by ichthyologists over the past two centuries, the taxonomy of WIO fishes is ongoing. Of the 329 new marine species described between the years 2002 and 2012, 140 were from the WIO (<http://www.saiab.ac.za/coastal-fishes-of-the-western-indian-ocean.htm>).

Long-term fish species surveys are scanty in the Indian Ocean. The South African line fishery however, has been monitored since the late 1900's. This fishery is multispecies targeting over 200 species with about 50 being economically important. Due to concerns of overfishing, management measures were first introduced in the 1940s. Stock assessment of the line fishery has been based on both fishery dependent and independent data, as well as data from marine protected areas. Since 1985, the South African line fishery has been one of the largest spatially referenced marine line fishery data sets. After the introduction of management measures, monitoring results have indicated that, generally, the over-exploited line fish stocks are now slowly recovering except for *Polysteganus undulosus* which has remained significantly reduced (SWIOFC, 2012).

This chapter has identified key gaps in relation to the Indian Ocean fisheries, as follows:

- Total catch statistics data is mostly still poor in terms of temporal and spatial coverage, and catches are in many cases estimates of actual catches. This is attributed to lack of human and financial capacity as well as remoteness of some of the fish landing sites;
- Lack of a comprehensive species' composition data. To date, the largest proportion of catches is categorized as "unidentified". This is attributed mainly to the inadequate knowledge in fish taxonomy in the region;
- Long-term research surveys in the region are rare due to lack of professional expertise, infrastructure and financial capacity. Most of the research surveys are short term and sporadic depending on availability of donor funding. The International Indian Ocean Expedition, if regularly implemented could be the best source of long-term research survey data.
- The impacts of fishing gears on target fisheries, by-catches and habitats are hardly studied, and bottom contacting fishing gears are used indiscriminately in the region, resulting in biodiversity losses.

3.2 Tuna Species

Tuna and tuna-like species form the most important resources of the offshore pelagic fishery. In the Indian Ocean, both the EIO and the WIO, at least seven different tuna species, including tuna-like species, have been reported in the landing statistics. The

four main commercially fished tuna species in the Indian Ocean are: albacore (*Thunnus alalunga*), skipjack tuna (*Katsuwonus pelamis*), yellowfin tuna (*T. albacares*) and bigeye tuna (*T. obesus*). The other species are: frigate and bullet tunas (*Auxis* sp.), kawakawa (*Euthynnus affinis*), southern bluefin tuna (*Thunnus maccoyii*), and tuna-like species. Since 2010, after three years (2007–09) during which piracy negatively affected fishing in the WIO, tuna catches have recovered. During the 2007-2009 period, total tuna catches decreased by 30 per cent as piracy deterred fishing operations (FAO, 2014). Among the 23 major fish species in the global marine capture fisheries, skipjack tuna ranked third with increasing landings of 2.2 million tons in 2003, 2.6 million tons in 2011, and 2.8 million tons in 2012 (FAO, 2014). The yellowfin tuna was ranked eighth, however with variable landings of 1.5, 1.2 and 1.4 million tons in 2003, 2011 and 2012 respectively.

In the last 5 decades, total landings of tuna and tuna-like species in the Indian Ocean have been increasing (Figure 6). This is especially evident in the WIO region, whose global contribution in total tuna landings is 30 per cent. The increasing trend of total tuna and tuna-like landings in the EIO region is not pronounced as landings have remained just about 20 000 tons annually for a long time between 1982 and 2010. During this period, a total of 7 tuna species and tuna-like species were recorded in the Indian Ocean (Figure 7). The contribution of tuna and tuna-like landings for the WIO region in the last 5 decades came from India, Kenya, Madagascar, Mauritius, Mayotte (France), Mozambique, Seychelles, South Africa and the United Republic of Tanzania. On the other hand, landings for the EIO during the same period were reported from Australia, India, Madagascar and Seychelles.

Figure 6. Long term trends in total tuna and tuna-like landings in the EIO, WIO and overall Indian Ocean (data source: FishstatJ – FAO Fishery and Aquaculture Global Statistics).

The landing statistics of tuna and tuna-like species in the last 5 decades in the Indian Ocean show a great variation in terms of species percent composition of total landings

(Figure 7). In this period, skipjacks, kawakawa and yellowfin tuna contributed the highest percent composition of 29 per cent, 24 per cent and 23 per cent respectively. The lowest percent composition was made up of albacore (0.4 per cent), tuna-like fishes nei (2 per cent), and bigeye tuna (4 per cent). The species frigate and bullet tunas, and southern bluefin tuna contributed intermediate percent composition of about 9 per cent each.

Figure 7. Species percent composition of total landings of tuna and tuna-like from the Indian Ocean based on total catch data from 1950-2010 (data source: FishstatJ – FAO Fishery and Aquaculture Global Statistics).

Recent stock assessment estimates from the Indian Ocean Tuna Commission (IOTC) indicate that yellowfin, bigeye tuna stocks, skipjack and albacore are not overfished and not subject to overfishing (IOTC, 2014). Estimates of the total and spawning stock biomasses show a marked decrease over the last decade, accelerated in recent years by the high catches of 2003-2006 (Figure 7). The Spawning Stock Biomass was estimated to be 57 per cent for the skipjack tuna, 38 per cent for the yellowfin tuna, 40 per cent for the bigeye tuna and 57 per cent for the albacore of the unfished level. However current fishing mortality has not exceeded the Maximum Sustainable Yield (MSY) level for these species (IOTC, 2014).

The estimated catches for the skipjack tuna was 455,000 tons in 2009 and 428,000 tons in 2010 with an average catch of 500,000 tons between 2005 and 2010 being lower than the median value of the estimated Maximum Sustainable Yield. IOTC recommended that catches should not exceed 500,000 tons. The MSY for yellowfin tuna for the whole Indian Ocean should not exceed 300,000 tons, while the MSY estimates for bigeye tuna is estimated at 102,664 tons. Based on available data, the major challenge in the region

at large is declining spawning stock biomass and the possibility of recruitment overfishing.

3.3 *Research gaps*

There is a need to research the impacts of the target fish catches and fishing gear on non-target fish or bycatch, food chains cycles and overall on species biodiversity, especially focusing on various taxa over long-term periods in order to also account for climate change effects.

4. **Plankton Diversity**

The contribution of the Indian Ocean plankton data into the World Ocean Database (WOD) is still very minimal. Similarly, except for India and South Africa and to some extent Indonesia and Pakistan, very little research is undertaken by the countries of the Indian Ocean region. The national contribution of plankton data work in the WOD09 by the countries bordering the Indian Ocean is less than 1.5 per cent. Likewise, among the major international oceanographic projects that contribute to the plankton data, only a minimum has involved the Indian Ocean.

4.1 *Phytoplankton*

Marine phytoplankton are an essential component in marine life as they play a fundamental role in the biodiversity and bio-productivity of the marine ecosystem. They are mainly microscopic plants that float passively throughout the pelagic zone, pushed by the dominant ocean current. They also play a crucial role in the food chains and food webs, as phytoplankton represent the primary producers of organic matter and zooplankton are the link between the phytoplankton and higher trophic levels. In addition, plankton play a crucial role in the biogeochemical cycle of numerous chemical elements in the ocean.

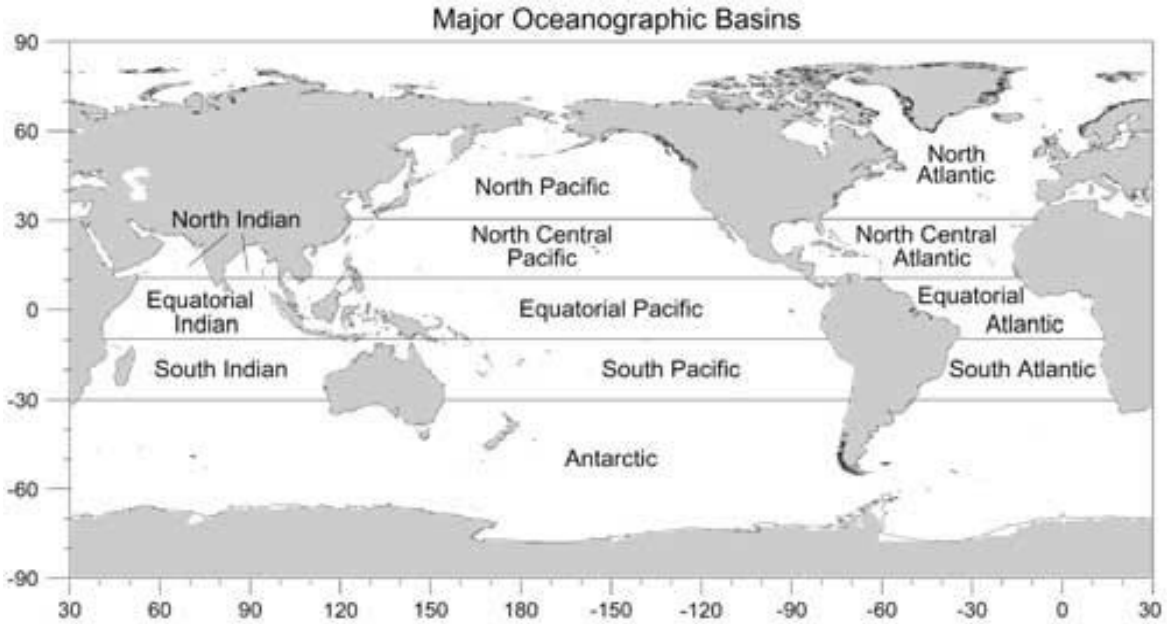

In a balanced ecosystem, phytoplankton provide food for a wide range of sea creatures including whales, shrimp, snails and jellyfish. During unusually high availability of nutrients, phytoplankton may grow out of control and form harmful algal blooms (HABs). These blooms can produce extremely toxic compounds that have harmful effects on fish, shellfish, mammals, birds, and even humans. The Intergovernmental Oceanographic Commission of the United Nations Educational, Scientific and Cultural Organization (IOC-UNESCO) has supported effort towards the detection, identification and management of HABs in the WIO region but the data are still inadequate to generate trends.

Results from the Tyro Expedition in the WIO under the Netherlands Indian Ocean Programme (NIOP, 1991-1995) established that the seasonal change in monsoon regime affect the nitrogen nutrition of marine phytoplankton conspicuously (Wafar et al.,

2011). Seasonal variation of phytoplankton abundance and diversity is a common occurrence in many bays and creeks of the Indian Ocean. This is driven by the interchanging monsoon regime almost every half year as well as by water quality as result of land based activities.

Research undertaken by India in its west coast, in the Arabian Sea, and east coast, in the Bay of Bengal, has demonstrated strong monsoonal seasonality using satellite and remote sensing technology and sampling cruises (Moharana and Patra, 2013) to measure chlorophyll and analyze patterns of distribution over time. The same technology has also been used to study the global impact of climate change on in primary production in oceans using chlorophyll concentrations (Gregg et al., 2003)

Climate change effects on primary production in the oceans have been a major subject of study globally. Using satellite technology to study chlorophyll records over 22 years, from 1980, in 12 major oceanographic basins (Figure 8), it has been established that the global annual ocean primary production has declined by 6 per cent since 1980. The question is whether the Indian Ocean has behaved similarly. The Indian Ocean is divided in three major oceanographic basins which are: North Indian Ocean, Equatorial Indian Ocean and South Indian Ocean. On the basis of the differences between the SeaWiFS (1997-2002) and CZCS (1979-1986), the analysis which not only involved primary production but also environmental parameters including surface sea temperatures, nutrients and wind stress in the 12 major oceanographic basins (Figure 9 and 10), is summarized in Table 2. It is clear from this analysis that primary production increases in the North and Equatorial Indian Ocean but decreases in the South Indian Ocean basin, which is at higher latitudes and close to the Antarctica basin, where also the primary production decreases. It was further noted that the highest increase occurs in the western portion of the Arabian Sea, in the west coast of India, and in the North Indian oceanographic basin, which experiences upwelling (Gregg et al., 2003). Chaturvedi et al., (2013) observing the chlorophyll behaviour around the coast of India, recorded that there was higher chlorophyll from December to March in the Arabian Sea whereas in the Bay of Bengal, the peak occurs in February to March.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 8. Boundaries for the 12 major oceanographic basins (Source: Gregg et al., 2003).

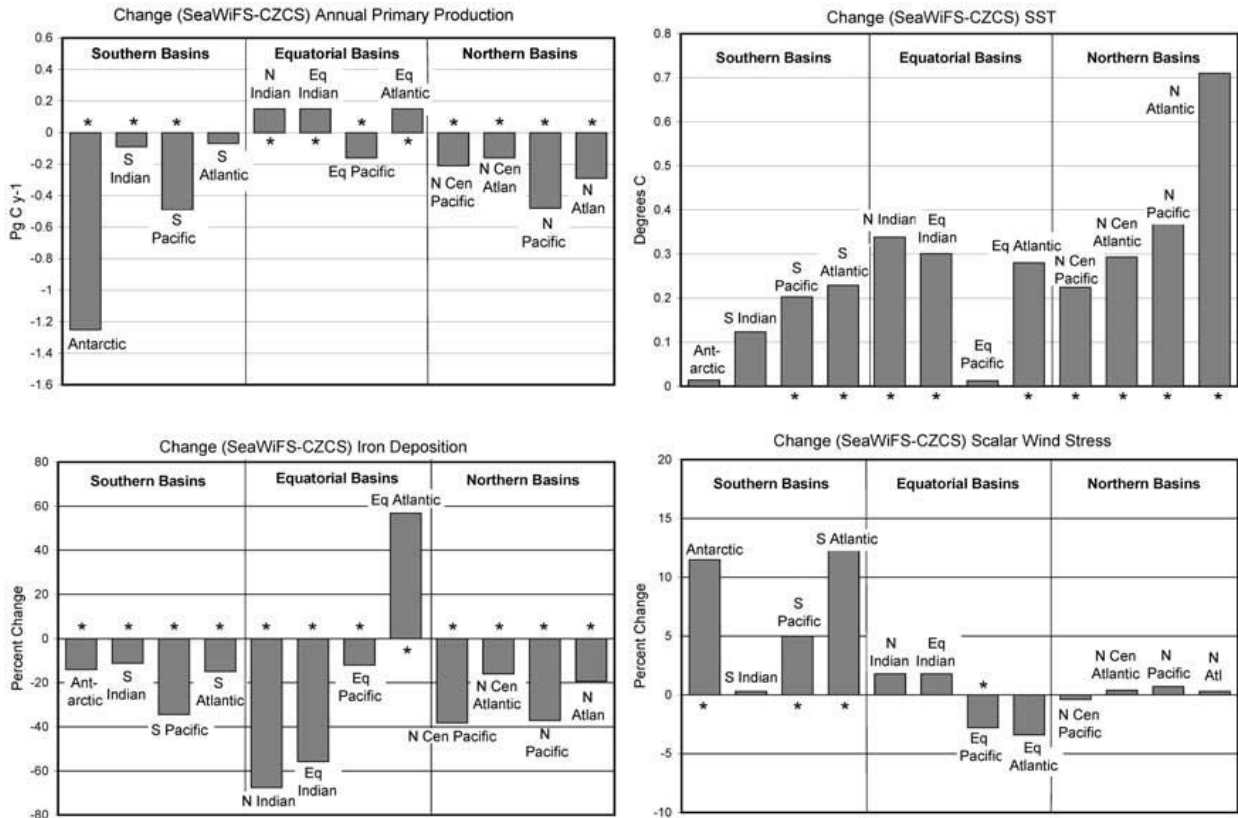

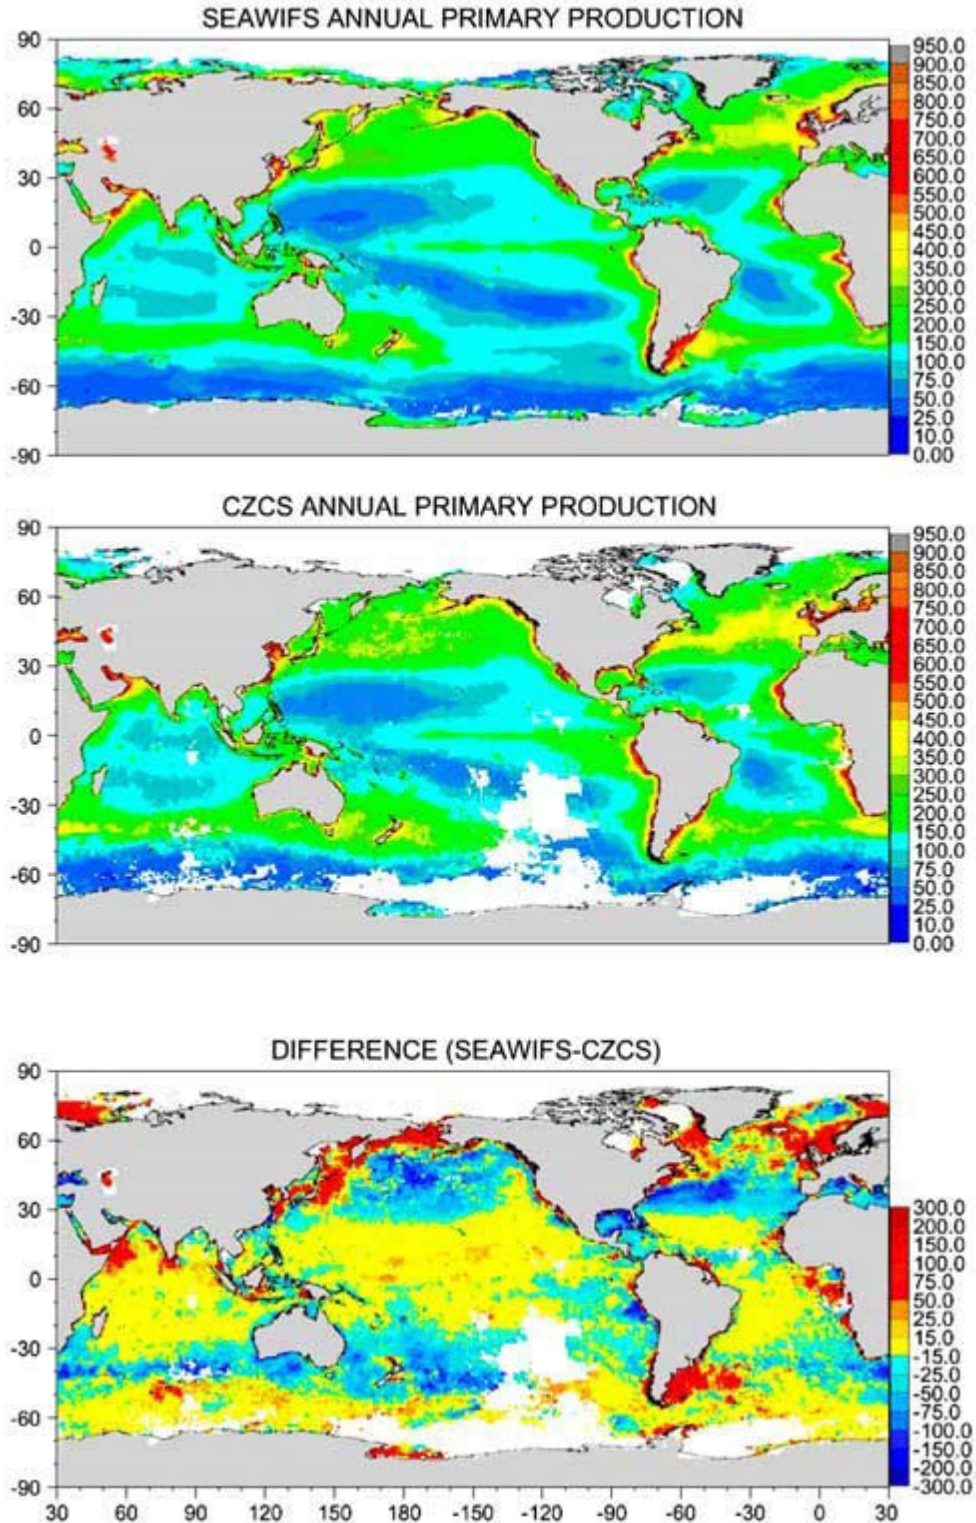

Figure 9. Differences between SeaWiFS (1997–2002) and CZCS (1979–1986) in the 12 major oceanographic basins. Differences are expressed as SeaWiFS-CZCS. Top left: Annual primary production (Pg C y^{-1}). An asterisk indicates the difference is statistically significant at $P < 0.05$. Top right: SST (degrees C). Bottom left: iron deposition (%). Bottom right: mean scalar wind stress (%) (Source: Gregg et al., 2003).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 10: Primary production distributions for the SeaWiFS era (1997-mid-2002), the CZCS era (1979-mid-1986) 327 and the difference. Units are $\text{gCm}^{-2}\text{y}^{-1}$. White indicates missing data (Source: Gregg et al., 2003).

Table 2: Percent change in ocean primary production (SeaWiFS-CZCS) by basin and surface area of the basins (10km²) where data from both SeaWiFS and CZCS were sampled (Source: Gregg et al., 2003).

OCEAN BASIN	AREA	CHANGE
N. Atlantic	1.83	- 6.7%
N.Pacific	2.32	- 9.3%
N.Central Atlantic	1.53	-7.0%
N. Central Pacific	3.22	-5,8%
N. Indian	0.46	13.6%
E. Atlantic	1.15	6.9%
E. Pacific	3.72	-3.8%
Eq. Indian	1.37	8.8%
S. Atlantic	1.20	-3.8%
S. Pacific	2.69	-14.0%
S. Indian	1.77	-4.2%
Antarctic	8.28	-10,4%
Global	29.73	-6.3%

4.2 Zooplankton

Implementation of the Indian Ocean chapter of the Census of Marine Life Programme (IOCoML) inaugurated in 2003 has vastly increased the knowledge of marine biodiversity of the Indian Ocean countries. Among the major achievement of IO-CoML is the discovery of more than 40 new zooplankton species including from groups of mysids, chaetognaths and sponges.

There are two types of zooplankton differentiated by aspects of their life cycles. There are categories of zooplankton that partly live as zooplankton, for example as larvae, and grow to sub-adults and then adults and leave the plankton community as they grow. Others live as zooplankton throughout their lives. Those that live partly as zooplankton are referred to as meroplankton, e.g. fish larvae, whereas those that live in planktonic form throughout their lives are known as holoplankton, e.g. copepods.

The biophysical factors that affect phytoplankton similarly affect zooplankton and their peaks tend to be in rhythm with a small time lag of 1-1.5 months because zooplankton depend on phytoplankton for food (Fabian et al., 2005). For vertebrate animals like fish the peak abundances are highly influenced by taxonomic category, since some taxa which are r-selected can produce eggs profusely throughout their short lives whereas k-selected tend to have fewer larvae which take long to mature and may not be in rhythm with other taxonomic groups. To discern these patterns, long-term research to cover various biophysical factors associated with seasonality, climate change, predation, pollution and eutrophication are essential and have to be multidisciplinary. These types of coordinated research protocols are lacking in the region, making it difficult to describe zooplankton status and trends.

Most studies are one-off events at short time intervals and can only be taken to represent season samples. Only in rare cases does sampling cover longer periods of the continuous cycles, although in most cases the abundance and species composition of the zooplankton vary considerably across seasons (Fazel et al., 2013). The situation is compounded by the lack of taxonomic expertise as well lack of taxonomic descriptions of many of the major zooplankton in the area (Chesalina et al., 2013). Since samples are rarely continuously collected for long-term monitoring, and most samples are collected to represent a part of a season, therefore the variances are high, making quantification of trends very difficult. This emphasizes the need to have permanent sampling platforms in the region for long-term continuous monitoring, preferably daily sampling to account for diel cycles also.

One of the clearest scenarios shown in the field relating to nutrient levels is the comparison of performance of production in the Arabian Sea and the Bay of Bengal. It is clearly observed that the production of zooplankton and phytoplankton shows a higher standing crop in the west coast of India, in the Arabian Sea, than in the east coast of India, in the Bay of Bengal. The difference is attributed to upwelling in the Arabian Sea whereas the Bay of Bengal depends only on nutrient inputs from the major rivers (Moharana and Patra 2013; Dorgham 2013).

4.3 *Research gaps*

The gaps identified requiring research in both phytoplankton and zooplankton are similar and therefore most efficiently addressed together as a plankton group, with emphasis appropriately made for either of the two groups when necessary. For regional and global comparisons of data and information to be effective the sampling methodologies need to be standardized, including equipment, and the time of cruises synchronized since plankton are highly affected by atmospheric processes and ocean currents which vary regionally and globally in time and space. There is therefore a need to establish the frequency and regular nature of sampling, number of sampling stations and their location, number of samples to be taken, methods of collection (net and/or water samples, depth of collection (surface and/or other defined and agreed depth as per sampling protocol)). Without such a coordinated research protocol approach the

studies will remain fragmented and consequently the data and information will be difficult to use for comparative studies, or to provide baselines for documenting trends. The following specific needs should be addressed:

- (a) Plan synchronized regular, multidisciplinary and comprehensive study for both phytoplankton and zooplankton and have a comprehensive database for the Indian Ocean;
- (b) Identify exotic plankton carried in various areas by ship ballast;
- (c) Collect detailed information about harmful algal blooms;
- (d) Establish fixed stations for continuous regular plankton studies for time series analysis;
- (e) Establish coastal fixed stations in water masses covering special benthic communities in critical habitats namely: Corals, seagrass, mangroves and intertidal zones;
- (f) Undertake continuous special studies on dinoflagellates cysts to establish potential of harmful algal species; and
- (g) Establish satellite networks for regional studies of primary production in relation to various environmental parameters in order to relate to climate change.

5. Benthos

Marine benthic organisms are organisms that live on or are associated with the seabed. Their usual mode of effective dispersal is through their planktonic larval or immature stages, transported by ocean currents. Key benthic habitats include: coastal water bottoms, mangrove habitats, coral reefs are benthic hot spots, seagrass beds, intertidal zones, deep water continental shelf and slopes or in the depth of ocean trenches. Since the initial IIOE in 1959-1965, there have been various other research expeditions to the northern part of the WIO that have yielded a substantial amount of results about the benthos. These have especially been conducted by the former USSR and also by the United States, the United Kingdom, Germany, France and the Netherlands. This region still lacks the capacity to support and execute research offshore. In fact the only States bordering the Indian Ocean that have demonstrated capability to conduct oceanographic research are Australia, India, Pakistan and South Africa. These countries have continued to conduct research even after the IIOE ended, especially in their own territorial waters.

As documented in Chapter 34, species diversity gradients exist across latitudes and from coastal waters to deep or oceanic water, such that there is an increase in species diversity from high to low latitudes and a decrease from shallow coastal waters to deep oceanic waters (Gray 1997, Chapter 34). However, little data and information exist in the Indian Ocean to describe these scenarios and establish how effectively this pattern

could be applied for conservation purposes especially when interlinked with within – habitat or alpha diversity (Fisher et al., 1943; Whittaker, 1967) and between habitat or beta biodiversity (Whittaker, 1975, 1977) and at a larger regional scale seascape gamma diversity (Ray 1991). Due to scanty studies and many undescribed benthic species in the Indian Ocean, the reliability of species diversity indices for the Indian Ocean benthos is similarly poor due to the likely underestimation of species numbers (richness underestimated) and relative abundance of species, particularly less common species (evenness not accurately measured) (Wafar et al., 2011).

Further challenges are due to threats to benthic biodiversity occurring at different intensities with time and space. The coastal and oceanic benthic habitats and species diversity are threatened by habitat loss and perturbations or alteration especially due to mining, sediment deposits, fishing with bottom-contacting gears, and dumping of solid wastes. Other threats are due to climate change, overexploitation of benthic species which affect their feeding cycles and ecological balances. There is a tendency for opportunistic species succession resulting from ecological population imbalances and pollution, especially in shallow coastal habitats where eutrophication and toxicity from algal blooms may lead to loss of species biodiversity. Sand and coral mining, including dynamite fishing which blasts coral reefs, can lead to complete loss of habitat, with restoration often difficult, if possible at all, and costly. There is evidence of various degrees of continuous benthic habitat loss especially coral, seagrass and mangrove in various parts of the Indian Ocean (Gray 1997; Wafar et al., 2011).

Due to taxonomic limitations, the major taxa encountered in cruises have also been limited to common names or groups but identified to species levels, even for species that have been described. Consequently, it is difficult to provide even snapshots of species richness or species diversity of any given space and time in the region, even for relatively well sampled areas like the Bay of Bengal and the Arabian Sea. The results from the latter areas have contributed to demonstration of the existence of species gradients with depths. However the need for multidisciplinary approaches to describe the drivers of these gradients in an ecosystem context cannot be overemphasized. Based on meiofauna and macrofauna occurrence across shallow to deep sea, from 20m to 6km water depth, both groups showed a similar gradient pattern that the density and species variety of the meiofauna and macrofauna decreased significantly with increasing water depth. The taxon-specific depth affinities have also formed the basis for macrobenthic organisms to be selected as suitable indicator organisms for environmental stress, taking advantage of their sedentary habits, so changes in population abundance and species composition reflect changes in habitat quality (Dauer and Corner, 1980). There is also a positive significant correlation between chlorophyll concentration and macrobenthic density (Pavithran et al., 2009). In the Arabian Sea, the surface water chlorophyll a is higher due to upwelling than that of Bay of Bengal (Prasanna et al., 2002; and Madhuparatap et al., 2003). Therefore the macrobenthic density is also higher in the Arabian Sea than in Bay of Bengal (Parulekar et al., 1982; Mahapatro et al., 2011). This highlights the need for bringing interdisciplinary ecological

relationships into focus through ecosystem approach rather than dealing with single factors in isolation.

5.1 *Research Gaps*

- There is a lack of, or there are relatively few, quantitative data on local species extirpations in the Indian Ocean region.
- Predatory gastropod snails are fished or collected to be used as souvenirs in various places and since they play key roles in controlling prey population their local extirpation can lead to major changes in biodiversity and this needs to be studied.
- Overexploitation of other benthic species is occurring and there is need to properly evaluate the status and trends in exploited benthos.
- Particularly where benthos are being over-exploited or suffering high stress from coastal inputs, there is a need to get better information about the rate and magnitude of loss of species and the implication of these losses for ecosystem processes, including trophodynamics.
- Coastal benthic critical habitats e.g. corals, seagrass and mangrove, are threatened by various anthropogenic activities e.g. overfishing, mining, dynamiting, pollution, beach seining and trawling. There is need to study the effect of these on latitudinal and longitudinal loss of biodiversity and species diversity focusing also on endemic species.
- There is a need to have coordinated rapid regional assessments of benthos to provide a baseline report on the status of species diversity in the various benthic habitats in the Indian Ocean.
- Taxonomic experts are generally lacking for the various numerous benthic taxa groups and there is need to train and create a critical number of taxonomists to develop accurate identification and complete databases for benthic species diversity.
- For deep-sea or ocean diversity, there is a need for scientific assessment of little-known benthic ocean species biodiversity, particularly because it is increasingly being threatened by various anthropogenic activities, especially ocean dumping, mining and climate change.
- There is an urgent need to undertake regional scale assessments and long-term monitoring of habitat loss and species loss, record and document it using Geographical Information Systems (GIS). The assessment methodology should be robust enough to discern effects due to climate change and seasonality that may cause habitat loss or disturbance that may cause species loss, abundance and population density.

- There is a need for monitoring marine litter disturbance of benthic habitats, especially intertidal zones due to dumping of solid wastes.
- There is a need for undertaking long-term regional assessments of root causes or causal chain analyses of habitat loss and degradation to combat loss of biodiversity.

6. Megafauna

The megafauna, namely marine mammals (cetaceans and the sirenians), seabirds, and reptiles (sea turtles and sea snakes) may be described characteristically as large species with low fecundity and productivity, slow growth, and late age at maturity. Such biological characteristics have important implications for their sustainability in fisheries, especially as by-catch because they can sustain only very low rates of mortality. Moreover, they typically depend on a healthy, stable environment and generally have limited capacity to sustain and recover from depleted populations, such as result from heavy fishing pressure.

The megafauna in marine ecosystems play a significant role in the structure and functions of the ecosystems and in the economic sector, especially in tourism. The representative groups in consideration are as follows: (a) marine mammals, (b) marine reptiles, and (c) seabirds. These groups have characteristic species whose lives are interconnected with maritime zones, coastal and shelf waters and deep sea oceanic habitats as grazers or primary consumers and predators or secondary consumers in the ecological food chain cycles. In these predator-prey relationships these megafauna groups play an important ecological role in regulation of marine biodiversity, species richness and environment quality. However, as much as they play their important roles, they face various challenges that threaten their lives and ability to play their roles efficiently and effectively. The major threats are primarily anthropogenic pressures, especially habitat loss and degradation, overexploitation or unsustainable exploitation, pollution and climate change, whose root causes are a major concern (Wafar et al., 2011; Chaturvedi et al., 2013; Bellard et al., 2014).

6.1 *Marine Mammals*

The entire Indian Ocean region has 31 species of marine mammals found in the pelagic shelf and near-shore waters (De Boer et al., 2003). Though well surveyed, with further surveys the number of species is likely to increase. The North Western Indian Ocean region has 25 species, the North Eastern Indian Ocean 28 species, the South Eastern Indian Ocean 30 species and the South Western Indian Ocean has 25 species (De Boer et al., 2003). Whales are known to be highly migratory over long distances, across the hemisphere, to their nesting and feeding grounds.

The marine mammals are threatened by various human activities especially fishing activities using gill nets, seine nets, beach seines and drift nets, in which they are caught as by-catch; habitat degradation and loss, as well as pollution, including marine debris. These threats lead to the destruction of their breeding and feeding grounds. A further threat is deliberate hunting for food. Being slow to grow and reach maturity, coupled with having low fecundity, overexploitation leads to population destruction and collapse, leading to extinction (Kiszka et al., 2008).

6.2 *Research Gaps*

- (a) Although the taxonomy of marine mammals is fairly well known, there is a need to train and equip local scientists and equip local institutions to effectively collect and archive quality data in suitable databases, to enable accurate analysis of status and trend of stock status of marine mammals across various time scales in various geographical locations, in a regional way due to their migratory behaviours.
- (b) The existing research studies are patchy and one-off event types and their data and information make it difficult to standardize and to generate trends. Therefore there is a need for coordinated long-term monitoring, using standardized multidisciplinary methodologies which will allow to document status and trends in time and space, including climate change impacts.
- (c) For conservation of whales, it is important to undertake analysis of the biology and ecology of the various species of whales to protect and avoid polluting their habitats.
- (d) Undertake regular by-catch research including the fishing gears that are used so that the impacts of fishing on whales are understood and appropriate mitigating measures can be undertaken.
- (e) Genetic studies are also needed to be able to understand the interconnectedness and dispersal nature of the similar species over the wider geographical ranges that are encountered in the region.

6.3 *Sea Turtles*

Sea turtles are herbivorous or sometimes invertebrate-eating reptiles that play a very important role in marine ecosystems in the maintenance of healthy seagrass beds and coral reefs and assist in avoiding trophic cascades. As part of their life is spent on land to breed, sea turtles also play an important role in nutrient cycling from land to water and vice-versa (through their faeces).

In the coral ecosystems, sea turtles also forage on sponges which are known to compete aggressively with corals and can reduce coral growth. Where sponges can colonize aggressively and grow, they can limit the growth of corals and modify the overall

structure of a given coral reef ecosystem. Sea turtle predation on sponges can prevent the expansion of sponges, and thus protect coral reefs. In terms of pelagic food webs, sea turtles predate on jelly fish and especially leatherback sea turtles which may be the dominant predator on jellyfish. Decline in this key predator may lead to jelly-fish population explosion, possibly leading to gradual replacement of once abundant fish species (Lynam et al., 2006, Purcell, J.E. et al., 2007).

The Taxonomy of sea turtles in the Indian Ocean is well known and they are represented by only a few species which migrate extensively to various oceans. According to WWF (2012), the sea-turtle taxa are:

- Leatherbacks (*Dermochelys coriacea*)
- Green sea turtles (*Chelonia mydas*)
- Hawksbills (*Eretmochelys imbricatea*)
- Olive ridleys (*Lepidochelys olivecea*)
- Loggerhead (*Caretta caretta*)

According to the Convention on International Trade in Endangered Species of Wild Fauna and Flora² (CITES) and IUCN all the species of sea turtles in the Indian Ocean require protection from anthropogenically induced activities. Specifically, CITES lists all sea turtle species under its Appendix I meaning that commercial international trade in the species is prohibited (CITES, 2015). The explanation of CITES listing is as follows:

- Appendix I lists species that are the most endangered among which are those threatened with extinction and CITES prohibits international trade in specimens of these species except when the purpose of the import is not commercial.
- Appendix II lists species that are not necessarily now threatened with extinction but that may become so unless trade is closely controlled.
- Appendix III is a list of species included at the request of a Party that already regulates trade in the species and that needs the cooperation of other countries to prevent unsustainable or illegal exploitation.

The IUCN Red List of Threatened Species (IUCN Red List) classified the status of leatherback turtles globally as 'Vulnerable' (IUCN, 2015). Specifically, the Southwest Indian Ocean subpopulations are 'Critically Endangered', while the Northeast Indian Ocean subpopulations are 'Data Deficient'. Green turtles and loggerhead turtles are listed in the IUCN Red List as globally 'Endangered', while Olive Ridley turtles are globally 'Vulnerable' and Hawksbill turtles are 'Critically Endangered'. Further threats to sea turtles are also discussed in chapter 39.

² United Nations, *Treaty Section*, vol. 993, No. 14537.

6.4 *Research Gaps on Sea Turtles*

- There is a need to undertake research on bycatch intensity by taxa and gear type for effective conservation management;
- Methods of assessment of bycatch should be standardized so that the data and information can be comparable using GIS and reduce high variances especially at regional levels;
- There is a need for long-term multidisciplinary research study to understand the life histories and ecology of the various species of sea-turtles in the various regions, how they relate to seasonality and climate change;
- There is a need to deploy observers in industrial fishing vessels to collect all the essential information for management of bycatch;
- Nesting and feeding grounds at national and regional levels need to be mapped;
- The genetic connectivity of the various taxa groups needs to be known in order to understand the nature of regional connectivity of the sea turtles.

6.5 *Seabirds*

Seabirds are characterized by their nature and behaviour to live partly in a terrestrial environment and partly in marine littoral, pelagic and oceanic habitats. Essentially they exploit the terrestrial environment for reproduction strategies and the benthic coastal marine and pelagic oceanic environment for foraging or feeding, playing the role of a fisher like human beings (Burger 1988, chapter 38).

Seabirds, in terms of their species numbers, contribute significantly to the overall marine species biodiversity and they can play a significant role in the predator – prey relationships in the marine food webs. Global patterns and trends in seabird biodiversity, and threats to the populations, are discussed in chapter 38.

Information exists on the seabird taxa in the Indian Ocean. These families are mainly *Diomedidae* (albatrosses), *Procellariidae* (petrels) *Hydrobatidae* (storm-petrels), *Pelecanoididae* (diving-petrels), *Phaethonidae* (tropic birds), *Sulidae* (gannets and boobies), *Fregatidae* (frigatebirds), *Stercorariidae* (skuas) *Phalacrocoracidae* (cormorants) and *Laridae* (gulls and terns). Most of these taxa are migrant seabirds from European and Asian regions and their most preferred habitats are the estuaries of large rivers along the African continent. There are many species of seabirds, but there is a low degree of endemism (Wanless, 2012). There are still very few studies on seabirds and these are mostly patchy. Long-term studies to analyze status and trends are lacking. There is a need to focus these studies on measuring the impacts of climate change and bycatch due to industrial commercial fishing, and their effects on biodiversity changes in the coastal, offshore and deep or open ocean ecosystems. Seabirds in the tropical Indian Ocean region are primarily migratory birds from breeding grounds in the Arctic,

Antarctic and temperate regions that come wintering in the tropics, after travelling tens of thousands kilometres. Chapter 38 discusses the major global threats to seabirds, including bycatch mortality in fisheries, habitat degradation and loss, over-exploitation of their food supply, bioaccumulation of pollutants and toxins, and sea-level rise. Because the seabirds use the Indian Ocean for only part of their annual cycle, it is very difficult to distinguish the impacts of pressures in the Indian Ocean from other pressures on the same populations. Combined with the few targeted studies of seabirds in the Indian Ocean, particularly offshore, it is hard to evaluate status and trends of most seabirds in the Indian Ocean and many research gaps exist.

6.6 *Research Gaps on Seabirds*

There is a need to address the following research gaps:

- Lack of comprehensive taxonomic knowledge of species of seabirds at national and regional levels in the various countries of the Indian Ocean region;
- Lack of data and information of the bioaccumulation of toxic substances in seabirds arising from marine food chains and their impacts on species biodiversity;
- Lack of comprehensive long-term biophysical impacts due to habitat degradation and loss including sea-level rise impacts on seabirds migration and their biodiversity at taxa levels;
- Lack of comprehensive understanding of long-term bycatch impacts due to various fishing methods and gears on seabirds at taxa levels and different habitats ranging from coastal to open sea at various depths where the seabirds forage;
- Need to create GIS maps for various migratory routes of the seabirds encountered in the region and their hotspots at taxa levels;
- Need to undertake coordinated research using harmonized methodologies for improved quality of data and information and facilitate comparisons.

7. Conclusion

Compared to other world oceans, the Indian Ocean biodiversity is relatively still scarcely known in terms of the taxonomic composition of the species found therein and their geographical distribution, except for some continental shelf areas around the Indian Subcontinent, Southwestern Australia and Southern Africa. However, deep sea species remain the most unknown, hence the need for concerted research efforts to understand their ecological roles in the diverse ecosystems of the Indian Ocean where they may be encountered. It is known that fish taxa and their geographical distribution are comparatively fairly well known and documented but from a fisheries activity perspective, which also generates ecological bycatch concerns. Since fish do not live in

isolation and are part of the ecological systems, their role in relation to other biological taxa including their interaction with the environment can be fully understood if comprehensive integrated ecological studies are undertaken across seasons and time scales.

Chapter 36F. Open Ocean Deep Sea

Contributors: Jeroen Ingels (Convenor), Malcolm R. Clark, Michael Vecchione, Jose Angel A. Perez, Lisa A. Levin, Imants G. Priede, Tracey Sutton, Ashley A. Rowden, Craig R. Smith, Moriaki Yasuhara, Andrew K. Sweetman, Thomas Soltwedel, Ricardo Santos, Bhavani E. Narayanaswamy, Henry A. Ruhl, Katsunori Fujikura, Linda Amaral Zettler, Daniel O. B. Jones, Andrew R. Gates, Paul Snelgrove, Patricio Bernal (Lead Member), Saskia Van Gaever (Co-Lead Member)

Introduction to the open ocean deep sea

The deep sea comprises the seafloor, water column and biota therein below a specified depth contour. There are differences in views among experts and agencies regarding the appropriate depth to delineate the “deep sea”. This chapter uses a 200 metre depth contour as a starting point, so that the “deep sea” represents 63 per cent of the Earth’s surface area and about 98.5 per cent of Earth’s habitat volume (96.5 per cent of which is pelagic). However, much of the information presented in this chapter focuses on biodiversity of waters substantially deeper than 200 m. Many of the other regional divisions of Chapter 36 include treatments of shelf and slope biodiversity in continental-shelf and slope areas deeper than 200 m. Moreover Chapters 42 and 45 on cold water corals and vents and seeps, respectively, and 51 on canyons, seamounts and other specialized morphological habitat types address aspects of areas in greater detail. The estimates of global biodiversity of the deep sea in this chapter do include all biodiversity in waters and the seafloor below 200 m. However, in the other sections of this chapter redundancy with the other regional chapters is avoided, so that biodiversity of shelf, slope, reef, vents, and specialized habitats is assessed in the respective regional or thematic chapters.

This truly vast deep-sea realm constitutes the largest source of species and ecosystem diversity on Earth, with great potential for mineral, energy, and living resources (e.g., Koslow, 2007). Despite major technological advances and increased deep-sea exploration in the past few decades (Danovaro et al., 2014), a remarkably small portion of the deep sea has been investigated in detail (Ramirez-Llodra et al., 2010), particularly in terms of time-series research (Glover et al., 2010). For the pelagic areas much less than 0.0001 per cent of the over 1.3 billion km³ of deep water has been studied. The inevitable result is weaker characterization of deep-sea biodiversity compared to the shelf, slope and terrestrial realms. Correspondingly this also means that continued scientific and surveying efforts may potentially change our current understanding of deep-sea biodiversity. There is strong evidence that the richness and diversity of organisms in the deep sea exceeds all other known biomes from the metazoan to the microbial realms (Rex and Etter, 2010; Zinger et al., 2011) and supports the diverse ecosystem processes and functions necessary for the Earth’s natural systems to function (Thurber et al., 2014). Moreover, the extensive species, genetic, enzymatic, metabolic, and biogeochemical diversity

hosted by the deep ocean also holds the potential for new pharmaceutical and industrial applications. With up to millions of estimated deep-sea species (cf. Chapter 34; CoML, 2010; Grassle and Maciolek, 1992), although the true number of species may be less, (Appeltans et al., 2012, Costello et al., 2013; Mora et al., 2013a), it would take many generations to document deep-sea diversity in its entirety. In fact, this may not even be possible given the huge taxonomic effort required (Mora et al., 2013a) and the rate of species extinctions (Pimm et al., 1995). Nor is it necessary to have fully quantified deep-sea biodiversity to commence identification of risks and opportunities, and design of programmes for its conservation and sustainable use, even if new knowledge is later acquired that enables such programmes to be improved.

Over the years, deep-sea ecologists have posited several theories to explain high deep-sea biodiversity; many highlight aspects of habitat heterogeneity and the extended time scales at which the deep sea is thought to operate (e.g. Levin and Dayton, 2009; Rex and Etter, 2010; Snelgrove and Smith, 2002). Most experts agree that the presence of different habitats, along with temporal variation, critically support deep-sea diversity; for instance, geomorphological structures such as canyons, seamounts (Figure 36F.1; cf. Chapter 51), hydrothermal vents and methane seeps (cf. Chapter 45), as well as biotic structures, such as cold-water coral reefs (Figure 36F.1; Chapter 42), and whale falls sustain unique assemblages of organisms, diversifying the deep-sea species pool (Reed et al., 2013). At the same time, however, many deep-sea species are widely distributed (e.g., Havermans et al., 2013; Ingels et al., 2006; Pawlowski et al., 2007), although new genetic tools already suggest many species are less cosmopolitan than was previously thought. Small-scale heterogeneity further enhances diversity, through the provision of phytodetrital patches, biogenic structures such as sponges and xenophyophores, organic food falls, pits, and hillocks, (Buhl-Mortensen et al., 2010). Anthropogenic structures such as deep-water oil rigs and shipwrecks harbouring highly diverse faunal assemblages reflect deep-sea faunal responses to smaller-scale habitat heterogeneity (Church et al., 2009; Taylor et al., 2014; Friedlander et al., 2014).

Deep-sea ecosystems are crucial for global functioning; e.g., remineralization of organic matter in the deep sea regenerates nutrients that help fuel the oceanic primary production that accounts for about half of atmospheric oxygen production. Whilst coastal and shallow-water processes and functions produce services within tangible time scales and local and regional spatial scales, the deep-sea processes and ecosystem functions that occur on the scale of microns to meters and time scales up to years often translate to useful services only after centuries of integrated activity (Thurber et al., 2014). Evidence demonstrates, however, that interannual changes in climate can influence deep-sea systems over time scales not fundamentally different from terrestrial habitats. Climatically driven changes in sinking particulate organic matter can alter deep-sea abundance, community structure, diversity and functioning within days to months, depending in part on body size (Ruhl et al., 2008; Ruhl and Smith, 2004) along with temperature-driven interannual diversity changes (Danovaro et al., 2014).

Numerous human activities affect deep-sea ecosystems, goods, and services directly and indirectly now and will do so increasingly in the future (Glover and Smith, 2003;

Mengerink et al., 2014; Ramirez-Llodra et al., 2011). These are addressed in various chapters of Parts IV and V of this Assessment, with Chapters 11 (Capture Fisheries), 21 (Offshore Hydrocarbon Industries), 20 (Land-based Inputs), 23 (Other Mining Industries), 25 (Marine debris) and 27 (Tourism) of particular relevance.

Benthic realm

2.1 Deep-sea margins

The global continental margins extend for ~150,000 km (Jahnke, 2010) and encompass estuarine, open coast, shelf, canyon, slope, and enclosed-sea ecosystems (Levin and Sibuet, 2012). Deep-sea margins are those areas that lie beyond the shelf break, where the seafloor slopes down to the continental rise at abyssal depths, and encompasses bathyal depths. Numerous canyons and channels incise the continental slope (see Chapter 51), often featuring cold-water coral reefs (Chapter 42) or oxygen minimum zones (OMZs) as distinct habitats along the deep margin. Sediment covers much of the deep continental margin, but with exposed bedrock in areas where topography is too steep for sediment accumulation (e.g., steep canyon walls) or where sediment is washed away (e.g., parts of seamounts). Different faunas inhabit soft- and hard-bottom substrates.

Relative to their area, the margins account for a disproportionately large fraction of global primary production (10-15 per cent), nutrient recycling, carbon burial (>60 per cent of total settling organic carbon), and fisheries production (Muller-Karger et al., 2005). They are also exceptionally dynamic systems with ecosystem structures that can oscillate slowly or shift abruptly, but rarely remain static (Levin et al., 2014).

1.1.1 Status of and trends for biodiversity

In the well-studied North Atlantic, local macrofaunal (300 µm-3 cm) species diversity on the continental slope exceeds that of the adjacent continental shelf, and estimates of bathyal diversity in other parts of the world ocean are comparably high (Rex and Etter, 2010), but local environmental conditions drive regional differences: e.g., the Gulf of Mexico, the Norwegian and Mediterranean Seas (Narayanaswamy et al., 2013), the Eastern Pacific and the Arabian Sea (Levin et al., 2001). Most researchers agree that habitat heterogeneity on different spatial scales drives high diversity along the margins (Narayanaswamy et al., 2013) and that margins often exhibit upwelling and increased production that enhances biodiversity. Nonetheless, excess food availability can reduce diversity.

Depth-related species diversity gradients in macrofauna often peak unimodally at mid-bathyal depths of about 1500-2000 m (Rex and Etter, 2010), although shallower peaks in diversity have been observed in Arctic waters (Narayanaswamy et al., 2005; 2010; Svavarsson, 1997; Yasuhara et al., 2012b) for bivalves, polychaetes, gastropods and cumaceans (Rex, 1981), as well as for the entire macrofauna (Etter and Mullineaux, 2000; Levin et al., 2001) and some meiofauna (Yasuhara et al., 2012b) (32 µm-1000 µm). Even regions with very low diversity can host highly specialized species (e.g., OMZs) and contribute to overall margin diversity (Gooday et al., 2010).

Thus, throughout their depth gradient, continental margin slope areas exhibit the highest macrofaunal diversity and offer a potentially important refuge against future climate change, as mobile organisms could migrate upslope or downslope in search of suitable conditions (Rodriguez-Lazaro and Cronin, 1999; Yasuhara et al., 2008; 2009).

The diversity of meiofauna (32 μm -1,000 μm) exceeds that of the macrofauna and their diversity generally increases with depth; however, groups such as foraminifera and ostracods exhibit unimodal peaks in diversity (Yasuhara et al., 2012b). Meiofaunal diversity may decline or increase with increasing bathyal depths (Narayanaswamy et al., 2013), generally driven by food availability and intensity and regularity of disturbance regimes, as well as by temperature and local environmental conditions (Corliss et al., 2009; Yasuhara et al., 2012a; 2009; 2012b; 2014).

Russian and Scandinavian deep-sea expeditions described peak benthic megafaunal (>3 cm) diversity at mid-bathyal depths as early as the 1950s and 1960s, despite observing much lower megafaunal than meio- and macrofaunal diversity (Vinogradova, 1959). Sponges, cnidarians, crustaceans (decapods and isopods) and echinoderms (echinoids, asteroids, crinoids, holothurians) all display this pattern; however later studies confirmed the pattern for some megafaunal invertebrates, but showed a decline or even increase in diversity with increasing depth for some taxa. Evidence to date suggests lower species richness in deep-sea bacterial communities than in coastal benthic environments, with the caveat that deep-sea environments remain underexplored (Zinger et al., 2011). However, the presence of extreme environments in the deep sea which have high phylogenetic diversity promises a rich source of bacterial diversity and genetic innovation (Sogin et al., 2006).

Several faunal groups also exhibit latitudinal gradients in species diversity (Narayanaswamy et al., 2010; Rex and Etter, 2010; Yasuhara et al., 2009): diversity of crustaceans, molluscs and foraminifera declines poleward (Gage et al., 2004; Rex et al., 2000), whilst others such as nematodes respond to phytodetrital input (Lambshhead et al., 2000). Latitudinal gradients have also been identified in bacteria (Fuhrman et al., 2008; Sul et al., 2013) but recent modelling indicates peak bacterial richness in temperate areas in winter (Ladau et al., 2013). The effect of seasons on macro-ecological patterns in the microbial ocean warrants continued investigation to test the mechanisms that underlie latitudinal patterns in different fauna.

Broad-scale depth and latitudinal patterns in benthic diversity are modified regionally by a variety of environmental factors operating at different scales. For example, OMZs strongly affect diversity where they impinge on the seafloor. OMZs typically occur between 200 m and 1000 m, often at major carbon burial sites along the continental margins where high productivity results in high carbon fluxes to the seafloor and low oxygen. The organic-rich sediments of these regions often support mats of large sulphide-oxidizing bacteria (*Thioploca*, *Beggiatoa*, *Thiomargarita*), and high-density, low-diversity metazoan assemblages. Protists are also well represented in OMZs such as the Cariaco Basin, where representatives of all major protistan clades occur (Edgcomb et al., 2011). Depressed diversity near OMZs centres favours taxa that can tolerate hypoxia, such as nematodes (Cook et al., 2000; Levin, 2003) and certain annelids and foraminifera (Levin, 2003). Other taxa that cannot tolerate

low-oxygen conditions may aggregate at the OMZs fringes where food is often abundant.

1.1.2 Major pressures

Multiple anthropogenic influences affect deep-sea habitats located close to land (e.g., canyons, fjords, upper slopes when continental shelves are very narrow), including organic matter loading (see Chapter 20), mine tailings disposal (Kvassnes and Iversen, 2013; Kvassnes et al., 2009), litter (Pham et al., 2014), bottom trawling (Pusceddu et al., 2014) and overfishing (Clark et al., 2007), enhanced or decreased terrestrial input, oil and gas exploitation (Ramirez-Llodra et al., 2011) and, potentially in future, deep-sea mining (see Chapter 23). Fishing on margins can also have indirect ecological effects at deeper depths (Bailey et al., 2009). These anthropogenic influences can modify deep-margin habitats through physical smothering and disturbance, sediment resuspension, organic loading, and toxic contamination and plume formation, with concomitant losses in biodiversity, declining energy flow back to higher trophic levels, and impacts on physiology from exposure to toxic compounds (e.g., hydrocarbons, polycyclic aromatic hydrocarbons (PAHs), heavy metals) (see Ramirez-Llodra et al., 2011 for review).

2.2 Abyss

2.2.1 Status and trends for biodiversity

The abyss (~3-6 km water depth) encompasses the largest area on Earth. Its vast areas of seafloor plains and rolling hills are generally covered in fine sediments with hard substrates associated with manganese nodules, rock outcrops and topographic highs (e.g. seamounts). The absence of *in situ* primary production in this comparatively stable habitat (apart from scant occurrence of chemosynthesis at hydrothermal vents and cold seeps; cf. Chapter 45) characterize an ecosystem adapted to a limiting and variable rain of particulate detrital material that sinks from euphotic zones. Nonetheless, the abyss supports higher levels of alpha and beta diversity of meiofauna, macrofauna and megafauna than was recognized only decades ago (Rex and Etter, 2010). The prevalence of environmental DNA preserved in the deep sea biases estimates of richness, at least in the microbial domain, adding a challenge to biodiversity study in the abyss using molecular methods (Pawlowski et al., 2011).

Despite poorly known biodiversity patterns at regional to global scales (especially regarding species ranges and connectivity), some regions, such as the abyssal Southern Ocean (Brandt et al., 2007; Griffiths, 2010) and the Pacific equatorial abyss, are likely to represent major reservoirs of biodiversity (Smith et al., 2008).

2.2.2 Major pressures

The food-limited nature of abyssal ecosystems, and reliance on particulate organic carbon (POC) flux from above, suggest that all groups, from microbes to megafauna, will be highly sensitive to changes in phytoplankton productivity and community structure, and especially to changes in the quantity and quality of the export flux (Billett et al., 2010; Ruhl et al., 2008; Ruhl and Smith, 2004; Smith et al., 2008; Smith

et al.,2013). Climate warming in some broad areas may increase ocean stratification, reduce primary production, and shift the dominant phytoplankton community structure from diatoms to picoplankton, and reduce export efficiency, driving biotic changes over major regions of the abyss, such as the equatorial Pacific (Smith et al., 2008). However the effects of climate change, including ocean warming, on biodiversity are likely to vary regionally and among species groups in ways that are poorly resolved with current models and knowledge of ecosystem dynamics in the deep sea. In the future, deep sea mining may also become a pressure on abyssal areas of the deep sea, and potential effects are addressed in Chapter 21.

2.3 *Hadal*

2.3.1 *The Hadal zone*

The Hadal zone, comprising ocean floor deeper than 6000 m, encompasses 3,437,930 km², or less than 1 per cent of total ocean area (Harris et al., 2014) and represents 45 per cent of its depth and related gradients. Over 80 separate basins or depressions in the sea floor comprise the hadal zone, dominated by 7 great trenches (>6500 m) around the margins of the Pacific Ocean, five of which extend to over 10 km depth: the Japan-Kuril-Kamchatka, Kermadec, Tonga, Mariana, and Philippine trenches. The Arctic Ocean and Mediterranean Sea lack hadal depths. These trenches are often at the intersection of tectonic plates, exposing them as potential epicentres of severe earthquakes which can directly cause local and catastrophic disturbance to the trench fauna.

2.3.2 *Status and trends for biodiversity*

Although the hadal zone contains a wide range of macro- and megafaunal taxa (cnidarians, polychaetes, bivalves, gastropods, amphipods, decapods, echinurids, holothurians, asteroids, echinoids, sipunculids, ophiuroids and fishes (Beliaev, 1989; Wolff, 1970), all trenches occur below the Carbonate Compensation Depth (CCD), reducing the numbers of calcified protozoan and metazoan species found there (Jamieson, 2011). Chemosynthetic seep biota, including vesicomid and thyasirid clams, occur in hadal depths in the Japan Trench; the deepest known methane seeps and associated communities are found at 7,434 m in this area (Fujikura et al., 1999; Watanabe et al., 2010). Cold seep communities also commonly occur in trench areas, such as the Aleutian and Kuril Trenches (Juniper and Sibuet, 1987; Ogawa et al., 1996; Suess et al., 1998). Benthic foraminifera are among the most widespread taxa at hadal depths and include calcareous, large agglutinated, and organic walled species (Beliaev, 1989; Gooday et al., 2008). Abundant metazoan meiofaunal taxa, such as nematodes, at hadal depths (Gambi et al., 2003; Itoh et al., 2011; Kitahashi et al., 2013; Tietjen, 1989; Vanhove et al., 2004) may exceed those found at bathyal depths by 10-fold (Danovaro et al., 2002); small numbers of ostracods, halacarids, cumaceans, kinorhynch, and meiofaunal-sized bivalves are also found there (Vanhove et al., 2004). Nematode and copepod communities in trenches differ greatly from those found at bathyal and abyssal depths (Gambi et al., 2003; Kitahashi et al., 2013), driven by opportunistic taxa and meiofaunal dwarfism in trench systems (Danovaro et al., 2002; Gambi et al., 2003).

Although not yet well quantified, and the mechanisms remain to be discerned, higher densities of fauna (Jamieson et al., 2009) and respiration have been found at trench axis points than would be expected from a purely vertical rain of POC flux (Glud et al., 2013). The exact number of species in trenches is not known, but the few quantitative studies made so far suggest that diversity is lower compared to diversity at abyssal depths (Grassle, 1989). Reasons for the lower diversity levels are not well understood but the high pressure, relatively high food supply and organic matter accumulation, relatively elevated temperature (due to adiabatic heating), or a combination thereof may attenuate trench diversity.

Sampling to date suggests that hadal basins are populated by a higher proportion of endemic species compared to much shallower waters, species that can survive the extreme hydrostatic pressure and, in some instances, remoteness from surface food supply (Wolff, 1970). Physiological and other evidence suggests that fishes cannot survive at depths greater than 8000 m (Yancey et al., 2014); the deepest hadal fish, the liparids (snail-fish), are unique to each trench system. Decapod crustaceans have been observed only to 8200 m (Gallo et al., in revision).

At depths over 8000 m, scavenging amphipod crustaceans dominate the mobile megafauna, along with potential predators, including penaeid shrimp, princaxelid amphipods and ulmarid jellyfish, as observed in the New Britain Trench and the Sirena Deep (Mariana Trench). Comparison of scavenging and epibenthic/demersal biota suggests that density, diversity, and incidence of demersal (near bottom) lifestyles all increase with greater food supply (Blankenship and Levin, 2007; Blankenship et al., 2006).

Wide separation between trenches in the northern and southern hemispheres and between the different oceans has likely facilitated speciation to result in distinct assemblages of fauna in each hadal basin (Fujii et al., 2013). Some 75 per cent of the species in Pacific Ocean trenches may be endemic to each trench. Despite their remoteness from the surface, many hadal trenches are close to land and receive organic inputs from terrestrial and coastal sources, yielding higher mega-, macro- and meio-faunal densities than expected for greater depths (Danovaro et al., 2003; Danovaro et al., 2002; Jamieson, 2011; Jumars and Hessler, 1976; Vanhove et al., 2004).

2.3.3 Major pressures

The proximity of some trenches to land also increases their vulnerability to human activity in terms of dumping of materials and effluents, as well as from disaster debris, run off from land and pollution from ships. Some of these items, including anthropogenic litter, have been observed down to 7,200 m depth (George and Higgins, 1979). Evidence for the vulnerability of trench fauna is also provided by the levels of the radioisotope ¹³⁴Cs detected in sediments in the Japan Trench, four months after the Fukushima Dai-ichi nuclear disaster (Oguri et al., 2013).

2.3.4 Knowledge gaps

Trenches are arguably the most difficult deep-sea environments to access and current facilities are very limited worldwide, and consequently knowledge of their biodiversity is particularly incomplete.

In general, biodiversity patterns of non-nematode meiofauna and non-foraminiferal protists are especially poorly known in the deep sea.

Most information about biodiversity in the deep sea is for the predominant soft-substrate habitats. However, hard substrates abound in the deep sea in nearly all settings, and organisms that cannot be seen in a photograph or video image are hard to sample and study quantitatively. Thus knowledge of small-taxon biodiversity is best developed for deep-sea sediments.

Beyond cataloguing diversity, even in those systems we have characterized, almost nothing is known about the ranges of species, connectivity patterns or resilience of assemblages and their sensitivity to climate stressors or direct human disturbance. There is also currently a lack of appropriate tools to adequately evaluate human benefits that are derived from the deep sea (Jobstvogt et al., 2014a; 2014b; Thurber et al., 2014).

Pelagic realm

3.1 Status and trends for biodiversity

Between the deep-sea bottom and the sunlit surface waters are the open waters of the deep pelagic or “midwater” environment. This huge volume of water is the least explored environment on our planet (Webb et al., 2010). The deep pelagic realm is very diffuse, with generally low apparent abundances of inhabitants, although recent observations from submersibles indicate that some species may concentrate into narrow depth bands (Herring, 2002).

The major physical characteristics structuring the pelagic ecosystems are depth and pressure, temperature, and the penetration of sunlight. Below the surface zone (or epipelagic, down to about 200 m), the deep layer where sunlight penetrates with insufficient intensity to support primary production, is called the mesopelagic zone. In some geographic areas, microbial degradation of organic matter sinking from the surface zone results in low oxygen concentrations in the mesopelagic, called OMZs (Robinson et al., 2010). This mesopelagic zone is a particularly important habitat for fauna controlling the depth of CO₂ sequestration (Giering et al., 2014).

Below the depth to which sunlight can penetrate (about 1,000 m) is the largest layer of the deep pelagic realm and by far the largest ecosystem on our planet, the bathypelagic region. This comprises almost 75 per cent of the volume of the ocean and is mostly remote from the influence of the bottom and its communities. Temperatures there are usually just a few degrees Celsius above zero. The boundary layer where both physical and biological interactions with the bottom occur is called ‘benthopelagic’.

The transitions between the various vertical layers are gradients, not fixed surfaces; hence ecological distinctions among the zones are somewhat blurred across the transitions. Recent surveys have shown a great deal of connectivity between the major pelagic depth zones (Sutton, 2013). The abundance and biomass of organisms generally varies among these layers from a maximum near the surface, decreasing

through the mesopelagic, to very low levels in the bathypelagic, increasing somewhat in the benthopelagic (Angel, 1997; Haedrich, 1996). Although abundances are low, because such a huge volume of the ocean is bathypelagic, even species that are rarely encountered may have very large total population numbers (Herring, 2002).

The life cycles of deep-sea animals often involve shifts in vertical distribution among developmental stages. Even more spectacular are the daily vertical migrations of many mesopelagic species (Benoit-Bird and Au, 2006; Hays, 2003). This vertical migration may increase physical mixing of the ocean water and also contributes to a "biological pump" that drives the movement of carbon compounds and nutrients from the surface waters into the deep ocean (Robinson et al., 2010).

Sampling the deep pelagic biome shares the logistical difficulties of other deep-sea sampling, compounded by the extremely large volume and temporal variability of the environment and the widely dispersed populations of its inhabitants. New species continue to be discovered regularly. Whereas scientific information on the composition of mesopelagic assemblages is rapidly improving, very little is known of the structure of the deeper lower bathyal and abyssal pelagic zones.

Possibly because of high mobility and transport by ocean current, the overall diversity of species seems to be less than that found in other ecosystems (Angel, 1997). However, the number of distinct major evolutionary groups (i.e., phyla, classes, etc.) found in the deep pelagic is high.

Studies of microbes and their roles in the deep pelagic ecosystems are just beginning to reveal the great diversity of such organisms. The species richness of deep ocean bacteria surpasses that of the surface open ocean (Zinger et al., 2011).

As is true in other pelagic systems, crustaceans make up a large percentage of the deep zooplankton in both abundance and numbers of species. These crustaceans include numerous and diverse copepods, amphipods, ostracods and other major groups. Some groups, like arrow worms, are almost all pelagic and are important in deep waters. Large gelatinous animals, including comb jellies, jellyfishes, colonial siphonophores, salps and pyrosomes, are extremely important in deep pelagic ecosystems (Robison, 2004).

The strong swimmers of the deep pelagic, the "nekton", include many species of fishes and some sharks, crustaceans (shrimps, krill, and other shrimplike animals), and cephalopods (including squids, "dumbo" and other octopods, and "vampire squids") (Hoving et al., 2014). In terms of global fish abundance, deep pelagic fishes are by far the numerically dominant constituents; the genus *Cyclothone* alone outnumbers all coastal fishes combined and is likely to be the most abundant vertebrate on earth. Furthermore, at an estimated ~1,000 million tons, mesopelagic fishes dominate the world's total fish biomass and constitute a major component of the global carbon cycle. Acoustic surveys now suggest that an accurate figure of mesopelagic fish biomass may be an order of magnitude higher (10,000 - 15,000 million tons; Irigoien et al., 2014; Kaartvedt et al., 2012; Koslow, 2009). When bathypelagic fish biomass is included, deep pelagic fish biomass is likely to be the overwhelming majority of fish biomass on Earth (Sutton, 2013). The deep pelagic fauna is also important prey for mammals (toothed whales and elephant seals) and

even birds (emperor penguins) and reptiles (leatherback sea turtles). The amount of deep-sea squids consumed by sperm whales alone annually has been estimated to exceed the total landings of fisheries worldwide (Rodhouse and Nigmatullin, 1996).

Horizontal patterns exist in the global distribution of deep pelagic organisms. However, the faunal boundaries of deep pelagic assemblages are less distinct than those of near-surface or benthic assemblages (Pierrot-Bults and Angel, 2012). Generally, the low-latitude oligotrophic regimes that make up the majority of the global ocean house more species than higher-latitude regimes (Hopkins et al., 1996). Some major oceanic frontal boundaries, such as the polar and subpolar fronts, extend down into deep waters and appear to form biogeographic boundaries, although the distinctness of those boundaries may decrease with increasing depth.

The dark environment also means that production of light by bioluminescence is almost universal among deep pelagic organisms. Some animals produce the light independently, whereas others are symbiotic with luminescent bacteria.

3.2 *Major pressures*

A fundamental biological characteristic throughout the deep pelagic biome is that little or no primary production occurs and deep pelagic organisms are dependent on food produced elsewhere. Therefore, changes in surface productivity will be reflected in changes in the deep midwater. When midwater animals migrate into the surface waters at night, they are subjected to predation by near-surface species. Shifts in the abundance of those predators will affect the populations of the migrators and, indirectly, the deeper species that interact with the vertical migrators at their deeper daytime depths. Either or both of these effects may be caused by global climate change, fishing pressure and the impact of pollutants in surface waters (Robinson et al., 2010; Robison, 2009).

Climate change will likely increase stratification caused by warming of surface waters and expanded OMZs resulting from the interaction of shifts in productivity with increased stratification. If the so-called conveyor-belt of global circulation weakens, transport of oxygen by the production of deep water will affect the entire deep sea. The biomass of mesopelagic fishes in the California Current, for instance, has declined dramatically during recent decades of reduced midwater oxygen concentrations (Koslow et al., 2011). Furthermore, increases in carbon dioxide resulting in acidification may affect diverse deep pelagic animals, including pteropods (swimming snails) and crustaceans which use calcium carbonate to build their exoskeletons, fishes that need it for internal skeletons, and cephalopods for their balance organs. Acidification also changes how oxygen is transported in the blood of animals and those living in areas of low oxygen concentration may therefore be less capable of survival and reproduction (Rosa and Seibel, 2008).

Few fisheries currently target deep pelagic species, but fisheries do affect the ecosystem. Whaling reduced worldwide populations of sperm whales and pilot whales to a small fraction of historical levels (Roman et al., 2014). Similarly, fisheries for surface predators such as sharks, tunas and billfishes, and on seamounts, reduce

predation pressure, particularly on vertical migrators like squids and lantern fishes (Zeidberg and Robison, 2007).

Increasing extraction of deep-sea hydrocarbon resources increases the likelihood of accidental deep release of oil and methane (Mengerink et al., 2014), as well as the deep use of dispersants to minimize apparent effects of such spills at the surface (See Chapter 21).

Deep sea mining and some forms of renewable energy production may also affect the pelagic realm of the deep ocean (Ramirez-Llodra et al., 2011), and potential effects are addressed in Chapters 23 and 22 respectively.

3.3 *Knowledge gaps*

Any summary of deep pelagic ecosystems emphasizes how little is known, especially relative to coastal systems. Sampling has been intensively conducted in only a few geographic areas, using selective methods, each of which illuminates only a fraction of the biodiversity. Sampling at lower bathyal or abyssal depths has been limited, and virtually nothing is known about pelagic fauna associated with deep trenches. There is also limited knowledge of the performance of conservation and management measures developed for coastal and shelf marine ecosystems when applied in deep ocean systems characterized by large spatial scales and variable but sometimes vertically and/or horizontally high-mobility organisms, and incomplete knowledge of ecosystem structure and processes.

Special areas typical for the open ocean deep sea

4.1 *Ocean ridges*

The Mid-Ocean Ridge system is a continuous single feature on the earth's surface extending ca. 50,000 km around the planet; it defines the axis along which new oceanic crust is generated at tectonic plate boundaries (Heezen, 1969). The ridge sea floor is elevated above the surrounding abyssal plains, reaching the sea surface at mid-ocean islands, such as Iceland, the Azores and Ascension Island in the Atlantic Ocean, Easter Island and Galapagos in the Pacific Ocean. Typically there is a central axial rift valley bounded by ridges on both sides. A series of sediment-covered terraces slope down on the two sides of the ridge axis to the abyssal plains. The global ridge system, including associated island slopes, seamounts and knolls, represents a vast area of mid-ocean habitat at bathyal depths, accessible to fauna normally associated with narrow strips of suitable habitat on the continental slopes. The ocean ridges sub-divide the major ocean basins, but fracture zones at intervals permit movement of deep water and abyssal organisms between the two sides of the ridge.

Much attention has been directed to the importance of Mid-Ocean Ridges as sites of the hydrothermal vents and their unique fauna found close to the geothermally active ridge axis (German et al., 2011). However, the total area of hydrothermal vents is small and the dominant fauna on the mid-ocean ridges is made up of typical

bathyal species known from adjacent continental margins (See Chapter 45). The biomass of benthic fauna and demersal fishes on the ridges is generally similar to that found at corresponding depths on the nearest continental slopes (Priede et al., 2013). New species, potentially endemic to mid-ocean ridges, have been discovered (Priede et al., 2012). But these are likely to be found elsewhere as exploration of the deep sea progresses. The island slopes and summits of seamounts associated with ocean ridges are important areas for fisheries; evidence suggests that biodiversity, including large pelagic predators, is enhanced around such features (Morato et al., 2010; Morato et al., 2008). Chapter 51 considers the biodiversity of these mid-ocean ridges, and its threats, in greater detail.

4.2 *Polar deep sea*

Polar marine ecosystems differ in many ways from other marine ecosystems on the planet (see Chapters 36G and 36H).

4.3 *Arctic*

Arctic deep-sea areas have generally been poorly studied; although several studies over the past two decades have greatly advanced our knowledge of its marine diversity and deep-sea processes. They indicate that the Arctic deep sea is an oligotrophic area, featuring steep gradients in benthic biomass with increasing depth that are primarily driven by food availability (Bluhm et al., 2005, 2011).

The Arctic deep basins comprise ~50 per cent of the Arctic Ocean seafloor and differ from those of the North Atlantic, as the Arctic Sea is relatively young in age, semi-isolated from the world's oceans, and largely ice-covered. Moreover, the high Arctic experiences more pronounced seasonality in light, and hence in primary production, than lower latitudes.

The history and semi-isolation of the Arctic basin play a major role in its biodiversity patterns (Golikov and Scarlato, 1990). Originally an embayment of the North Pacific, the Arctic deep sea was influenced by Pacific fauna until ~80 million years ago, when the deep-water connection closed (Marincovich Jr. et al., 1990). Exchange with the deep Atlantic began ~40 Ma ago, coinciding with a strong cooling period (Savin et al., 1975). Although some Arctic shelf and deep-sea fauna were removed by Pleistocene glaciations, other shelf fauna in the Atlantic sector of the Arctic found refuge in the deep sea and are considered the ancestral fauna at least for some of the recent Arctic deep-sea fauna (Nesis, 1984). The bottom of the Arctic basin is filled with water originating from the North Atlantic (Rudels et al., 1994); the sediments are primarily silt and clay whilst the ridges and plateaus have a higher sand fraction (Stein et al., 1994). Exceptions include ice-rafted dropstones, enhancing diversity by providing isolated hard substrata and enhanced habitat heterogeneity for benthic fauna (Hasemann et al., 2013; Oschmann, 1990). Considerable inputs of refractory terrestrial organic matter from the large Russian and North American rivers characterize the organic component of sediments along the slopes, and in the basins (Stein and Macdonald, 2004). The only present-day deep-water connection to the Arctic is via the Fram Strait (~2,500m), providing immigrating species access via the

high water flux through this gateway. Submarine ridges within the Arctic form physical barriers, but current evidence suggests that these do not form biogeographic barriers (Deubel, 2000; Kosobokova et al., 2011; Vinogradova, 1997).

Bluhm et al. (2011) conservatively estimated the number of benthic invertebrate taxa in the Arctic deep sea to be ~1,125. As in other soft-sediment habitats, foraminiferans and nematodes generally dominate the meiofauna, whereas annelids, crustaceans and bivalves dominate the macrofauna, and echinoderms dominate the megafauna. The degree of endemism at the level of both genera and species is far lower than in the Antarctic, which has a similarly harsh environment. Just over 700 benthic species were catalogued from the central basin a decade ago (Sirenko, 2001). The latitudinal species-diversity gradient has been observed in the Arctic Ocean (Yasuhara et al., 2012b) and the peak of the unimodal species-diversity depth gradient occurs at much shallower depths compared to other oceans (Clarke, 2003; Svavarsson, 1997; Yasuhara et al., 2012b).

The Arctic, is populated by species that have experienced selection pressure for generalism and high vagility (Jansson and Dynesius, 2002), and should have inherent resilience in the face of climate change.

In a warmer future Arctic with less sea ice altered algal abundance and composition will affect zooplankton community structure (Caron and Hutchins, 2012) and subsequently the flux of particulate organic matter to the seafloor (Wohlers et al., 2009), where the changing quantity and quality of this matter will impact benthic communities (Jones et al., 2014; Kortsch et al., 2012).

4.4 *Antarctic*

The Southern Ocean comprises three major deep ocean basins, i.e., the Pacific, Indian and Atlantic Basins, separated by submarine ridges and the Scotia Arc island chain. Oceanographically, the Southern Ocean is a major driver of global ocean circulation and plays a vital role in interacting with the deep water circulation in each of the major oceans.

Chapter 36H describes the general dynamics of the Southern Ocean, including seasonal changes. The winter sea-ice formation creates cold, dense, salty water that sinks to the seafloor and forms very dense Antarctic Bottom Water (Bullister et al., 2013). This in turn pushes the ocean's nutrient-rich, deep water closer to the surface, generating areas of high primary productivity in Antarctic waters, similar to areas of upwelling elsewhere in the world.

The remote Southern Ocean is home to a diverse and rich community of life that thrives in an environment dominated by glaciations and strong currents (Griffiths, 2010). However, although relatively little is known about the deep-sea fauna, or about the complex interactions between the highly seasonally variable physical environment and the species that inhabit the Southern Ocean, but our knowledge of Southern Ocean deep-sea fauna and biogeography is increasing rapidly (Griffiths, 2010; Kaiser et al., 2013). The range of ecosystems found in each of the marine realms can vary greatly within a small geographic area (e.g. Grange and Smith, 2013), or in other cases remain relatively constant across vast areas of the Southern Ocean.

The region also contains many completely un-sampled areas for which nothing is known (e.g., Amundsen Sea, Western Weddell Sea, Eastern Ross Sea). These areas include the majority of the intertidal zone, areas under the floating ice shelves, and the greater benthic part of the deep sea. However, several characteristic features of Southern Ocean ecosystems include circumpolar distributions and eurybathy of many species (Kaiser et al., 2013).

Both pelagic and benthic communities tend to show a high degree of patchiness in both diversity and abundance. The benthic populations show a decrease in biomass with increasing depth (Arntz et al., 1994), with notable differences in areas of disturbance due to anchor ice and icebergs in the shallows (Smale et al., 2008) and in highly productive deep fjord ecosystems (Grange and Smith, 2013). Hard and soft sediments from the region are known to be capable of supporting both extremes of diversity and biomass. In some cases, levels of biomass are far higher than those in equivalent habitats in temperate or tropical regions. A major international study led by Brandt revealed comparably high levels of biodiversity (higher than in the Arctic), thereby challenging suggestions that deep-sea diversity is depressed in the Southern Ocean (Brandt et al., 2007). Understanding of large-scale diversity distributions is improving (Brandt and Ebbe, 2009; Kaiser et al., 2013). For example, depth-diversity gradients of several taxa are known to be unimodal with a shallow peak comparable to those of the Arctic Ocean (Brandt et al., 2007; Brandt and Ebbe, 2009).

Longline fishing continues in the Southern Ocean, where the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) has been implementing conservation measures for toothfish, icefish and krill fisheries, and has closed almost all of the regulatory area to bottom trawling since the 1980s (Reid et al., 2010; Hanchet et al., 2015). Climate change, is also a significant potential threat to the Antarctic marine communities (Griffiths, 2010; Smith et al., 2012), for reasons similar to those presented for the Arctic.

4.5 *Seamounts*

Seamounts are important topographic features of the open ocean. Although they are small in area relative to the vast expanse of the abyssal plains, accounting for <5 per cent of the seafloor (Yesson et al., 2011), three important characteristics distinguish them from the surrounding deep-sea habitat (Figure 36F.1; see Chapter 34). First, they are “islands” of shallow sea floor, and provide a range of depths for different communities. Second, bare rock surfaces can be common, enabling sessile organisms to attach to the rock, in contrast to the majority of the ocean sea floor, which is covered with fine unconsolidated sediments. Third, the physical structure of some seamounts drives the formation of localised hydrographic features and current flows that can keep species and production processes concentrated over the seamount, even increasing the local deep pelagic biomass. They are a sufficiently important part of marine deep-sea biodiversity that seamounts are fully treated in Chapter 51 of this Assessment.

4.6 *Organic falls*

The decay of large sources of organic matter (e.g., whales, wood, jellyfish) that ‘fall’ from surface or midwater provide a concentrated source of food on the deep sea floor directly, and indirectly through the decay of the organic matter, can yield hydrogen sulphide and methane. An array of scavenging species (hagfish, amphipods, ophiuroids, and crabs) is adapted to rapidly finding and consuming organic matter on the deep seabed. In addition, lipid-rich whale bones and wood support specialized taxa that have evolutionarily adapted to consume the substrate via symbionts (Smith and Baco, 2003; Smith et al., 2015). At least 30 species of polychaetes in the genus *Osedax* colonize and degrade whale bones, with the aid of heterotrophic symbionts in the group Oceanspirales (Goffredi et al., 2005; Rouse et al., 2009; Smith et al., 2015). *Osedax* and other taxa colonizing whale falls exhibit biogeographic separation, succession during the life of the whale fall (Smith and Baco, 2003; Braby et al., 2007; Glover et al., 2005; Smith et al., 2015), *Adipicola* and other deep-sea mussels also harbour chemoautotrophic endosymbionts and colonize sulphide-rich whale remains (Fujiwara et al., 2007; Thubaut et al., 2013). Similarly, members of the bivalve genus *Xylophaga* colonize and consume wood in the deep sea, with symbionts that aid cellulose degradation and nitrogen fixation. The activities of these ‘keystone’ species, in conjunction with microbial decay, transform the environment and facilitate colonization by a high diversity of other taxa, for example >100 species thus far found only on deep-sea whale falls (Smith et al., 2015). Human impacts have likely already affected these organic-fall ecosystems. For example, 20th century whaling drastically reduced the flux of whale carcasses to the deep seafloor (Roman et al., 2014; Smith, 2006; Smith et al., 2015).

Numerous areas throughout the world’s oceans have experienced large jellyfish population expansions. Although numerous studies have sought to identify the driving forces behind and the impacts of live jellyfish on marine ecosystems (Purcell, 2012; Purcell et al., 2007), very few have focused on the environmental consequences from the deposition of jellyfish carcasses (from natural die-off events). Recently it has become apparent that jellyfish carcasses have very high sinking speeds (1,500 m d⁻¹, Lebrato et al., 2013a; 2013b). Thus, jellyfish blooms may affect seafloor habitats through the sedimentation of jellyfish carcasses (but also of macrozooplankton, see Smith et al. (2014)), the smothering of extensive areas of seafloor and reducing oxygen flux into seafloor sediments leading to hypoxic/anoxic conditions. Jelly falls may also be actively consumed by typical deep-sea scavengers, enhancing food-flux into deep-sea food webs (Sweetman et al., 2014). Jellyfish falls have so far been observed in the Atlantic, Indian and Pacific oceans (Billett et al., 2006; Lebrato and Jones, 2009; Yamamoto et al., 2008; Lebrato et al., 2013a; 2013b; Sweetman and Chapman, (2011), and are reviewed in Lebrato et al. (2012).

4.7 *Methane seeps*

Continental margins host a vast array of geomorphic environments associated with methane seepage and other types of seeps. Many support assemblages reliant on chemosynthesis fuelled by methane and sulphide oxidation (Levin and Sibuet, 2012;

Sibuet and Olu, 1998). Their specialized biodiversity features are assessed in Chapter 45.

Major ecosystem services being affected by the pressures

Despite its apparent remoteness and inhospitability, the deep ocean and seafloor play a crucial role in human social and economic wellbeing through the ecosystem goods and services they provide (Armstrong et al., 2012; Thurber et al., 2014; van den Hove and Moreau, 2007) (Table 1). Whilst some services, such as deep-sea fisheries, oil and gas energy resources, potential CO₂ storage, and mineral resources directly benefit humans, other services support the processes that drive deep-sea and global ecosystem functioning. Despite its inaccessibility to most people, the deep sea nonetheless supports important cultural and existence values. The deep sea acts as a sink for anthropogenic CO₂, provides habitat, regenerates nutrients, is a site of primary (including chemosynthetic) and secondary biomass production, as well as providing other biodiversity-related functions and services, including those the deep water and benthic assemblages provide (Irigoien et al., 2014).

Ocean warming and acidification associated with climate change already affect the deep sea, reaching abyssal depths in some areas (Østerhus and Gammelsrød, 1999). Ongoing global climatic changes driven by increasing anthropogenic emissions and subsequent biogeochemical changes portend further impacts for all ocean areas, including the deep-sea and open ocean (Mora et al., 2013b). Data from pre-anthropocene times indicates millennial-scale climate variability on deep-sea biodiversity (Cronin and Raymo, 1997; Cronin et al., 1999; Hunt et al., 2005; Wollenburg et al., 2007; Yasuhara and Cronin, 2008; Yasuhara et al., 2012a; 2009), as well as decadal-centennial climate events (Yasuhara et al., 2008; 2014). The potential impacts of climate change on the ocean are addressed in Part II of the Intergovernmental Panel on Climate Change (IPCC) 5th Assessment Report, Working Group II Chapters 6 and 30. Consistent with the mandate of this Assessment, they are only briefly summarized here.

Some impacts of climate change will be direct. For example, altered distributions and health of open-ocean and deep-sea fisheries are expected to result from warming-induced latitudinal or depth shifts (Brander, 2010); deoxygenation will induce habitat compression (Prince and Goodyear, 2006; Stramma et al., 2012; Koslow et al., 2011); and acidification will stress organismal function and thus organismal distribution. Climate change-related stressors are also likely to act in concert, and effects could be cumulative (Rosa and Seibel, 2008). Shifts in bottom-up, competitive, or top-down forcing will produce complex and indirect effects on the services described above. Acidification-slowed growth of carbonate skeletons, delayed development under hypoxic conditions, and increased respiratory demands with declining food availability illustrate how climate change could exacerbate anthropogenic impacts and compromise deep-sea ecosystem structure and function and ultimately benefits to human welfare.

The most important ecosystem service of the deep pelagic region is arguably the “biological pump”, in which biological processes, such as the daily vertical migration, package and accelerate the transport of carbon compounds, nutrients, and other materials out of surface waters and into the deep sea. However, the microbial diversity and processes of the deep-pelagic realm are not sufficiently known to predict confidently how the biological pump ecosystem service will respond to perturbations.

Deep-sea exploitation

6.1 Deep-sea fisheries

Deep-sea fishing has a long history, but it did not become an important activity until the mid-twentieth century, when technological advancement allowed the construction of large and powerful vessels, and the development of line and trawl gear that could be deployed to continental slope depths. FAO (2009) acknowledges that deep-sea fisheries often exploit species which have relatively slower growth rates, reach sexual maturity later and reproduce at lower rates than shelf and coastal species.

Deep-sea fish species were the basis of major commercial fisheries in the 1970s to early 2000s (Japp and Wilkinson, 2007) but started to decline as aggregations were fished out, and realisation grew about the low productivity, and hence low yields, of these species (Clark, 2001; Sissenwine and Mace, 2007) and impacts of some of these fisheries on seafloor structure and benthos (Clark and Dunn 2012). Globally the main commercial deep-sea fish species at present number about 20, comprising alfonsino, toothfish, redfish, slickheads, cardinalfish, scabbardfish, armourhead, orange roughy, oreos, roundnose and rough-headed grenadiers, blue ling and moras. The current commercial catch of these main deep-sea species is about 150,000 tons, and has been similar over the last five years, although the proportional species mix has changed. The ecosystem effects of these fisheries are discussed in Chapter 11 of this Assessment and in Chapter 51 relative to the seamounts which are centres for many of these fisheries.

6.2 Deep gas and oil reserves

The oil and gas industry has been active in the open ocean since the 1970s. Over 10,000 hydrocarbon wells have been drilled globally; at least 1,000 are routinely drilled in water depths >200 m, and as deep as 2,896 m in the Gulf of Mexico. The scale of the exploration and development of hydrocarbon reserves and then ecosystem effects are discussed in Chapter 21.

6.3 Minerals

Great interest exists in exploiting the deep sea for its various reserves of minerals, which include polymetallic nodules, seafloor massive sulphide (SMS) deposits,

mineral-rich sediments and cobalt-rich crusts. Currently no commercial mining projects have started, although several projects are in the exploratory or permitting phase. From those exploratory studies and related research some knowledge of potential ecosystem effects is accumulating.

Experimental studies to assess the potential impact of mining polymetallic nodules in the abyss have indicated that seafloor communities may take many decades before showing signs of recovery from disturbance (Bluhm, 2001; Miljutin et al., 2011), and may never recover if they rely directly on the nodules for habitat.

The recovery of communities at active hydrothermal vents where SMS deposits may be exploited may be relatively rapid, because vent sites undergo natural disturbances which have seen some communities appear to recover from catastrophic volcanic activity within a few years (Tunnicliffe et al., 1997). However, the rates of recovery of benthic communities are likely to vary among sites.

Other potential mining activities include exploiting mineral-rich sediments. For example in some deep marine sediments, phosphorite occurs as “nodules” (2 to >150 mm in diameter), in a mud or sand matrix, which can extend beneath the seafloor sediment surface to tens of centimetres depth.

No mining has yet been authorized for such deposits but could result in the removal of large volumes of both the phosphorite nodules and the surrounding soft sediments, together with associated faunal communities and generate large sediment plumes. In addition, cobalt-rich ferromanganese crusts are promising sources of cobalt and rare minerals required to sustain growing human population demands and emerging high and green technologies (Hein et al., 2013). Conditions favouring their formation are found in abrupt topography, especially on the flanks and summits of oceanic seamounts and ridges at depths of 800-2500 m, where the most Cobalt-rich deposits are known to concentrate, in habitats dominated by suspension-feeding sessile organisms (mostly cold-water corals and sponges) and comparatively rich biological communities (Clark, 2013; Clark et al., 2011; Fukushima, 2007; Schlacher et al. 2013). Interest in cobalt-rich crust resources is growing, although mining for cobalt-rich crusts has not yet started, and technological challenges mean it may develop later than for polymetallic nodule or SMS resources. Further information on these mining activities is found in Chapter 23, and the seamount and seep/vent habitats in Chapters 51 and 45, respectively.

Special conservation/management issues and sustainability for the future

7.1 Special habitats (VMEs, EBSAs, MPAs) and conservation measures

The United Nations General Assembly has adopted a number of resolutions that called for the identification and protection of vulnerable marine ecosystems (VMEs) from significant adverse impacts of bottom fishing (for example 61/105 of 2006), which has facilitated the development of the 2008 International Guidelines for the Management of Deep-Sea Fisheries in the High Seas (FAO, 2009). The concept and developments of VMEs and their protection is addressed in Chapter 11. Also in the

2000s, in response to the call in the World Summit on Sustainable Development (WSSD) for greater protection of the open ocean, the Conference of Parties to the Convention on Biological Diversity (CBD) developed and adopted criteria for the description of ecologically or biologically significant areas (EBSAs) in open-ocean waters and deep-sea habitats. The application of the EBSA criteria is a scientific and technical exercise, and areas that are described as meeting the criteria may receive protection through a variety of means, according to the choices of States and competent intergovernmental organizations (decision X/29 of the CBD COP10). Expert reviews have concluded that both approaches can be complementary in achieving effective sustainable management in the deep sea (Rice et al., 2014; Dunn et al., 2014).

7.2 Protection of the marine environment in the Area

With regard to deep-sea mining the International Seabed Authority (ISA), established in 1994, is required to take the necessary measures ensure that the marine environment is protected from harmful effects from activities in the Area under its jurisdiction. Such measures may include assessing potential environmental impacts of deep-sea activities (exploration and possible mining) and setting standards for environmental data collection, establishment of environmental baselines, and monitoring programmes (ISA, 2000, 2007 2013).

7.3 Deep-ocean observatories-ocean networks

Deep-sea observatories are becoming increasingly important in monitoring deep-sea ecosystems and the environmental changes that will affect them. The first long-term and real-time deep-sea observatory was deployed in 1993 at a methane seep site at 1,174 m depth in Sagami Bay, Japan (JAMSTEC, Japan), and is still operating. Several internationally organized projects have been initiated to achieve global integration of deep-sea observatories (e.g., Global Ocean Observing System (GOOS, NSF); FixO3 (Fixed Point Open Ocean Observatories, European Union Framework Programme 7), largely based on existing observing networks (e.g., Porcupine Abyssal Plain in the North Atlantic, (NOC, UK), Hausgarten Site in the transition between the North Atlantic and the Arctic (AWI, Germany), Ocean Network Canada with the Neptune Observatory on Canada's west coast) and aiming at achieving multidisciplinary integration, including physics, climate, biogeochemistry, biodiversity and ecosystems, geophysics with integration across sectors, and economics and sociology. Whilst moving towards a global strategy to obtain maximum efficiency, one of the major goals of deep-sea observatory initiatives is to better understand and predict the effects of climate change on the linked ocean-atmosphere system, and on marine ecosystems, biodiversity and community structure, In terms of biodiversity and ecosystems, several objectives need addressing: exploration and observation; prediction of future biological resources; understanding the functioning of deep-sea ecosystems; and understanding the roles of relationships between ecosystems and the services they provide.

Figure 1. Deep-sea habitats. Top left: coral garden in the Whittard Canyon, NE Atlantic at approx. 500 metres depth (2010; image courtesy of Jeroen Ingels); top right: A sea anemone, *Boloceroides daphneae*, on cobalt crust covering a seamount off Hawaii, 1000 metres depth (image courtesy of Chris Kelly, HURL); bottom left: An orange roughy (*Hoplostethus atlanticus*) aggregation at 890 metres depth near the summit of a small seamount (termed "Morgue") off the east coast of New Zealand (image courtesy of Malcolm Clark); bottom right: A reef-like coverage by stony corals (*Solenosmilia variabilis*) together with prominent orange brisingid seastars on the summit of a small seamount (termed "Ghoul") feature at 950 metres off the east coast of New Zealand (image courtesy of Malcolm Clark).

1. Introduction

1.1 State

The Central Arctic Ocean and the marginal seas such as the Chukchi, East Siberian, Laptev, Kara, White, Greenland, Beaufort, and Bering Seas, Baffin Bay and the Canadian Archipelago (Figure 1) are among the least-known basins and bodies of water in the world ocean, because of their remoteness, hostile weather, and the multi-year (i.e., perennial) or seasonal ice cover. Even the well-studied Barents and Norwegian Seas are partly ice covered during winter and information during this period is sparse or lacking. The Arctic has warmed at twice the global rate, with sea-ice loss accelerating (Figure 2, ACIA, 2004; Stroeve et al., 2012, Chapter 46 in this report), especially along the coasts of Russia, Alaska, and the Canadian Archipelago (Post et al., 2013). Changes in ice cover, ocean warming, altered salt stratification, alterations in water circulation and fronts, and shifts in advection patterns show that oceans within the Arctic are subjected to significant change, and may face even more change in future (Wassmann, 2011 and references within). The Central Arctic Ocean and the marginal seas are home to a diverse array of algae and animals, some iconic (e.g., polar bear), some obscure, and many yet to be discovered. Physical characteristics of the Arctic, important for structuring biodiversity, include extreme seasonality resulting in short growing seasons and annual to multi-annual ice cover. The Central Arctic Ocean has a deep central basin (>4000 m depth) surrounded by the most extensive shelves of all the world's oceans, and is characterized by extensive (albeit declining) ice cover for much of the year. This offers a vast number of different habitats created by the shape of the seabed, latitude, history of glaciations, proximity to the coastline and rivers, oceanic currents, and both the seabed and the ice as a substrate. Barriers for dispersal, such as the ice plug in the Canadian High Arctic, effectively separate stocks of some marine mammals (Dyke et al., 1996). Polynyas, which are open water areas surrounded by ice, provide important foraging and refuge areas and contribute to Arctic biodiversity. Differences in ice cover, mixing between warm- and cold-water currents, or currents with different nutrient content, create a mosaic of nutrient-poor areas which is reflected in species diversity (ABA, 2014, Figure 3). Despite this heterogeneity, the Arctic is less diverse than lower-latitude areas for several taxa, including mammals and birds, but equal to, or higher than those areas for bottom animals (Renaud et al., 2009; Piepenburg et al., 2011), marine crustaceans and phytoplankton (algae

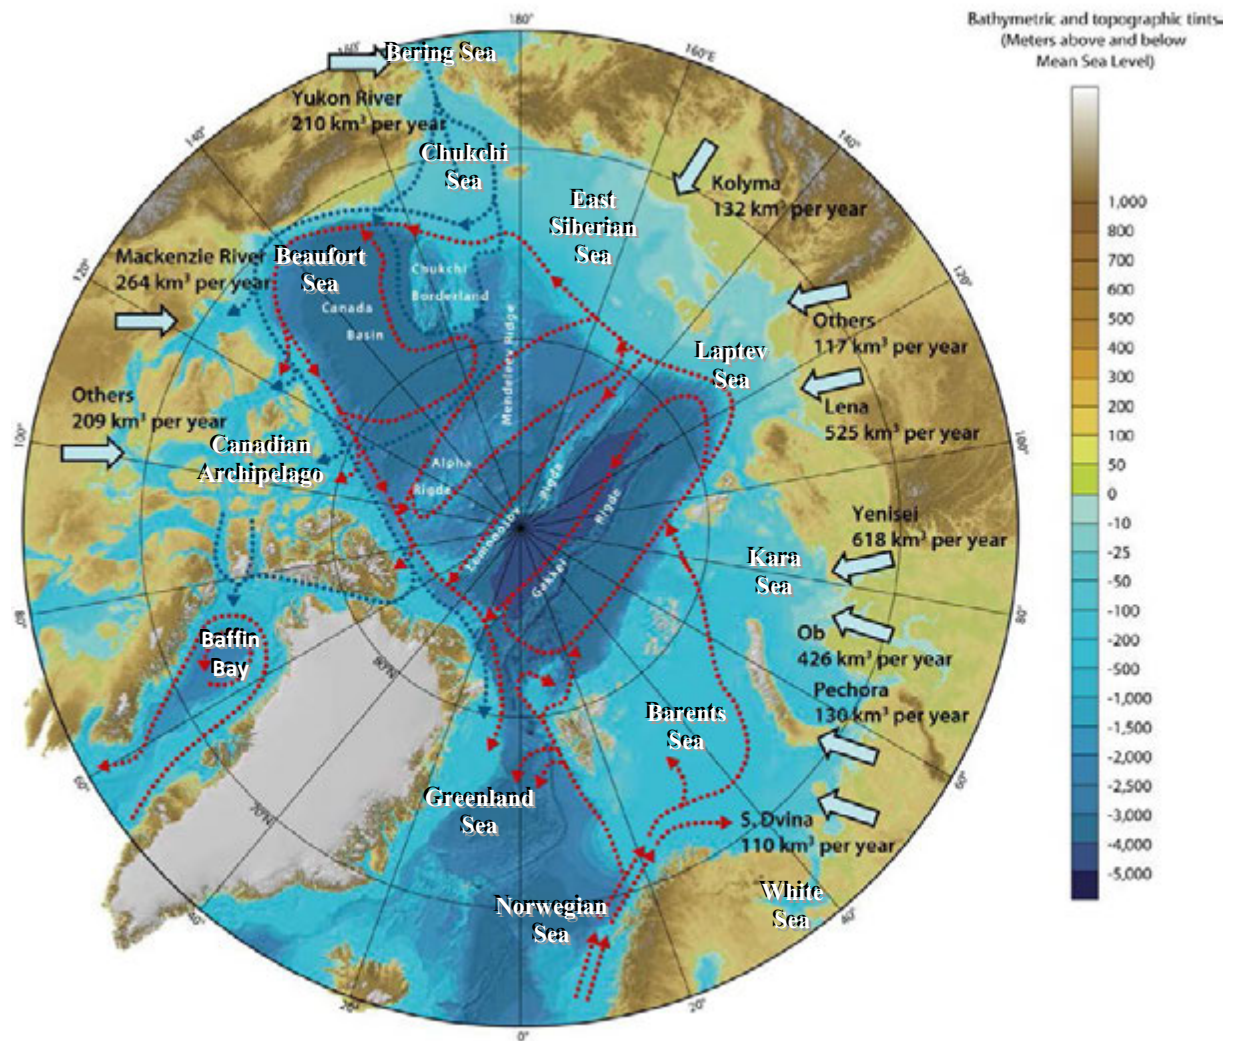

plankton) (Archambault et al., 2010). The marine areas in the Arctic support species of algae, plankton, nekton, fish, benthos, mammals, and birds (see sections below) but also thousands of species of fungi, endoparasites and microorganisms (Figure 3, see also ABA 2014 for more information). Due to mixing of sub-Arctic and Arctic fauna, the biodiversity is high in the vicinity of the Arctic Gateways of the North Atlantic and Pacific Oceans (ABA, 2014). The Red List of the International Union for Conservation of Nature (IUCN) includes 13 Arctic or seasonal mammalian inhabitants and 21 Arctic or Arctic-breeding seabirds as threatened species (IUCN, 2012), and eight targeted fish stocks and five Arctic fish species are evaluated according to the IUCN red list criteria (Christiansen et al., 2014, <http://www.iucnredlist.org/technical-documents/categories-and-criteria>). Humans in the Arctic lead lives based on traditional hunting, fishing and gathering of marine resources or commercial fishing and other economic and recreational activities. Along the coast and on islands, the marine environment plays a central role in food, housing, settlement patterns, and cultural practices and boundaries.

1.2 Trends and Pressures

Climatically, ecologically, culturally and economically, the Arctic is changing, with implications throughout the region (ABA, 2014). Primary producers, such as sea-ice algae and sub-ice phytoplankton, have lost over 2 million km² of Arctic ice since the end of the last century (Figure 2, Kinnard et al., 2011), representing a loss of habitat. The largest changes will take place in the northern sections of today's seasonal ice zones, which will expand and eventually cover the entire Arctic Ocean while the multi-year ice will be declining (Wassmann, 2011). The seasonal timing of the ice-algal bloom, driven by light penetration through thinning sea ice, is critical to reproduction of some zooplankton, and the subsequent algal bloom is critical for the survival of zooplankton offspring (Søreide et al., 2010). The annual zoo- and phytoplanktonic pulses of productivity fuel the Arctic marine food web (Darnis et al., 2012) affecting zooplankton production and the Arctic cod that feed on them (Ji et al., 2013), as well as their seabird and marine mammalian predators (Post et al., 2013). It also affects the underlying benthic communities such as bivalves, crabs, sea urchins, which are in turn key prey for seabottom feeding specialists, such as diving sea ducks, bearded seals, walrus, and gray whales (Grebmeier and Barry, 2007). Vertebrate species are also directly affected and walrus and polar bears are moving their habitats from the diminishing sea ice to land (Fischbach et al., 2009). Arctic warming and sea-ice loss will facilitate invasion by new species, hosts, harmful microorganisms, and diseases (Post et al., 2013).

As sea ice retreats (see also chapter 46) and living commercial resources migrate northward, shipping (AMSA, 2009), fishing, petroleum activities, tourists, and consequently the risks of oil spills, noise, pollution and disturbances follow. These risks are often found where fish and marine mammals are abundant (AMSA IIc, 2013). Some of the largest populations of seabirds in the northern hemisphere are intersected by major shipping routes. Boreal fish stocks may move into unexploited parts of the Arctic, depending on the sensitivity and adaptive capacity of the affected species (Hollowed et al. 2013). New Arctic and sub-Arctic species have recently been reported from the Canadian Beaufort Sea and harvested Atlantic species have

moved poleward into Arctic Seas. These patterns likely represent both altered distributions resulting from climate change and previously occurring but unsampled species. (Mueter et al., 2013). As targeted boreal stocks move into as yet unexploited parts of the seas, Arctic fish species turn up as unprecedented by-catch and could be vulnerable to large-scale industrial fisheries (Christiansen et al., 2014, ABA 2014). Bottom-dwelling fisheries harvest near the seabed and they reshape bottom morphology and impoverish, perturb and change the functional composition of benthic communities (Puig et al., 2012). Cold-water coral, sponges and sea pens, which form a more complex habitat, are protected species (Fuller et al. 2008, FAO 2009) and areas potentially inhabited by these vulnerable taxonomic groups are mainly found north of 80°N in the Barents Sea, the Greenland Sea, and North of Greenland (Jørgensen et al, 2015; Jørgensen et al 2013; Boertmann and Mosbech 2011; Tendal et al 2013; Klitgaard and Tendal, 2004). Bans on industrial fisheries in the Chukchi and Beaufort Seas are currently in place in the USA (<http://alaskafisheries.noaa.gov>), along with restrictions on new commercial fishing operations in the Canadian Beaufort (<http://news.gc.ca/web/article-en.do?mthd=index&ctr.page=1&nid=894639>) and "protected areas" (those regions with reduced or strictly controlled fishing) are debated for the Arctic region (Barry and Price, 2012). Competition for use of marine space might increase in the Arctic, together with increased demand for products from the sea (food, minerals, recreation, etc). Climate-induced changes in the severity of storms and intensity of extreme events might pose challenges to the exploitation of resources in the Arctic. Arctic oil and gas fields provide a substantial part of the world's supply at present, and many fields have yet to be developed. There might be a threat of oil spills and introduction of invasive species (AMAP, 2009). Contaminants are present in organisms at the base of the food web, and they accumulate from one level of the food web (trophic level) to the next (AMAP, 2011). In addition to coastal wave erosion and changes in wildlife movement patterns and cycles, managers also face increases in ocean acidity due to increased CO₂ concentrations. The oceans within the Arctic are especially vulnerable to ocean acidification and Arctic marine ecosystems are highly likely to undergo significant change due to ocean acidification (AMAP 2013). The suite of stressors experienced by species living in the Arctic today is novel, making past periods of climate change an imperfect analogue for the challenges now facing biodiversity in the Arctic (ABA 2014). Global climate change threatens to alter the population dynamics of many species for which rates of demographic change and estimates of population size are imprecise or lacking. There is an urgent need to continuously monitor their distribution and occurrence as significant changes occur in the ecosystem. At present, scientists are unable to provide valid answers to questions about safe and sustainable operations. The availability of solid interdisciplinary baseline data is rare but crucial, and it is clear that ongoing and future changes can only be detected through long-term monitoring of key species, communities and processes, providing adequate seasonal coverage in key regions of the Arctic, utilizing new technologies, and making existing historical data accessible to the international research community. Up-to-date knowledge is needed and gaps in knowledge and key mechanisms driving change must be identified in order to secure Arctic biodiversity.

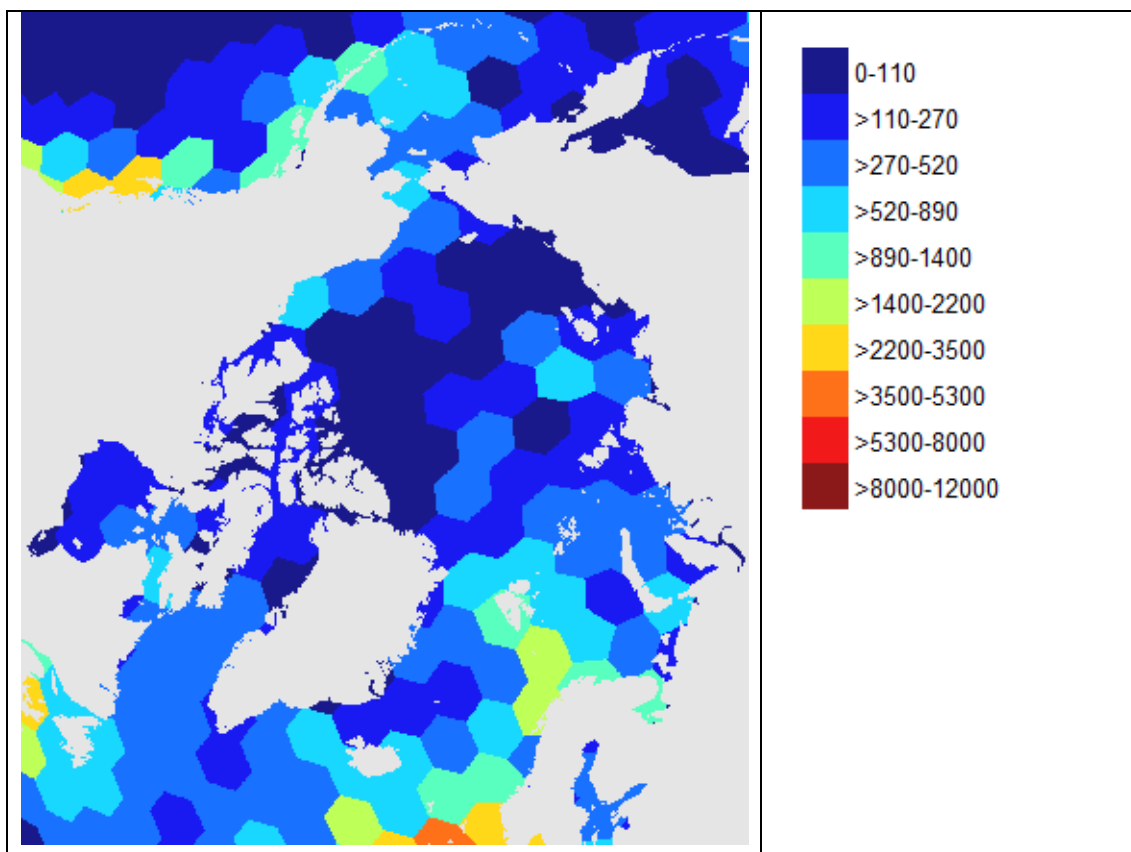

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. The deep Central Arctic Ocean and the marginal seas such as the Chukchi, East Siberian, Laptev, Kara, White, Greenland, Beaufort, Barents, Norwegian and Bering Seas, Baffin Bay and the Canadian Archipelago. Blue arrows show freshwater inflow, red arrows water circulation. (adapted from CAFF 2013, Arctic Biodiversity Assessment, figure 14.1).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Sea ice acts as an air conditioner for the planet, reflecting energy from the Sun. On September 17, the Arctic sea ice reached its minimum extent for 2014 — at 1.94 million square miles (5.02 million square kilometres) the sixth lowest extent of the satellite record. With warmer temperatures and thinner, less resilient ice, the Arctic sea ice is on a downward trend. The red line in the still image indicates the average ice extent over the 30 year period between 1981 and 2011. NASA/Goddard Scientific Visualization Studio, 2014. Figure 3. Pan-Arctic map showing the number of marine species from the OBIS database in a gridded view of hexagonal cells (OBIS, 2015).

2. Primary producers

General information on primary producers

Primary producers (algae) in Arctic marine waters are dominated by small, solitary photosynthetic cells containing different types of pigments, and reproducing by the formation of spores and gametes (Daniëls et al., 2013). They consist of numerous heterogeneous and evolutionarily different groups (Adl et al., 2012) and include both single-celled organisms (microalgae) and multicellular organisms (macroalgae). In addition, the prokaryotic Cyanobacteria also occur throughout the ocean. Microalgae occur as solitary cells or form colonies with different shape and structure. The size varies between 0.2 and 200 μm , a few up to 400 μm (pico: < 2 μm , nano: 2-20 μm , micro: 20-200 μm). Macroalgae are seaweeds that are visible to the naked eye, take a wide range of forms, and range from simple crusts, foliose and filamentous forms with simple branching structures, to more complex forms with highly specialized structures for light capture, reproduction, support, flotation, and

attachment (Diaz-Pulido and McCook, 2008).

2.1 Introduction

Arctic microalgae can be divided by function (e.g., ice algae and phytoplankton). Phytoplankton live suspended in the upper layer of the water column, but ice algae live attached to ice crystals, in the interstitial water between crystals, or associated with the under-surface of the ice (Horner et al., 1988).

2.2 Status

The study of phytoplankton, ice algae and macroalgae of Arctic seas dates back more than one hundred years (e.g., Ehrenberg, 1841; Cleve, 1873; Kjellmann, 1883; Rosenvinge, 1898). Early studies concentrated on diversity and on temporal changes in species composition or distribution relative to oceanographic structure, and were of local or regional character. Poulin et al. (2010) reported 2,016 taxa with 1,874 phytoplankton and 1,027 sympagic (ice algae) taxa in Arctic waters. Daniëls et al. (2013) concluded that few biodiversity assessments of benthic microalgae exist across the Arctic, but estimate ca. 215 seaweed species. Most of the algal species in the Arctic are cold water or temperate species, although some are distributed globally and a few are warm water species (Hasle and Syvertsen, 1996; von Quillfeldt, 1996). The species composition in different Arctic areas is often comparable, which is likely to be due to advection (horizontal transportation) of cells by the currents in the Arctic (Carmack and Swift, 1990; Abelman, 1992). Differences occur on a smaller scale, often as a result of local environmental conditions (Cota et al., 1991; von Quillfeldt, 2000). Prominent forcing factors on species diversity in the Arctic include the extreme seasonality of light, combined with sea-ice distribution (Bluhm et al., 2011), but the result (increase/decrease) depends on season and locality. However, a suite of environmental variables (e.g., nutrients, light, water stratification, salinity, temperature) determines abundance, biomass and taxonomic composition over time (Poulin et al., 2010). Many species have a wide environmental tolerance (Degerlund and Eilertsen, 2009).

The composition of the phytoplankton varies seasonally (von Quillfeldt, 2000; Lovejoy et al., 2002; Ratkova and Wassmann, 2002; Wassmann et al., 2006; Sukhanova et al., 2009). Most species can be characterized as winter, spring, summer or autumn species, but a few are seasonally independent. Several decades ago, few Arctic areas had been sampled during winter, but the importance of flagellates during winter had been suggested (Schandelmeier and Alexander, 1981; Horner and Schrader, 1982; Rey, 1986). Recently the importance of extremely small (< 20 µm) forms in Arctic waters throughout the year has been confirmed (e.g., Vørs, 1993; Lovejoy and Potvin, 2011; Niemi et al., 2011; Sørensen et al., 2012; Terrado et al., 2012; Kiliyas et al., 2013).

Ice communities are widespread throughout the Arctic (e.g., Apollonio, 1965; Meguro et al., 1967; Grainger, 1977; Hsiao, 1980; Horner et al., 1988, Horner et al., 1992, Syvertsen 1991), but the different types of communities are characterized by specific species (von Quillfeldt, 1997; Gradinger, 1999; Melnikov et al., 2002; Zheng et al., 2011). Solitary diatoms (a type of microalga) are common in interstitial

communities or sometimes in older ice, whereas the majority of colonial algae, except for *Melosira arctica*, are most common in sub-ice communities of one-year-old ice and in more offshore areas (Dunbar and Acreman, 1980; De Sève and Dunbar, 1990; von Quillfeldt, 1996; von Quillfeldt et al., 2003). Irradiance is the most important factor in determining abundance of ice algae. Snow depth and ice thickness control light in sea ice and thereby algal abundance, as does the ice structure (Gosselin et al., 1997; Robineau et al., 1997; Krembs et al., 2000). Ice algae are distributed throughout the ice during winter and become concentrated at the bottom in spring as a result of brine drainage and active migration of cells through brine channels (Hsiao, 1980; Horner, 1985). Furthermore, a south-north spatial gradient similar to the seasonally dependent gradient in the species composition is often observed. The oldest and most specialized ice community occurs in the far north (Syvertsen, 1991).

Lüning (1990) divided Arctic seaweeds into flora with a distinct vegetation structure; many species are distributed throughout the Arctic, and a few are found only within the Arctic Basin. Macroalgal (multi celled algae attached to the seabed) diversity decreases with increasing latitude and from the Atlantic to the Pacific sector (Pedersen, 2011). Temperature is a primary factor in macroalgal distribution (Lüning, 1990). Wulff et al. (2011) emphasized that macroalgae can be of either Atlantic or Pacific origin, but more macroalgae are of Pacific origin than previously thought. Substratum characteristics are important for the distribution of benthic algae (Zacher et al., 2011.) Along the Russian Arctic coast are areas where a soft substratum prevails and macroalgae are absent (Lüning, 1990). Areas exposed to mechanical effects of sea ice or icebergs will also be devoid of macroalgae (Gutt, 2001; Wulff et al., 2011). The Arctic is also strongly affected by marked changes in surface salinity due to melting of sea ice and freshwater input from rivers. Thus, macroalgae must be able to withstand large variations in salinity over the year. Fricke et al. (2008) described the succession of macroalgal communities in the Arctic and the effect of disturbances on communities of different ages and their changes with depth.

2.3 Trends

Daniëls et al. (2013) comment that it is difficult to estimate trends in Arctic phytoplankton, sea-ice algae and benthic algae due to the relatively poor knowledge of algal distributions prior to the period of rapid environmental changes. Baseline data are generally lacking, and it is challenging to distinguish between natural variations and changes in assemblages due to anthropogenic modification. The high variability in the number of single-celled algae across the Arctic can be related to sampling effort in time and space, rather than actual differences, and a strong bias towards large cells (Poulin et al., 2010) and sampling in coastal areas has been observed. Knowledge of the biodiversity improved recently as a result of improved sampling techniques, advanced microscopic and molecular methods, electronic databases and gene libraries, and increased international cooperation (Daniëls et al., 2013), as well as increased sampling in the central basins (e.g., Melnikov, 1997; Katsuki et al., 2009; Joo et al., 2012; Tonkes, 2012).

Some surveys indicate that climate-mediated changes appear to be occurring, but geographical differences are also found. For example, less sea ice and an increase in atmospheric low-pressure systems that generate stronger winds (and deeper mixing of the upper ocean), as well as a warming and freshening of the surface layer are likely to favour smaller species (Sakshaug, 2004; Li et al., 2009; Tremblay et al., 2012). However, Terrado et al. (2012) found that some small-celled phytoplankton species were specifically adapted to colder waters, and are likely to be vulnerable to ongoing effects of surface-layer warming. Altered discharge rates of rivers and accompanying changes of composition will also affect the composition of the phytoplankton (Kraberg et al., 2013). *Emiliana huxleyi*, a prymnesiophyte, has become increasingly important: blooms of this species have occurred in the Atlantic, presumably related to changing climate conditions (Sagen and Dalpadado, 2004; Hegseth and Sundfjord, 2008). The reappearance of the North Pacific planktonic diatom *Neodenticula seminae* may also be a consequence of regional climate warming (Poulin et al., 2010). Harrison et al. (2013) predict that northward movement of Atlantic waters will replace cold-water phytoplankton with temperate species and shift transition zones farther north. Increased amounts of annual sea ice relative to multi-year ice will influence ice-algal composition (Poulin et al., 2010). Warming could alter benthic algal distribution and favour invasion by temperate species (Campana et al., 2009). Models suggest that some macroalgal species will shift northwards and that the geographic changes will be most pronounced in the southern Arctic and the southern temperate provinces (Jueterbock et al., 2013). Reduced sea-ice cover and retreating glaciers will continue to alter light, salinity, sedimentation and disturbance processes (Campana et al., 2009).

3. Zooplankton

General information on zooplankton

Plankton are animals drifting in the sea. Many are microscopic, but some (such as jellyfish, medusa and comb jellies) are visible with the naked eye. Multicellular zooplankton, such as the copepods are called the ocean's "grass and grazers". In addition to copepods, amphipods, another group of small crustaceans are important. Larvaceans are solitary, free-swimming tunicates and live in the pelagic zone. They are transparent, planktonic animals with a tail. Chaetognaths (arrow worms) are transparent dart-shaped animals, while pteropod molluscs are pelagic snails.

3.1 Status

The zooplankton community structure in coastal and continental shelf waters of the Arctic is largely controlled by proximity to rivers and the areas of influx from the

Atlantic and Pacific. This community has been studied in a few restricted areas (e.g., Walkusz et al., 2010), but it has not been comprehensively reviewed. Many species known from the Atlantic and Pacific and reported from the neritic (shallow marine environment extending from mean low water down to 200m depths) Arctic are found only as advanced developmental stages, and therefore probably are non-reproductive expatriates. However, evidence is increasing that some North Atlantic species are reproducing in the polar Arctic.

Kosobokova et al. (2011) recently reviewed what is known about multicellular zooplankton in the central Arctic based largely on depth-stratified net collections from multiple projects during 1975-2007. They reported 174 oceanic species, of which 70 per cent were crustaceans. Although large copepods are very important in this assemblage, including *Calanus* species (Copepod) typical of the North Atlantic, as well as Arctic endemics (prevalent in or limited to a particular region), the abundance of this fauna is strongly dominated by small copepods. In addition to copepods, amphipods are important crustaceans, again including Arctic endemics, as well as Atlantic species; other important taxonomic groups include larvaceans (pelagic tunicates), chaetognaths (arrow worms), and pteropod molluscs (pelagic snails) (Gradinger et al., 2010). Relative to the westerlies and trade-wind regions, polar systems are relatively enriched with copepods and pteropods, and reduced in species with jelly-like bodies (Longhurst, 2007).

Despite “Thorson’s Rule” that the proportion of species with planktonic larvae decreases at high latitudes, many benthic invertebrates of the Arctic, North Atlantic, and North Pacific develop through planktonic stages. These species contribute seasonally to the diversity of the endemic assemblage, as well as to the many non-native species carried by currents into the Arctic from the Atlantic and Pacific Oceans, at times reaching abundances similar to those of the holoplankton (Hopcroft et al., 2010).

Vertical stratification of the zooplankton community in the central Arctic basins is strongly influenced by water-mass distribution and advective input of low-salinity surface water and layering of Pacific and Atlantic intrusions at mid-depths. Whereas the surface waters and waters below the surface layer are considered to be “well-characterized” (Gradinger et al., 2010), the large percentage of species in the very deep waters of the bathypelagic (i.e., open waters >1000 m depth) zone that are either new to science or previously unknown from the Arctic indicate that much remains to be learned about the truly deep pelagic fauna. The evidence to date indicates that little difference among the deep basins exists in the bathypelagic (depth generally between 1000-4000 m) zooplankton.

In-situ observations by remotely operated vehicles, as well as net collections, have shown that gelatinous megaplankton can be important in the central Arctic (Raskoff et al., 2010). This assemblage is dominated by “true” jellyfishes (medusae) and other, similar forms. Similarly to the net-collected mesozooplankton (planktonic animals in the size range 0.2-20 mm), the vertical structure of this assemblage is strongly associated with the vertical distribution of water masses. The overall abundance of gelatinous megaplankton, especially medusae, decreased dramatically over shallow slope, ridge and plateau areas relative to that found in the central basin, whereas the abundance of ctenophores (comb jellies), which are typically

present in the surface layer, remained high in these shallower areas (Raskoff et al., 2010).

In addition to water-mass dynamics, vertical distribution of zooplankton is strongly linked to the penetration of solar radiation and the availability of food. Although the seasonal irradiance signal is extreme in the Arctic, diel variability exists and may act as a physiological cue for diel vertical migration (Rabindranath et al., 2011). However, the major irradiance patterns in the Arctic are seasonal, with continuous darkness in winter and 24-h photoperiods in summer. In winter, many species reside deeper in the water column for a diapause, or resting, phase in their life cycle. Winter diapause is not universal; some species are reproductively active under the winter ice (Hirche and Kosobokova, 2011). Additional variability in summer results from breakup of sea ice. When present, ice cover strongly limits irradiance penetration and the seasonal melt further controls both the phytoplankton bloom and the release of ice algae, important factors for the timing of zooplankton life-cycle events and their vertical distribution. In deeper water the vertical linkage between phytoplankton and zooplankton becomes progressively weaker (Longhurst and Harrison, 1989).

Kosobokova et al. (2011) categorized 6 per cent of Arctic zooplankton species as ice-associated (“cryopelagic”). Grading et al. (2010) listed 39 invertebrate species as being ice-associated, although the division between cryopelagic and cryobenthic (or sympagic) is not clear. The association between the animals and the sea ice can be based on physical substrate or on the food web based on ice algae (Hop et al., 2011). Furthermore, the association may extend throughout the life cycle or just include a portion (e.g., dependence of a larval copepod stage on ice algae).

Where polynyas maintain open-water conditions in areas surrounded by solid ice cover, the zooplankton community is more similar to the open-water community rather than that found under ice. The pelagic food web of the polynya contributes to transfer of resources to the benthos (Deibel and Daly, 2007).

3.2 *Trends and pressures*

Limited long-term comparisons within the central Arctic indicate that species inventories, other than newly discovered species, seem to be unchanged. Whereas Pacific species on the shelves are probably non-reproducing populations transported from native waters of the North Pacific, at least some species typical of the Atlantic are found on Arctic shelves and seem to be reproducing successfully. Recent evidence (e.g., Kraft et al., 2013) indicates increasing reproductive success of Atlantic species. Therefore although the diversity inventory has not changed, physiological effects related to climate change appear to be shifting functions in the ecosystem. This “Atlantification” could have several possible results affecting the pelagic food web and transfer of energy to the benthos, in addition to the structure of the zooplankton community. Examples of such possible effects include differences in lipid-storage dynamics and timing of zooplankton reproduction relative to blooms of primary producers failing to provide adequate food to Arctic predators of zooplankton and changes in the production of “marine snow” (including faecal

pellets, moults, discarded mucus-feeding structures), which is important for transport of surface productivity necessary to feed the deep benthic communities.

3.3 *Climate Change and Oceanographic Drivers Affecting Zooplankton.*

Climate-induced changes in the timing and extent of sea-ice melt and breakup could have far-reaching effects on zooplankton structure and function within the pelagic food web, including coupling with the benthos and air-breathing vertebrates. The end of dormancy and initiation of feeding for lipid storage to fuel reproduction in the large Arctic copepods is linked to the ice-edge bloom. Because lipid dynamics differ in North Atlantic congeners, the “Atlantification” of the Arctic may be favoured by early and extensive breakup of the ice. The Atlantic species, which do not build up lipid reserves extensively prior to spawning, as do the Arctic endemics, may not provide adequate food for predators.

Increased ultra-violet (UV) radiation may have extensive effects on epipelagic species. This UV radiation can have substantial impacts on all plankton and can be lethal for zooplankton, especially eggs. Acidification can have a variety of effects, especially on species for which calcification is important, either for formation of exoskeletons (e.g., molluscs and crustaceans) or of sensory organs (e.g., otoliths of fish larvae and statoliths of cephalopods). Particular sensitivity can be expected in the abundant pteropod (swimming snail) species *Limacina helicina*, in which the aragonitic shell is even more vulnerable to dissolution than are calcite structures (see ocean acidification in chapter 5). Climate change impacts in the Arctic are expected to be significant and to be expressed earlier than in other oceanic realms due to the modification of the ice cover currently being observed (Stammerjohn et al., 2012).

4. Benthos

General information on the Benthos

The benthos, an important component of the ocean system, is the scientific term for the community of organisms that inhabit the seabed, ranging from the tidal coastal zone to the abyssal depths of the deep sea. The seabed environment includes a great variety of physically diverse habitats that differ from each other in terms of depth (intertidal to abyssal), temperature, light availability, and type of substratum (ranging from hard through soft, muddy bottoms). It encompasses organisms from a wide variety of taxa, sizes, life forms and ecological niches. Benthic animals, seaweeds (phytobenthos, incl. microalgae, macroalgae, seagrass), bacteria and protists (microbenthos), account for 98 per cent of the marine biodiversity in terms of species; the remaining 2 per cent are pelagic. Furthermore, some benthic fauna live in the sediment (endobenthos or infauna), attached to the seafloor (epibenthos or epifauna) or living above it (suprabenthos). Hyperbenthic (or suprabenthic) animals do not live directly on or in the seabed but very close above the seafloor in

the near-bottom part of the water column. The benthic fauna are typically classified into size categories. Microbenthic organisms are bacteria and protists smaller than 0.1 mm. Meiobenthos consists of tiny benthic organisms that are less than 0.5 mm but greater than 0.1 mm in size, mostly inhabiting the interstitial space between the sediment grains. By far the best-studied is the macrobenthos, encompassing forms larger than 0.5 mm that are visible to the naked eye, mostly polychaete worms, bivalves, crustaceans, anthozoans, echinoderms, sponges, and ascidians. Finally, the term megabenthos has been operationally defined as including large, often mobile benthic animals, mostly fish and crustaceans that are big enough to be visible in seabed images or to be caught by towed sampling gear.

4.1 *Status*

The current knowledge on the biodiversity of the benthic fauna in coastal, shelf and deep-sea regions has been summarized in three papers (Weslawski et al., 2011; Piepenburg et al., 2011; Bluhm et al., 2011a). These large-scale studies were conducted as contributions to the Arctic Ocean Diversity (ArcOD) project (<http://www.arcodiv.org>; Bluhm et al., 2011b), which in turn was part of the Census of Marine Life (<http://www.coml.org>; Snelgrove, 2010) and the International Polar Year 2007/2008. It aimed at coordinating research efforts examining the diversity in each of the three major realms (sea ice, water column, and sea floor) of Arctic marine ecosystems to consolidate what is known and fill gaps in our knowledge.

4.2 *Coasts*

Weslawski et al. (2011) reviewed the pattern of occurrence and recent changes in the distribution of macrobenthic organisms in fjords and coastal (nearshore) Arctic waters. In addition, likely future changes were hypothesized. The biodiversity patterns observed were demonstrated to differ among regions and habitat types. The North Atlantic Current along Scandinavia to Svalbard and the Bering Strait was shown to be a major area of biotic advection, where larvae and adult invertebrates are transported from the sub-Arctic areas to Arctic areas. There, increased temperature associated with increased advection in recent decades has favoured the immigration of more boreal-sub Arctic species, increasing the local biodiversity when local cold-water species may be suppressed. On the opposite side, in the Canadian Archipelago, the Nares Strait (between Greenland and Ellesmere Island), Lancaster Sound, Barrow Strait and M'Clure Strait are conduits for cold Arctic water flowing to the North Atlantic. Other large coastal areas, such as the Siberian shores, were shown to be little influenced by advected waters.

4.3 *Shelf seas (30 to 500 m)*

The knowledge of Arctic shelf seas has increased in the past decade, but benthic diversity was investigated at regional scales only. Piepenburg et al. (2011) presented a first pan-Arctic account of the species diversity of the macro- and megabenthic fauna inhabiting Arctic shelves. It was based on an analysis of 25 published and

unpublished species-level data sets, together encompassing 14 of the 19 marine Arctic shelf regions and comprising 2,636 species, including 847 Arthropoda, 668 Annelida (669 if we include the new species described by Olivier et al., 2013), 392 Mollusca, 228 Echinodermata, and 501 species of other phyla. Furthermore, gross estimates of the expected species numbers of the major four phyla were computed on a regional scale. Some areas, such as the Canadian Archipelagos, we have not compiled because of the lack of data. Extrapolating to the entire fauna and study area leads to a conservative estimate: 3,900-4,700 macro- and megabenthic species can be expected to occur on the Arctic shelves. These numbers are smaller than analogous estimates for the Antarctic shelf, but the difference is on the order of about two and thus is less pronounced than previously assumed. On a global scale, the Arctic shelves are apparently characterized by intermediate numbers of macro- and megabenthic species. This preliminary pan-Arctic inventory provided an urgently needed assessment of current diversity patterns that will be used by future investigations for evaluating the effects of climate change and anthropogenic activities in the Arctic.

4.4 *Central Arctic Ocean*

Bluhm et al. (2011a) compiled a benthic species inventory of 1,125 taxa from various sources for the central Arctic deeper than 500 m, and bounded towards the Atlantic by the Fram Strait. An additional 115 taxa were added from the Greenland–Iceland–Norwegian Seas (GIN). The inventory was dominated by taxa of Arthropoda (366), Foraminifera (197), Annelida (194), and Nematoda (140). A large overlap in taxa with Arctic shelf species supported previous findings that part of the deep-sea fauna originates from shelf species. Macrofaunal abundance, meiofaunal abundance and macrofaunal biomass decreased significantly with water depth. Species evenness increased with depth and latitude. No mid-depth peak in species richness was observed. Multivariate analysis of the Eurasian, Amerasian and GIN Seas polychaete occurrences revealed a strong Atlantic influence, the absence of modern Pacific fauna, and the lack of a barrier effect by mid-Arctic ridges. Regional differences are apparently moderate on the species level and minor on the family level, although the analysis was confounded by a lack of methodological standardization and inconsistent taxonomic resolution. Bluhm et al. (2011a) concluded that more consistent methods to observe temporal trends should be used in future efforts to help fill the largest sampling gaps (e.g., eastern Canada Basin, depths >3,000 m, megafauna). This is necessary to be able to adequately address how ocean warming, and the shrinking of the perennial ice cover, will alter deep-sea communities. The findings of Boetius et al. (2013) indicated that the benthic-pelagic coupling is more intense in the Arctic deep sea than expected and suggested strong alteration of this area in the future.

4.5 *Trends and pressures*

In a recent manuscript, Wassmann et al. (2011) reviewed the evidence reported in the scientific literature as of mid-2009 on whether – and how – climate change has already caused clearly discernible changes in marine Arctic ecosystems. In general,

they found that most reports concerned marine mammals, particularly polar bears, and fish, whereas the number of well-documented changes in planktonic and benthic systems was surprisingly low. Quantitative data on abundance and distribution are still generally lacking, and particularly few footprints of climate change have been reported from particularly remote and difficult-to-access regions, such as the wide Siberian shelf and the central Arctic Ocean, due to the limited research effort made in these environments. Wassmann et al. (2011) concluded that despite the alarming nature of climate change and its strong potential effects in the Arctic Ocean, the amount of reliable data on – as well as the research effort evaluating – the impacts of climate change in this region is rather limited. However, during a 30-year period (1980–2010), featuring a gradually increasing seawater temperature and decreasing sea-ice cover in Svalbard, Kortsch et al. (2012) documented rapid and extensive structural changes in the rocky-bottom communities of two Arctic fjords. They observed a reorganization of the benthic communities, led by an abrupt increase in macroalgal cover.

Because data on the effects of climate change on Arctic benthic fauna are limited, it is not yet possible to make sound predictions on trends and pressures on a quantitative level. However, some reports exist on general trends related to climate-change effects. Based on the available evidence of recent and on-going changes in Arctic systems, Wassmann et al. (2011) forecast that the ecological responses to climate change will encompass range shifts and changes in abundance, growth/condition, behaviour/phenology, as well as community/regime shifts, all of which will inevitably have a strong influence on regional and temporal patterns in diversity. In their attempt to predict possible changes in the diversity patterns of coastal benthic fauna in response to climate change, Weslawski et al. (2011) hypothesized that, in areas that are little influenced by advected waters, such as the Siberian shores and the coasts of the Canadian Archipelago, the local Arctic communities are exposed to increasing ocean temperature, decreasing salinity and a reduction in ice cover, with unpredictable effects on biodiversity. On the one hand, benthic species in Arctic fjords are exposed to increasing siltation from glacial meltwater and to decreasing salinities, which together may lead to habitat homogenization and a subsequent decrease in biodiversity. On the other hand, the innermost basins of Arctic fjords are able to maintain pockets of very cold, dense, saline water and thus may act as refugia for cold-water species.

Furthermore, all the current and anticipated climate-related changes in the Arctic are accompanied by an increase of anthropogenic activities, such as fisheries. These are known to impact marine ecosystems worldwide and have become an important environmental issue (Pauly et al. 1998; Link et al. 2010; Zhou et al. 2010). Particularly bottom trawling is assumed to be one of the most destructive fishing methods, causing severe damage to seafloor structure and benthic communities due to the passage of fishing gears and frequent by-catch (Jones 1992; Tillin et al. 2006; Thurstan et al. 2010). Using trawls is only feasible in largely ice-free areas, which are becoming more abundant. Trawling has recurrently been demonstrated to severely modify benthic communities (Watling and Norse 1998; Collie et al. 2000) and fish habitats (Auster 1998; Kaiser et al., 1999, Collie et al. 2000; Lindholm et al., 2001; Thrush et al., 2002; Moritz et al., 2015), primarily because of the reduction of

bottom complexity through the smoothening of sediments and removal of biogenic structures (Collie et al., 1997; Collie et al., 2000; Thrush et al., 1995; Thrush et al., 1998; Hall-Spencer and Moore, 2000). A number of field studies (Auster et al., 1995; Tupper and Boutillier, 1995a; Tupper and Boutillier, 1995b; Kaiser et al., 1999; Lindholm et al., 1999; Anderson and Gregory, 2000; Linehan, 2001; Stoner and Titgen, 2003) have related habitat complexity to survival of juvenile fishes. Cold-water corals, sponges and sea pens form biogenic structures that provide complex habitats for a diverse associated fauna. Although they are protected marine species (Fuller et al., 2008; FAO 2009), they are most vulnerable to the first passing of trawls. Areas protected from bottom trawling due to ice cover, thus remaining pristine and potentially inhabited by these vulnerable taxonomic groups, are mainly found north of 80° N in the Barents Sea, the Greenland Sea, and off northern Greenland (Jørgensen et al., accepted; Jørgensen et al., 2013; Boertmann and Mosbech, 2011; Tendal et al., 2013; Klitgaard and Tendal, 2004). Exploratory trawling fisheries will be carried out in a number of areas of the Canadian Arctic, such as Hudson Strait and northern Hudson Bay. Furthermore, there are shrimp pot fisheries, which are less damaging to benthic habitats, in Baffin Bay. There are currently no commercial fisheries in the Beaufort Sea. The United States has adopted a precautionary approach and placed a moratorium on fishing in the United States EEZ of the Arctic Ocean until further scientific information is available (Wilson and Ormseth, 2009). A similar strategy was recently adopted in the western Canadian Arctic with the signing of the Beaufort Sea Integrated Fisheries Management Framework (<http://news.gc.ca/web/article-en.do?nid=894639>), which outlines an agreement between the Government of Canada and Inuvialuit to co-manage marine mammal and fish resources in the Canadian Beaufort Sea.

5. Nekton (including demersal and holopelagic vertebrates and invertebrates)

General information on the Nekton

The nekton includes the bony fishes and the cartilaginous fishes (sharks and skate). Demersal fish species live and feed on or near the bottom, while pelagic fish live in open water. Brackish areas are usually inhabited by freshwater and anadromous fishes (whitefish, char, etc.). Cephalopod (a molluscan group consisting of, for example, octopus, squid, and cuttlefish) and shrimp species are also part of the nekton.

5.1 Status

Arctic fishes include two main groups – typically marine species which are confined to the marine environment, and anadromous species (fish migrating from salt water to spawn in fresh water such as salmonids and coregonids) which occur in freshwater and coastal areas, such as bays, inlets and estuaries, ascending rivers

from the sea for breeding. Depending on how widely the Arctic region is defined, total fish diversity ranges from 242 to 633 marine fish species (from 106 families) and 18-49 freshwater species that occur in marine/brackish waters (Chernova, 2011; Mecklenburg et al., 2011; Christiansen et al., 2013). Marine species comprise 88-90 per cent of total fish diversity. Species numbers in the Arctic are rather low, for both marine and freshwater species compared to the total number of fish species globally (approximately 16 and 12 thousand, respectively); 92 per cent of Arctic species are bony fishes; cartilaginous fishes (sharks and skate) comprise only 8 per cent. Most Arctic species are teleost (fishes with bony skeletons) fishes (92 per cent); cartilaginous (having a skeleton composed either entirely or mainly of cartilage) fishes (sharks and skates) comprise only 8 per cent (Lynghammar et al., 2013).

Fish diversity declines from the Arctic gateway regions near the Atlantic and Pacific Oceans, such as the Norwegian and Barents Seas (Atlantic) and Bering and Chukchi Seas (Pacific) to the farthest and most strictly Arctic seas. This diversity gradient is driven primarily by the presence of many boreal species in the Arctic gateway seas; such species cannot reproduce under the consistently colder conditions of the high Arctic. This spatial pattern holds in both the Eurasian and North American shelf seas (Karamushko, 2012; Christensen and Reist, 2013; Coad and Reist, 2004).

From a zoogeographic point of view, only 10.6 per cent of the bony fishes are considered as being strictly Arctic, and able to reproduce in waters below 0°C, whereas 72.2 per cent are boreal or Arctic-boreal species. Demersal fish species prevail in the group of strictly Arctic species (which includes 64 species or 14 per cent of the global marine fish fauna) (Chernova, 2011; Christensen and Reist, 2013).

Species composition and structure of fish communities vary in different depth zones and regions. Coastal brackish areas are usually inhabited by freshwater and anadromous fishes (whitefish, char, etc.). Fjords provide important habitats for fishes in some areas of the Arctic Seas, particularly along steep, bedrock-dominated coasts, such as are found in Greenland, Spitsbergen/Svalbard, Northern Norway, and the eastern parts of the Canadian Arctic Archipelago. Fjord fish faunas tend to be dominated numerically by the cryopelagic (of cold, deep oceanic waters) species (polar cod, Arctic cod), and by anadromous species. Fjord fish faunas include a wide cross-section of Arctic bottom-living (demersal) fishes (Christiansen et al., 2012), including diverse sculpins (Cottidae) and eelpouts (Zoarcidae) on sills and along fjord walls, as found in rocky areas of the continental shelves, and flatfish (Pleuronectidae) on sand and mud bottoms in fjord basins (Haedrich and Gagnon, 1991).

Fish communities of shelf seas are composed of common abundant pelagic (herring, capelin, polar cod, etc.) and demersal (gadoids, flatfish, sculpins, eelpouts, etc.) fishes.

Fish species composition in deeper waters in the Arctic Basin, as well as in many parts of the outer shelf regions, remains poorly investigated. Species richness is lower compared to coastal areas and especially shelf seas; the most abundant fishes are cryopelagic (e.g., polar cod, Arctic cod) (Andriashev et al., 1980; Melnikov and Chernova, 2013) or deepwater (e.g., snailfish) (Tsinovsky and Melnikov, 1980) fish. Cryopelagic species, which are ecologically dependent on sea ice, including the circumpolar polar cod *Boreogadus* and the ice cod *Arctogadus*, are important prey

species for many larger fish and marine mammals. Although the most abundant species are widely distributed in the Arctic and adjacent waters, the demersal fauna of the Arctic pseudo-abyss (the zone from 200 to 500–1,000 m in different parts of the ocean; characterized by a mixture of fauna) is represented mainly by endemic species (Chernova, 2011).

Commercial fisheries in the Arctic are located mainly in shelf seas where boreal species dominate. The most important areas are the Norwegian and Barents Sea in the Northeast Atlantic, Baffin Bay in the Northwest Atlantic, and in the Bering Sea in Pacific (Christiansen et al., 2014). In total 59 stocks are target species and 60 stocks are by-catch species taken by fisheries in Arctic and sub-Arctic areas. Most of the targeted species (50) are boreal species, six species are Arcto-boreal and three species are Arctic. The dominant families exploited in fisheries are herring (Clupeidae), capelin (Osmeridae), cod (Gadidae), flatfish (Pleuronectidae), and rockfish (called redfish in the Atlantic, Scorpaenidae). Wolf-fish (Anarhichadidae, an endemic Holarctic marine family) and grenadiers (Macrouridae) are important target species in the Eurasian Arctic, but in North America the effects of fisheries on these fish are dominantly through bycatch. High-latitude species in both families are considered to be endangered (Kearley, 2012). The landlocked Atlantic cod (*Gadus morhua*), found in meromictic (stratified lakes that consist of two layers that do not completely mix) Arctic lakes (Hardie and Hutchings, 2011), is considered to be of special concern.

The diversity of invertebrate nekton is much less than that of the fish, although some species are important prey for high-level predators (Gardiner and Dick, 2010). None are cryopelagic or estuarine, although some may be found in fjords. Nesis (2001) considered only seven cephalopod (a molluscan group consisting of, for example, octopus, squid, and cuttlefish) species to be resident in the Arctic. Although Arctic records of many other cephalopod species were added by Gardiner and Dick (2010) and Golikov et al. (2012), the only species that may be Arctic endemics are poorly known benthic octopods in the Bering and Chukchi Seas. Even fewer shrimp species are known from the Arctic and almost all have been reported from the North Atlantic, North Pacific, or both. One species, *Hymenodora glacialis*, is a major component of the pelagic biomass in the deep basins (Auel and Hagen, 2002).

5.2 Trends and pressures

Fisheries affect mainly the traditional marine target fish in the shelf seas located in the narrow Arctic to boreal regions of the Atlantic and Pacific Oceans (e.g., the Barents Sea and Bering Sea), and their effects are generally lower in other seas (e.g., the Laptev Sea and East Siberian Sea). But with further warming, fisheries areas are expected to shift into previously unfished Arctic regions where they will affect strictly Arctic fish communities (Christiansen et al., 2014). In coastal areas a few species, predominantly freshwater and anadromous, are harvested by indigenous peoples, but these catches are generally much lower than those of commercial fisheries. Furthermore, fisheries for anadromous species rarely involve mobile gear, which poses the greatest risk of causing extensive habitat damage in previously

unfished areas if used in ways that contact habitat features (e.g., Anderson and Clarke, 2003; Rice et al., 2006).

Under continuous ocean warming conditions, shifts of native species and new appearances of warm-water species may result in changes to fish community structure and subsequently to trophic pathways, depending on the sensitivity and adaptive capacity of the affected species (Hollowed et al. 2013). Higher water temperatures may cause an increase in the abundance and proportion of boreal species in the Arctic community. The deep Central Basin will probably be affected less than the shallower shelf seas of the Arctic, as most abundant boreal species are demersal or neritic (the relatively shallow part of the ocean above the drop-off of the continental shelf, approximately 200 m in depth) and such species are not likely to be found in areas deeper than 800-1000 m (Dolgov and Karsakov, 2011).

Occasional appearances of new species have been observed in the Arctic for decades, but these are apparently becoming more frequent. In 1950s, pink salmon was introduced from the Pacific to the Barents and White Seas (Atlas of Russian freshwater fishes, 2002). Norwegian pollock *Theragra finnmarchica* has been known in the Barents Sea since the 1950s (Christiansen et al., 2005; Privalikhin and Norvillo, 2010), but it is now considered to be a junior synonym of the Pacific walleye pollock *Gadus chalcogrammus* (Ursvik et al., 2007; Byrkjedal et al., 2008), reflecting the possibility of recent connections between Pacific and Atlantic waters across the Arctic. Range expansion of boreal species into the Arctic as ocean temperatures rise, has been observed both in the Eurasian Arctic (Christiansen et al. 2013) and in the North American Arctic, specifically in the Canadian Beaufort Sea (Mueter et al. 2013). If commercial fishing activities expand northward following these species, more bycatch may occur of endemic Arctic fish species that were previously unexploited and relatively unperturbed. In southern Newfoundland and Norwegian fjords, mesopelagic fish, especially the Myctophid (Lanternfish) *Benthoosema glaciale* and the sternoptychid (small deep-sea ray-finned fish of the stomiiform family Sternoptychidae) *Maurolicus muelleri*, are important elements. These cold-water fish, in places very abundant on the high seas, are very likely to move from the sub-Arctic to the full Arctic as ice retreats.

Although some high-latitude areas have high planktonic productivity and high fish production, e.g., the Barents Sea and Bering Sea, many strictly Arctic Seas have limited primary productivity due to ice cover, lack of nutrient replenishment, etc. Most Arctic fish, similar to deep-sea fish, have adapted to these low-productivity conditions with life-history characteristics that cause them to be readily overfished, either as directly targeted species or as by-catch (Koslow et al., 2000; Roberts, 2002; Baker et al., 2009). The risk of rapid overexploitation is high for Arctic fish populations, as it already seems to be for Greenland halibut (*Reinhardtius hippoglossoides*) in the Western Atlantic. By contrast, the Barents Sea stock has grown over the last decade, when the fishery was closed completely at first but later reopened at a low intensity.

As with many other groups, evidence exists that invertebrate nekton species are spreading into the Arctic from lower latitudes, especially the North Atlantic. Indeed, Hamilton et al. (2003) reported that fisheries in western Greenland have shifted to the northern shrimp, *Pandalis borealis*, a North Atlantic species also fished in the

Barents Sea (Standal, 2003). Furthermore, the presence of foraging schools of ommastrephid squid (Golikov et al., 2012) could indicate an important shift in the pelagic food web of the Arctic.

6. Mammals

General information on the marine mammals

Seals, together with toothed (killer whales, sperm whales, dolphins) and baleen (bowheads, blue whale) whales are part of the marine mammals.

6.1 Status

Thirty-five species of marine mammals are known to be present in Arctic waters. Seven of these (narwhal, beluga, bowhead whale, ringed seal, bearded seal, walrus, and polar bear) inhabit the Arctic year-round and are dependent upon sea ice for at least part of the year. Four additional species (spotted seal, ribbon seal, harp seal, and hooded seal) use sea ice for pupping in the winter and spring, but range widely in open waters of the Arctic and sub-Arctic the rest of the year. These eleven species of marine mammals are ice-dependent for at least some of their annual cycle; their reproduction, moulting, resting and/or feeding behaviour are closely linked to the presence of sea ice.

Another 24 marine mammal species occur in low Arctic waters or seasonally migrate to the Arctic to feed, including four species of pinnipeds, nineteen species of cetaceans, and a carnivore, the sea otter. The northern fur seal and Steller sea lion are found in the Okhotsk and Bering Seas; the gray seal is found in the Atlantic Arctic, and the harbour seal in Arctic waters of both the Atlantic and Pacific. Nineteen species of cetaceans use Arctic waters seasonally, including: the North Pacific right whale and gray whale that are confined to the Pacific Arctic; the North Atlantic right whale in Arctic waters near Greenland; the blue whale, fin whale, sei whale, minke whale, and humpback whale in both Pacific and Atlantic Arctic waters during summer; the sperm whale in low Arctic waters; Baird's beaked whale, Stejneger's beaked whale and Cuvier's beaked whale in the low Arctic waters of the Pacific; and the northern bottlenose whale in the low Arctic waters of the Atlantic. Delphinids that are present in the Arctic during summer include: killer whale, white-beaked dolphin, long-finned pilot whale and Atlantic white-sided dolphin. Dall's porpoise occur in low Arctic waters of the Pacific, and harbour porpoise in low Arctic waters of both the Atlantic and Pacific. These species occur in Arctic waters primarily to feed, based on the high seasonal productivity.

6.2 Trends

There is a history spanning several centuries of commercial whaling and seal hunting in the Arctic. In some cases, over-harvesting has reduced Arctic marine mammal populations to low numbers and contracted their ranges. Two of the three hooded seal populations were subjected to intense commercial hunting over the past two centuries. In the East Greenland Sea a substantial decrease in hooded seal abundance took place between the 1940s and 1980s (ICES, 2008), and recent surveys suggest that a downward trend continues. Regulation of commercial harvests has led to stabilization or recovery of some other marine mammal populations. All bowhead whale populations were severely depleted by commercial whaling, which began in the Atlantic in the 17th century (Ross, 1993). The global bowhead population now appears to be increasing, and the Bering-Chukchi-Beaufort subpopulation has recovered to close to its pre-whaling level. Indigenous harvesting of Arctic marine mammals also has a long history, and indigenous peoples have strong cultural and economic ties to marine mammals. In most cases the subsistence harvest is not a factor affecting marine mammal populations; however, a sharp decline of the Cook Inlet beluga population occurred in the 1990s and is attributed to subsistence overharvesting (Mahoney and Shelden, 2000); and they remain critically endangered.

Assessing Arctic marine mammal populations is challenging because of the difficulty of working in this region and the large seasonal ranges of many of these animals. Documenting changes in the abundance and distribution of marine mammals requires study on long time-scales. For the eleven ice-dependent marine mammal species, population trends are discussed here to illustrate the state of our knowledge. Trends in abundance are unavailable for most beluga sub-populations, but three subpopulations are known to be declining: the Cook Inlet (Hobbs et al., 2012), the eastern Hudson Bay (Gosselin et al., 2009), and the White Sea (Burdin et al., 2009). Although population estimates are available for most narwhal stocks (Heide-Jørgensen et al., 2010; Richard et al., 2010), they are not adequate to establish population trends. The Bering-Chukchi-Beaufort population of bowhead whales has increased since the late 1970s (George et al., 2004), and bowhead whales in West Greenland have increased since 2000 (Wiig et al., 2011), whereas trends in the bowhead subpopulations in the Svalbard-Barents Sea and the Sea of Okhotsk are unknown. Population trends for ringed seals are unknown, yet ringed seal density estimates in western Hudson Bay show an approximate 10-year cycle of fluctuation (Ferguson and Young, 2011). Walrus populations in West Greenland and the North Water have been in steady decline, whereas the population in East Greenland has been increasing (Witting and Born, 2005). Walrus numbers at Svalbard have increased slowly during 1993-2006 (Lydersen et al., 2008). Pacific Walrus populations recovered from a depleted state to historical high levels in the 1980s (Fay et al., 1997). Data are insufficient to estimate trends for spotted seals, ribbon seals and bearded seals. Harp seal birth rates in the White Sea stock have experienced significant declines since 2004 (Chernook and Boltnev, 2008). Recent models (ICES, 2008) revealed that since about 1970, the population of harp seals in East Greenland increased in size from its earlier depleted state. There was a moderate increase in the NW Atlantic hooded seal population between the mid-

1980s and 2005 (Hammill and Stenson, 2007), but the NE Atlantic hooded seal population has declined by 85-90 per cent over the last 40-60 years (Øigård et al., 2010). For nineteen polar bear subpopulations, seven are declining, four are stable, one is increasing, and insufficient data are available to determine a trend for seven subpopulations (Obbard et al., 2010). The sea otter is believed to have undergone a population decline exceeding 50 per cent over the past 30 years (Estes et al., 2005).

6.3 Pressures

Reductions in sea ice represent an on-going threat to marine mammals in the Arctic. Recent sea ice declines are well documented (Stroeve et al., 2012), and modelling predicts that the Arctic may be ice-free in summer within three decades (Wang and Overland, 2012). These reductions in sea ice are forcing ice-dependent marine mammals, such as polar bears, seals and walrus, to modify their feeding, reproduction and resting behaviour and locations. Pacific walrus have begun hauling out on land in the summer due to loss of annual Arctic sea ice and the summer retreat of the pack ice beyond the continental shelf (Garlich-Miller et al., 2011). Early sea-ice melt and longer open-water periods cause increased primary production in the Arctic (Arrigo and van Dijken, 2011), but are likely to decrease nutrient fluxes to the seafloor. As a result, walrus, bearded seals, and other marine mammals specializing in benthic feeding may experience reductions in prey availability (Bluhm and Gradinger, 2008).

The Arctic is also experiencing more human maritime activity, primarily related to hydrocarbon and mineral development and the opening of shipping routes. These changes bring risks for marine mammals of direct mortality, displacement from critical habitats, noise disturbance, and increased exposure to hunting. Arctic marine mammals also have high levels of contaminants (Norstrom and Muir, 1994), notably organo-chlorines (an organic compound containing at least one covalently bounded atom of chlorine) and heavy metals, as a result of the presence of these substances in the Arctic food web. Little evidence exists of demographic effects in wild marine mammals, but the need is growing to understand the origins of pollutants, and to coordinate efforts to reduce them at their source.

7. Marine birds

General information on the marine birds

Marine birds are adapted for the marine environment. Most species nest in colonies. Many undertake long annual migrations. Ducks, goose, auks (such as guillemots), loon, gulls, scoters, jaegers/skuas, terns, are all part of the marine birds.

7.1 Status

Arctic waters are host in summer to many millions of marine birds which come to nest. Unlike many animal groups, marine birds are more diverse and abundant in cold seas than they are in warm ones (Gaston, 2004). In the Northern Hemisphere, the highest breeding densities of seabirds occur in Arctic waters (Cairns et al., 2008). Forty-four species of seabirds, ten sea ducks (eiders and scoters) and one marine goose (brant) are listed by Ganter and Gaston (2013) as breeding in the Arctic, of which 23 species of seabirds, seven sea ducks and the brant occur in the high Arctic, with most being endemic to the region. The majority of Arctic marine birds are members of the order Charadriiformes (34 species), including four endemic genera, all containing only one immediately subordinate taxon (little auk, ivory gull, Sabine's gull, Ross's gull). Nineteen species are circumpolar, breeding in Canada, Alaska and over most of the Russian Arctic, whereas 11 occur only in the Atlantic basin (East Canada-Svalbard) and 14 in the Pacific basin (East Siberia-Yukon). Four species of sea ducks, one loon, one gull and one auk are considered to be vulnerable, near-threatened or endangered by Birdlife/IUCN (IUCN, 2012).

Most Arctic marine birds are migrants, occurring in Arctic waters only in summer, and moving to boreal or warmer waters, or in some cases to the Southern Hemisphere, in winter (Newton, 2007). Only two species of gull (Ross's and ivory), two auks (black guillemot and thick-billed murre/Brunnich's guillemot) and the four species of eider occur in Arctic waters throughout the year. The extent of migratory behaviour means that the population sizes and trends of many Arctic marine birds are potentially affected by events on their wintering ranges outside the Arctic (Ganter and Gaston, 2013).

Scoters, jaegers/skuas, some terns and some gulls occur mainly in terrestrial or freshwater habitats while breeding, but make use of marine waters while in passage, and, in the case of scoters, while moulting. Other marine birds, although feeding at sea, must all visit land to breed, so that all have a presence in the coastal zone in summer. The vast majority feed in shelf waters, although some may also feed away from the continental shelf. The most numerous birds making use of Arctic marine waters in summer are the northern fulmar, black-legged kittiwake, thick-billed murre, and little auk, all of which have world populations centred in the Arctic and numbering more than 10 million individuals (Ganter and Gaston, 2013). All these species make use of pelagic habitats. The number of seabirds making use of the central Arctic Ocean is small, although this is a major post-breeding dispersal area for Ross's Gull (Hjort et al., 1997).

Some Arctic marine bird populations provide valuable subsistence resources in the Arctic. Eiders, or their eggs and down, are harvested throughout the region and they are important for traditional food and lifestyle, not only in many Arctic communities, but also in SE Canada and the Baltic region (Merkel and Barry, 2008). In some countries, especially Iceland, down-feather collection constitutes a significant commercial industry (Bédard et al., 2008). Auks are also harvested by native peoples in Alaska and Canada.

7.2 Trends

Most Arctic seabird populations for which reliable information is available have shown negative trends in recent years. These current trends are superimposed on a situation where several important populations were substantially depressed by anthropogenic mortality, compared with numbers in the first half of the 20th century (Ganter and Gaston, 2013).

Some evidence exists for the recent northward spread of predominantly temperate or low Arctic species: e.g., glaucous-winged gull (Winker et al., 2002) in the Bering Sea, horned puffin in the Beaufort Sea (Moline et al., 2008), great skua in Svalbard (Anker-Nilssen et al., 2000; Krasnov and Lorentsen, 2000) and lesser black-backed gull in Greenland (Boertmann, 2008). At the same time, evidence exists of a retreat for at least one high Arctic species: the range of the ivory gull has contracted in Canada; most colonies in the southern part of the Canadian range are deserted, whereas numbers have remained stable farther north (Environment Canada, 2010). Southern colonies of ivory gull are also decreasing in Greenland (Gilg et al., 2009b).

Black-legged kittiwake, an abundant species throughout circumpolar Arctic waters, has shown significant population declines throughout almost the entire Atlantic sector of the Arctic, especially around the Barents Sea (Barrett et al., 2006), in Iceland (Garðarsson, 2006) and in West Greenland (Labansen et al., 2010). Thick-billed murre populations have shown downward trends over much of their range in the past thirty years. The population of thick-billed murre in central West Greenland is much lower than it was in the early 20th century, as a result of heavy harvesting of adults at colonies (Evans and Kampp, 1991; Kampp et al., 1994) and shows no sign of recovery (K. Kampp and F. Merkel, pers. comm.). Similarly, numbers in Novaya Zemlya are considerably lower than in the early 20th century: down from two million to one million birds (Bakken and Pokrovskaya, 2000). In Svalbard, numbers of thick-billed murre were thought to be stable up to the 1990s, but they have since decreased, especially in the southern part of the archipelago (CAFF Circumpolar Seabird Working Group, unpubl.). In Iceland, numbers of thick-billed murre decreased at 7 per cent per year between 1983 and 1985 and 2005-2008, whereas numbers of common murre and Atlantic puffins decreased between 1999-2005 after modest increases earlier (Garðarsson, 2006; Garðarsson, 2009).

7.3 Pressures

Eider populations declined in the 1980s and 1990s in Alaska, Canada, Greenland and Russia; in some cases because of human disturbances, excessive harvest of eggs and birds, together with severe climatic events (Robertson and Gilchrist, 1998; Suydam et al., 2000; Merkel 2004a). The current trend of common eider populations varies, but at least some populations in Alaska, Canada and Greenland are now recovering with improved harvest management (Chaulk et al., 2005; Gilliland et al., 2009; Merkel, 2010). Breeding populations in the Barents Sea region appear stable (Bustnes and Tertitski, 2000). A recent outbreak (2005-present) of avian cholera in the East Canadian Arctic reversed a population increase and reduced the population of a large colony by 30 per cent in just three years (Buttler, 2009). Bycatch in

fisheries gillnets is also a significant problem in some areas (Bustnes and Tertitski, 2000; Merkel, 2004b; Merkel, 2011) and may be a more widespread concern.

Some recent changes in the status of Arctic seabirds have been linked with climate changes, mostly ascribed to causes operating through the food chain (Durant et al., 2004; Durant et al., 2006; Sandvik et al., 2005; Irons et al., 2008), but direct effects have been documented in a few cases: White et al. (2011) showed that expansion of the great cormorant population in central West Greenland may be related to increased sea-surface temperature. Several potential causes of the decline of ivory gulls in Canada have been identified: mortality from hunting of adults in Greenland (Stenhouse et al., 2004), high levels of mercury in eggs (Braune et al., 2006) and changes in ice conditions (Gilchrist et al., 2008; Environment Canada, 2010). In Hudson Bay in recent years a combination of warm summer weather and earlier emergence by mosquitoes caused the death or reproductive failure among thick-billed murrets (Gaston et al., 2002). In addition, polar bears, coming ashore earlier than usual, ate many eggs, chicks and adults of murrets and common eiders, leading to complete reproductive failure at some colonies (Gaston and Elliott, 2013; Iverson et al., 2014). Such mortality has increased sharply over the past three decades.

Substantial research has been carried out on concentrations and trends of contaminants in Arctic marine birds, especially organohaline compounds and heavy metals (Braune et al., 2001; Helgason et al., 2008; Letcher et al., 2010). Very high levels of mercury have been found in the eggs of ivory gulls from Canada (Braune et al., 2006) and high levels of organohaline compounds in those from Svalbard (Miljeteig et al., 2009). High organohaline concentrations occur also in glaucous gulls from Svalbard (Bustnes et al., 2003; Bustnes et al., 2004), perhaps causing mortality in some cases (Gabrielsen et al., 1995; Sagerup et al., 2009). These species scavenge marine mammal carcasses, which places them high up the food chain and hence they become subjected to an increasing concentration of a substance, such as a toxic chemical, in the tissues of organisms at successively higher levels in a food chain (biomagnifications). As a result of biomagnification, organisms at the top of the food chain generally suffer greater harm from a persistent toxin or pollutant than those at lower levels. The extension of offshore oil and gas exploitation and transport in and through Arctic waters poses a potential threat to all marine birds (Meltofte et al., 2013), especially auks and sea ducks, which are among the birds most vulnerable to mortality from oil spills (Clark, 1984). These two groups, along with cormorants, are also very susceptible to drowning in gill nets (Tasker et al., 2000). If, as expected, a general retreat of Arctic sea ice allows an extension of hydrocarbon exploitation, shipping and fisheries in Arctic waters, then special care will be required to safeguard populations of these birds. Moreover, changes in the timing of the open-water season are affecting the timing of seasonal events in marine ecosystems, and this is affecting the optimal timing of breeding for marine birds, especially in low Arctic areas (Gaston et al., 2009). Changes in the distributions of predators and parasites have also been noted, and these may have important consequences for Arctic seabirds (Gaston and Elliott, 2013). Because of the number of Arctic endemic marine bird taxa, the decline of Arctic marine birds presages a significant loss of global biodiversity.

8. Socioeconomic Aspects

8.1 *Biodiversity and ecosystem services in the Arctic*

Biodiversity, whether it is functional, genetic or species-based, plays a role in fundamental processes of nature, i.e., so-called ecosystem processes or intermediate ecosystem services¹, which feed into all final ecosystem services, whether these are provisioning, regulating or cultural services. These latter services contribute directly to human wellbeing, and these benefits can often be valued in economic terms.

Although the ecosystem processes/intermediate services of biodiversity may be essential for most final services, their values as such cannot be added to the value of benefits from final services, as this would imply a double counting. However, it is important to ascertain the significance of biodiversity as an intermediate service in order to ensure that human actions do not limit these services to such a degree that a loss in final services occurs, and that the value of this loss exceeds the value from the human actions that led to them. And despite the remote nature of the Arctic, ecosystem processes related to biodiversity taking place there may provide important services far removed in space and time.

Biodiversity may also be a final service and, for example, it may be included in cultural services, in the sense that humans value biodiversity directly. The Arctic is a sparsely populated part of the world, but indigenous and commercial uses related to Arctic biodiversity are nevertheless present. Furthermore, humans who may never set foot in the Arctic may value the existence of Arctic biodiversity, hence the services in the Arctic may have greater importance than what immediately meets the eye.

In the following we focus on ecosystem services from Arctic biodiversity being affected by climate change pressures, where these involve services to the ecosystem (i.e., ecosystem processes or intermediate services) and services to humans (provisioning, regulating or cultural services).

8.2 *Services to ecosystems being affected*

Climate change will make species of boreal ecosystems move into what are now sub-Arctic areas, transforming these into boreal ecosystems, whereas sub-Arctic ecosystems will move into more Arctic areas. Consequently, Arctic ecosystems will remain in smaller and possibly more fragmented areas such as cold, dense, saline water basins (inner fjords and the abyss) and may thus act as important refugia for cold-water species.

¹ The Millennium Ecosystem Assessment (2005) coined the expression *Supporting services*, which was later referred to as *Ecosystem processes or Intermediate services* by the UK National Ecosystem Assessment (2011) and others.

In a spatial context, Arctic biodiversity will therefore decline. In some areas, Arctic biodiversity will disappear, but species of boreal ecosystems will increasingly move northwards, increasing boreal biodiversity in these areas. However, the absolute biodiversity may increase, decrease or remain unchanged, due to the combination of extinction and immigration. Increased biodiversity may especially be the case in the shallow marginal seas of the Arctic, but also in a presumed interim period, where both Arctic and boreal species co-exist. This may temporarily affect ecosystem processes/intermediate services. The biodiversity dynamics depend on a number of factors, such as immigration, extinctions, possible hybridization, competitive pressures and new pathogens/parasites, as well as human pressures (harvesting, bycatch of Arctic species in targeted harvests of boreal species, bioaccumulation of pollution, stress from ship traffic and oil exploitation, harvesting of eggs and birds, ocean acidification).

As the ice cover declines, the Arctic biodiversity comes under pressure, and some ecosystem services may be lost due to smaller and possibly fragmented suitable areas. This is particularly the case for species that have parts of their life cycle/history strategy dependent on ice (e.g., seals nursing on ice). A loss of ecosystem processes/intermediate services involving failures in reproduction, predator-prey interactions and habitat composition is then likely.

8.3 Services to humans being affected

On current sub-Arctic shelf areas, where boreal species will become more prominent, ecosystem services, such as those related to fisheries, may increase. This may be advantageous for human coastal communities, indigenous and otherwise, by increasing or securing values connected to benefits of cultural and provisioning services from fisheries. Off-shelf areas may not give increased ecosystem services, despite ice-cover decline, due to stratification inhibiting the mixing of the water masses and thereby limiting the nutrients needed for productive ecosystems (Wassmann, 2011). However, great uncertainty remains regarding these future processes.

Ice decline will have consequences for Arctic biodiversity. This is particularly the case for species that spend part of their life cycle on land and part on ice (e.g., polar bears, seals and walrus). These species supply provisioning and cultural services for commercial and indigenous users in the Arctic, and cultural services for people worldwide due to existence values.

IPCC (2014) identifies a number of climatic change effects that are expected to affect directly the way of life of Arctic indigenous peoples. The indirect effects via marine biodiversity change are more uncertain. Yet as mentioned above, both positive effects regarding fisheries and negative effects in relation to marine mammals may be possible. Where, how, what, and when changes may arise are unsure, and point towards significant knowledge gaps with regard to socio-economic consequences of climate change for indigenous peoples.

8.4 Management

The loss or reduction of services from Arctic ecosystems points to the need to protect the remaining Arctic and Arctic ice areas against activities that might reduce biodiversity (pollution, diseases/parasites, physical and vocal stress); e.g., securing protection in relation to activities of exploitation (fish, oil, minerals, tourism) in ice areas, and transport routes through the Arctic and Arctic ice.

The final service losses likewise point to the need for adaptive and ecosystem based management efforts to limit negative effects of existing and potential human use. This involves sustainable management of current use of resources, and restrictions on aggregating anthropogenic effects in relation to vulnerable Arctic ecosystems and species. It is clear that we will discover and develop ecosystem services in the future that we are not aware of today. Option values related to these services, for example from bioprospecting, underline the need to secure ecosystem services for the future.

The Southern Ocean is the common denomination given to the southern extrema of the Indian, Pacific and Atlantic Oceans, extending southwards to the Antarctic Continent. Its main oceanographic feature, the Antarctic Circumpolar Current (ACC), is the world's only global current, flowing eastwards around Antarctica in a closed circulation with its flow unimpeded by continents. The ACC is today the largest ocean current, and the major means of exchange of water between oceans; it is believed to be the cause of the development of Antarctic continental glaciation by reducing meridional heat transport across the Southern Ocean (e.g., Kennett, 1977; Barker et al., 2007). The formation of eddies in the Antarctic Circumpolar Current has a significant role in the distribution of plankton and in the warming observed in the Southern Ocean.

As with the ACC, the westward-flowing Antarctic Coastal Current, or East Wind Drift (EWD), is wind-driven. These two current systems are connected by a series of gyres and retroflexions (e.g., gyres in the Prydz Bay region, in the Weddell Sea, in the Bellingshausen Sea) (Figure 1).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. From Turner et al. (eds.), 2009. Schematic map of major currents south of 20°S (F = Front; C = Current; G = Gyre) (Rintoul et al., 2001); showing (i) the Polar Front and Sub-Antarctic Front, which are the major fronts of the Antarctic Circumpolar Current; (ii) other regional currents; (iii) the Weddell and Ross Sea Gyres; and (iv) depths shallower than 3,500m shaded (all from Rintoul et al., 2001). In orange are shown (a) the cyclonic circulation west of the Kerguelen Plateau, (b) the Australian-Antarctic Gyre (south of Australia), (c) the slope current, and the (d) cyclonic circulation in the Bellingshausen Sea, as suggested by recent modelling studies (Wang and Meredith, 2008), and observations – e.g., the eastern Weddell Gyre - Prydz Bay Gyre (Smith et al., 1984), westward flow through Princess Elizabeth Trough (Heywood et al., 1999), and circulation east of Kerguelen Plateau (McCartney and Donohue, 2007).

The circumpolarity of the circulation is the principal factor determining the development of circumpolar frontal zones associated with this system of currents (Orsi et al., 1995). The biogeographical importance of these fronts was recognized practically from the beginning of Antarctic research (Tate Regan, 1914); their approximate positions are shown in Figure 2.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. From Turner et al. (eds.), 2009. South (left) to north (right) section through the overturning circulation in the Southern Ocean. South-flowing products of deep convection in the North Atlantic are converted into upper-layer mode and intermediate waters and deeper bottom waters and returned northward. Marked are the positions of the main fronts (PF – Polar Front; SAF – Sub-Antarctic Front; and STF – Subtropical Front), and water masses (AABW – Antarctic Bottom Water; LCDW and UCDW, Lower and Upper Circumpolar Deep Waters; NADW – North Atlantic Deep Water; AAIW – Antarctic Intermediate Water and SAMW – Sub- Antarctic Mode Water) (from Speer et al., 2000, ©American Meteorological Society. Used with permission.). Note that as well as water moving north to south or *vice-versa*, it is also generally moving eastward (i.e., towards the observer in the case of this cross-section), except along the coast where coastal currents move water westward (away from the observer).

The ACC is usually considered to be the northern border of the Southern Ocean. As the ACC links the ocean basins of the Atlantic, Indian and Pacific Oceans, the waters carried in the ACC contain a mix of waters originating in different parts of the world. Water flows away from the ACC, to the north and to the south, where it becomes a primary source for the Antarctic Bottom Water. In the ACC the three oceans exchange heat, salinity and nutrients, playing an important role in the regulation of temperature and flow of the global conveyor belt. Along its course in the ACC, the water exchanges oxygen and carbon dioxide with the atmosphere while cooling; the resulting dense water sinks and transfers heat and gases into the deep ocean. These exchanges create water masses with different properties and distribution patterns which are responsible for water properties in all the world's oceans (Figure 3); see Turner et al. (eds.) (2009) for further information.

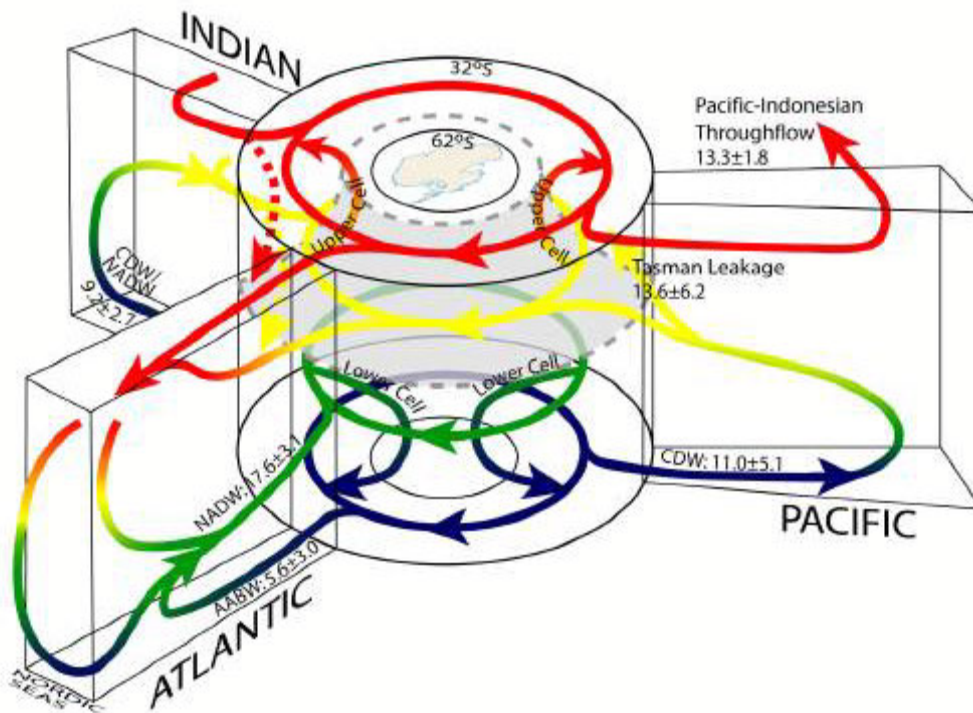

Figure 3. Model of the global ocean circulation, emphasizing the central role played by the Southern Ocean. NADW = North Atlantic Deep Water; CDW = Circumpolar Deep Water; AABW = Antarctic Bottom Water. Units are in Sverdrups ($1 \text{ Sv} = 10^6 \times \text{m}^3$ of water per second). The two primary overturning cells are the Upper Cell (red and yellow), and the Lower Cell (blue, green, yellow). The bottom water of the Lower Cell (blue) wells up and joins with the southward-flowing deep water (green or yellow), which connects with the upper cell (yellow and red). This demonstrates the global link between Southern Ocean convection and bottom water formation and convective processes in the Northern Hemisphere. From Lumpkin and Speer (2007; ©American Meteorological Society. Used with permission.) in Turner et al. (eds.), 2009.

About 50 per cent of the Southern Ocean is covered by ice in winter, decreasing to 10 per cent in summer. Ice cover has important effects both on climate and on the biota (e.g., Ainley et al., 2003). It is a defining structure in polar ecosystems. Antarctic sea ice is inhabited by prokaryotes, protists, algae, crustacea, worms (Schnack-Schiel et al., 1998), fish eggs and larvae (Vacchi et al., 2012), birds and seals (Ainley and DeMaster, 1990).

Overall, the Antarctic sea-ice cover has been increasing in the satellite records from 1978 to 2010 (Parkinson and Cavalieri, 2012; see Chapter 47), but modelling predicts a reduction of 33 per cent by the end of this century. This masks dramatic regional trends; declines in sea ice in the Bellingshausen Sea region have been matched by opposing increases in the Ross Sea (Maksym et al., 2012). Besides the seasonal sea ice, large portions of coastal waters are covered by permanent ice shelves. Ice shelves derive from land ice where glaciers or whole ice sheets flow towards the coastline and over the ocean surface (Trathan et al., 2013). Ice cover defines three biogeographic zones (Tréguer and Jacques, 1992): the northernmost part of the ACC, permanently ice free with high nutrient concentrations but low primary productivity

(see below); the region that is covered seasonally, where the movements of the ice margin significantly affect the cycle of primary production and zooplankton aggregations, and the sea below ice shelves where the fauna develop under unique oligotrophic conditions (Gutt et al., 2010). Of particular interest are the regions of contact between the sea-ice cover and the shelf ice, where regions of highly productive open-water areas develop (Comiso and Gordon, 1996; Smith and Comiso, 2008).

The present characteristics of the Antarctic were established at the time of the separation between Antarctica and South America, allowing the unimpeded flow of the ACC (Barker et al., 2007; Turner et al. (eds.), 2009) and the development of the Polar Front. Uncertainty exists with regard to the date of the opening, but it is widely accepted that it occurred about 34 million years ago in the Eocene/Oligocene limit (Barker et al., 2007).

From that time onwards, the oceans south of the Polar Front have been part of a single system comprising the basins of the Atlantic, Indian and Pacific Oceans and isolated from other shelf areas in the Southern Hemisphere. The Antarctic marine environment experienced a slow transition from warm water conditions to the present cold water system (from 15°C to 1.87°C) (Turner et al. (eds.), 2009). The result of evolution under these conditions is a highly specialized marine biota with high Antarctic endemism and little tolerance for warming (Bilyk and DeVries, 2011).

1. Primary Production

Research on Antarctic primary productivity started around 1840, the age of the pioneering expeditions to Antarctica. For some 100 years, most studies were of a qualitative nature and largely focused on net phytoplankton (>20 µm: diatoms, dinoflagellates, silicoflagellates, etc). The results of these investigations showed that phytoplankton distribution was linked to seasonality and latitude, with a fast and early growth in northern sectors and a southward shift of growth maxima as summer progresses.

A period of change started around 1950 with the development and application of new methods which involved a faster collection of quantitative data associated with the amount of biomass produced per unit of space and time. Such methods enabled estimating, for example, chlorophyll-a concentration as a proxy for actual phytoplankton biomass and primary productivity, and assimilation of dissolved inorganic carbon by phytoplankton as a proxy for the rate of photosynthetic production of organic matter in the euphotic zone. To date, these methods are the most widely used for estimating *in situ* primary productivity in Antarctic ecosystems at all scales, and at a global level as well.

More sophisticated techniques and equipment developed during the 1980s enabled quantifying fragile cells that are difficult to preserve. These improvements represented a substantial progress in the knowledge of newly identified taxa contributing to phytoplankton biomass, such as flagellates, and of some groups' capability of alternating their trophic strategies following the fluctuations of certain

environmental variables, such as nutrient and/or prey availability and light. Phytoplanktonic communities comprise at least three main size classes of algae: picoplankton (<2 µm), nanoplankton (2-20 µm) and microplankton (>20 µm). Blooms of microplanktonic and nanoplanktonic algae (e.g., diatoms, dinoflagellates, colonial and flagellated *Phaeocystis* cells) are mostly detected during the summer within the marginal ice zone (e.g., Buma et al., 1992; Olguín and Alder, 2011). However, little knowledge exists about the importance of mixotrophic groups, such as flagellates and dinoflagellates, as food for primary consumers (some of commercial importance) and their contribution to phytoplanktonic biomass (and chlorophyll-a levels) and primary productivity.

Finally, from 1990 on, many investigations on productivity have been largely based on data provided by satellites equipped with colour scanners. At present, ocean color remote sensing is our most effective tool for understanding ocean ecology and biogeochemistry at basin-to-global scales (Figure 4). Many of the algorithms used in satellite data processing and a number of predictive mathematical models employed at different ecological levels (fisheries, CO₂ dynamics, etc.) are based on *in situ* measurements which yield differing results depending on the methods used and are a cause of much current debate (Strutton et al., 2012).

At any scale, light and nutrients are the most crucial resources for phytoplankton growth. In addition, diverse physical, chemical and biological variables act as conditioning factors for phytoplankton development and biomass levels. For example, temperature, water column stability, advection, grazing, sinking, bottom topography, offshore distance, etc., usually lead to temporal and spatial variations in primary producers at different scales and also in primary productivity levels.

The overall distribution of phytoplankton biomass and primary production is associated with the position of frontal zones and water circulation resulting from the cyclonic circulation linked to the topography. This general scheme of distribution has been known since the first reports on Antarctic phytoplankton (Hardy and Gunther, 1935; Balech, 1968; El-Sayed, 1968a; 1968b; 1970). High local variability is superimposed on this general pattern as demonstrated by satellite information showing spots of very high chlorophyll concentration within areas of generally low concentration (El-Sayed and Hofmann, 1986).

Knox (2007) reviewed the levels reached by phytoplankton, chlorophyll and primary productivity in distinct Antarctic areas and showed the strong variability associated with different processes and sectors. In the case of Antarctic phytoplankton, variability is generally attributed to (a) extreme seasonal variability in solar radiation, (b) availability of iron (Fe), which is considered as a key limiting factor in the deep and open waters of the Southern Ocean, and (c) the extent, duration, and seasonality of sea ice and glacial discharge, which influence the life cycles of most Antarctic organisms (Ducklow et al., 2013). The annual retreat and melting of sea ice in spring causes the stratification of the upper ocean layer, thus activating the development of important phytoplankton blooms. The magnitude of these blooms is related to the winter extent of ice cover, which acts as a barrier to wind mixing (Ducklow et al., 2012; 2013).

Antarctic continental shelf regions have an annual productivity that ranges from 10 g C m⁻² to 200 g C m⁻²; the greatest rates occur in the Ross Sea and the western Antarctic Peninsula, but elevated productivity is found in nearly all coastal polynyas (Catalano et al., 2010; Smith et al., 2010).

Large variability in primary productivity was observed along a twelve-year time series (1995-2006; Palmer Long-Term Ecological Research). The average daily integrated primary productivity varied by an order of magnitude, from 250 C m⁻² d⁻¹ to 1100 mg C m⁻² d⁻¹, with an average of 745 mg C m⁻² d⁻¹. A marked onshore-offshore gradient from 1000 C m⁻² d⁻¹ to 100 mg C m⁻² d⁻¹ was found along the shelf with higher production rates inshore. Inter-annual regional variability ranged from 248 C m⁻² d⁻¹ to 1788 mg C m⁻² d⁻¹ (Vernet et al., 2008).

Satellite (SeaWiF) measurements of chlorophyll concentrations in the Southern Ocean from October 1997 through September 1998 reveal: (a) low-mean values (0.3 mg m⁻²- 0.4 mg m⁻²); (b) phytoplankton blooms and highest chlorophyll concentrations (>1.0 mg m⁻²) located in three areas: coastal waters above the continental shelf, the seasonally retreating sea ice, and the vicinity of the major fronts; (c) the SeaWiFS global chlorophyll algorithm works better than the Coastal Zone Color Scanner (CZCS); (d) based on the production model of Behrenfeld and Falkowski (1997), annual primary production south of 50°S was estimated in 2.9 Gt C yr⁻² (Moore and Abbott, 2000).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 4. From Strutton et al. (2012). Austral summer ocean pigment concentrations from the Coastal Zone Colour Scanner (CZCS). The data are available at 4 km and 9 km (this image) spatial resolution. The northern and southern solid lines represent the subtropical front and the polar front, respectively.

Marine food webs depend on primary productivity, which also contributes to the sequestration of carbon in the oceanic reservoir. In this region the models and observations for the global balance of CO₂ differ most in magnitude (Gruber et al., 2009). This disagreement highlights the importance of obtaining better estimates of all terms in the oceanic carbon budget, including primary productivity (Strutton et al., 2012).

In the seasonally ice-covered region, microalgae grow on sea ice. Their production is greatly exceeded by phytoplankton production in open waters, but their ecological role is significant. They constitute an important environment that provides refuge to cells and spores that will later seed blooms in open water (Lizotte, 2001) and provide food for ice-associated grazers, such as developmental stages of krill.

2. Zooplankton and Nekton

Multicellular animals in the water column are generally divided by size and swimming ability. This distinction is not always clear, however; some active swimmers may be quite small, whereas some large animals may be such poor swimmers that they are little more than drifters. Zooplankton species range from microscopic animals so small that the water is for them a very viscous environment, to large (sometimes very large) but slow-moving gelatinous animals from several evolutionary lineages. In addition to animals that are planktonic throughout their life cycles, zooplankton sometimes include eggs and larvae or, for some species, spawning stages of bottom-living (benthic) animals. The nekton include generally larger animals with swimming ability adequate to overcome movement by currents, e.g., primarily fish, shrimp, and cephalopods. The term nekton also encompasses diving air-breathers, including marine mammals, birds (e.g., penguins) and, in more temperate regions, reptiles; the first two groups are addressed in separate sections of this chapter.

Important for understanding zooplankton and especially for nekton is the distinction between the swimming animals that live on or closely associated with the bottom (i.e., demersal and benthopelagic) and those that spend their lives higher up in the water column and are not dependent on the bottom (pelagic). A further distinction in polar regions involves the species that are dependent, at least at some stage in their life, on sea ice (cryopelagic).

The overlap between the zooplankton and nekton that occurs in the smallest nekton (=micronekton) and large plankton (=megaplankton) is particularly important in the Southern Ocean. A unique characteristic of pelagic marine ecosystems is the alternating dominance as keystone grazers in the food webs by species from two very different evolutionary and ecological groups (Atkinson et al., 2004). These two groups are euphausiids, primarily the Antarctic Krill (*Euphausia superba*), and salps (especially *Salpa thompsoni*). The former are actively swimming shrimp-like crustaceans, the adults of which dominate the micronekton community, whereas the latter form “blooms” and colonial chains of gelatinous megaplankton.

Good reviews of current knowledge about zooplankton and nekton in the Southern Ocean have recently been published. These include several chapters in Knox (2007), products of the Census of Antarctic Marine Life (Gutt et al., 2010; DeBroyer et al. (ed.), 2011; Schiaparelli and Hopcroft (eds.), 2011 and papers within that volume), and recent summaries of national research programmes, particularly around the Antarctic Peninsula (e.g., Ducklow et al., 2007; Steinberg et al., 2012) and in the Ross Sea (Faranda et al. (eds.), 2000).

Because of their swarming behaviour, krill form large patches of extremely high abundance and biomass, which are targeted by many Antarctic predators, including fish, squid, birds and mammals (Knox, 2007). The patches are also targeted for harvesting by humans (Nicol et al., 2012). The commercial potential of krill has, in turn, stimulated studies of zooplankton and micronekton assemblages and pelagic ecology more generally around Antarctica, especially near the Peninsula and in the Ross Sea.

Salps, which are megaplankton with jelly-like bodies, are chordates more closely related to vertebrates than to true jellyfish. They have complex life cycles, including both sexual and asexual (budding) reproduction and alternating generations of solitary individuals and chain-like colonial aggregates. Because they are capable of asexual reproduction, population abundance can respond rapidly to favourable conditions, resulting in a “bloom” (i.e., very high abundance).

Because a developmental stage of krill is dependent on ice algae and therefore on the amount of sea-ice habitat during that stage in the krill life cycle, alternation between high abundances of krill and salps is related to the amount of sea ice during the previous winter (Loeb et al., 1997). This alternation has very important implications for food webs in the Southern Ocean, especially pelagic food webs, but for benthic food webs as well. Krill are the preferred prey of many mid-level Antarctic predators (Knox, 2007). Although many of them can also feed on salps, the food quality obtained from salps compared with the energy expended in feeding is much less than for krill. Therefore, krill swarms are very important to maintain population levels for many species in the Southern Ocean.

Other than salps and krill, the numerically dominant group of zooplankton is the copepod crustaceans. Copepods are also the most diverse group of zooplankton, with more than 70 species in the upper 100 m of the water column. Another important crustacean group is the amphipods, which may be free-swimming or associated as predators or commensals with gelatinous megaplankton.

Other important zooplankton groups, sometimes abundant although not diverse, include pteropod mollusks, pelagic polychaete worms, chaetognaths (arrow worms), larvaceans, and ostracods.

Because many Antarctic species develop directly in large eggs rather than as larvae hatching from many small eggs, benthic species that spend their early life history in the water column (meroplankton) make up a less important component of the zooplankton in the Southern Ocean than elsewhere, although larvae may be seasonally abundant in some coastal areas.

Among the nektonic fish, cephalopods, and shrimp, the fish are clearly dominant in diversity, abundance and biomass. Only about 300 fish species are found south of the South Polar Front; of these, slightly over 100 species are considered to be endemic to the Southern Ocean (Knox, 2007). Most of these fish species are closely associated with the bottom (demersal). The common demersal fish are dominated by a unique evolutionary group, the suborder Notothenioidei, referred to as Antarctic blennies or southern cod-icefish.

The few species of shrimp (Caridea, <10 species) are primarily demersal. Three species have been reported locally in high abundances (Gorny et al., 1992). Southern Ocean cephalopods include both pelagic squid and demersal octopods. The former includes a few species each in at least nine families. Although rarely collected in large numbers, squid are important prey for many fish, birds and mammals, indicating that current sampling methods are not representative. Some attain large sizes, including *Mesonychoteuthis hamiltoni*, one of the largest known invertebrates.

The octopods include one finned (Cirrata) species that can be locally very abundant (Vecchione et al., 1998) and a surprising diversity of incirrate species. Whereas the incirrate fauna were long thought to comprise a few variable species, careful examination of both morphology and DNA sequences has shown the species to number at least two dozen, including one very large species, *Megaleledone setebos* (the giant Antarctic octopus). One genus, *Pareledone*, is especially diverse and is an example of both circumpolar distributions and “ring evolution” of cryptic species around the Antarctic continent (Allcock et al., 2011). The incirrate octopods have also been shown to be both an evolutionary source of species for the world’s deep oceans (Strugnell et al., 2008) and to have colonized the Southern Ocean from deep oceans elsewhere (Strugnell et al., 2011).

In general, both zooplankton and nekton include some nearshore species that are circumpolar and others for which distribution appears to be regionally limited. Some of the former, however, might include complexes of cryptic species with limited distributions. The regional patterns are strongest closest to shore. For both fully pelagic and demersal animals, a gradient exists from coastal through continental shelf and slope to fully oceanic assemblages. Also, species interactions occur across the Polar Front where some subpolar zooplankton and nekton species intrude into polar waters and the ranges of some Southern Ocean species extend into lower latitudes.

In spite of the extreme polar light regime, pelagic animals of the Southern Ocean undertake vertical migrations as are well known from other oceans. Daily variability in light intensity penetrates into the upper waters and diel vertical migrations by pelagic zooplankton and nekton follow this signal. Of course the seasonal variability in light is extreme, resulting from both the angle of solar incidence and seasonal expansion and contraction of sea ice. This seasonal variability results in extensive changes in the vertical distribution of many pelagic species, usually manifested by different life-history stages occupying different depths in the water (ontogenic vertical migration). In addition to the importance (e.g., role in the food web, development through life-history stages, etc.) of these vertical migrations to the individual species, they are also important in understanding the flow of biomass, nutrients, carbon, etc., between the surface and deeper waters and ultimately to the benthic environment.

Another important association for pelagic animals in the Southern Ocean is with ice, in the form of sea ice and icebergs. As mentioned above, some stages of some species, notably krill, are dependent on the protection of the physical ice structure and on the food that grows on sea ice (Thomas and Dieckmann, 2003). Furthermore, it has recently been demonstrated that drifting icebergs are “hotspots” of pelagic productivity and biomass (Smith et al., 2007; Vernet et al., 2012). As regards prokaryotic assemblages, a very high abundance has been reported for the bottom layer of sea ice (Archer et al., 1996; Delille and Rosiers, 1996) and the platelet ice (Guglielmo et al., 2000; Riaux-Gobin et al., 2000).

3. Microbes

The microbial community plays a pivotal role in the pelagic food web of the Southern Ocean; it controls many processes, including primary production, turnover of biogenic elements, degradation of organic matter and mineralization of xenobiotics and pollutants (Azam et al., 1991; Azzaro et al., 2006; Fuhrman and Azam, 1980; Karl, 1993; Manganello et al., 2009; Smith et al., 2010; Yakimov et al., 2003). Prokaryotic abundance and activity shift significantly over the annual cycle as sea ice melts and phytoplankton blooms develop (Ducklow et al., 2001; Pearce et al., 2007). Microbial food chains develop even in regions where large euphausiids are abundant. These chains involve small metazoans and predominate in the northern open waters (Atkinson et al., 2012) with multiple trophic levels (copepods, chaetognaths, amphipods, myctophids, fish and birds) in contrast with the classical short chain of diatoms – krill – vertebrates. Marine microbes exhibit a diversity which also depends on the timing, location and sampling method (Pearce 2008; Murray et al., 1998); research devoted to this group is increasing, using genetic and molecular approaches in Antarctic surface (Murray and Grzyski, 2007) and deep waters (Moreira et al., 2004). Studies on diversity of bacterioplankton suggest that the diversity seems to rival that found in other ocean systems, although many polar phylotypes host a distinct biogeographic signal (Pommier et al., 2005). The Archaea (DeLong et al., 1994) have a distinct seasonal cycle in which Marine Group I, the Crenarchaeota, are abundant in late winter in surface Antarctic waters (Murray et al., 1998; Church et al., 2003; Murray and Grzyski, 2007). Southern Ocean environmental genomic studies focusing on identifying organisms and metabolic capabilities of the microbial community are limited (Béja et al., 2002; Grzyski et al., 2006). Grzyski et al. (2012) found that the most noteworthy change in the bacterioplanktonic community in nearshore surface waters of the Antarctic Peninsula was the presence of chemolithoautotrophic organisms in winter and their virtual absence in summer when incident solar irradiance is at a maximum and primary productivity is high. If chemolithoautotrophy is widespread in the Southern Ocean in winter, this process may be a previously unidentified carbon sink. Research trends point to microbial diversity in marine invertebrates (Webster et al., 2004; Webster and Bourne, 2007; Riesenfeld et al., 2008).

4. Benthos

Antarctic shelves are very deep, a process that developed from the glaciation that began with the isolation of the Southern Oceans because of the weight of the continent's massive ice sheet. Due to the isostatic depression of the Antarctic continent by the extant ice sheets, the features of Antarctic continental margins are distinct from those of the rest of the ocean and the continental shelf break occurs at a depth of ca. 1,000 m compared to about 200 m and less elsewhere in the world (Smith et al., 2010). Such evidence implies that (a) the continental margins tend to be narrow and often have deep canyons, (b) essentially no organic matter is derived from continental sources, and (c) the only significant effects of the continent are to

provide mineral material to the continental shelves via ice-rafted debris and glacial meltwater to restricted coastal environments. More than 95 per cent of the shelves are at depths outside the reach of photosynthetically active radiation (Turner et al. (eds.), 2009). Some 33 per cent of the continental shelves are covered by the floating ice shelves.

The shelf benthic fauna are dominated by sessile particle feeders with high biomass and low productivity. Many species are long-lived, have low metabolic rates, lack the pelagic larval phase and need longer development time. Benthic communities cover a full range from an extremely high biomass of several kg wet-weight m⁻² to extremely low biomass, abundances and metabolic processes below ice shelves (Azam et al., 1979).

Knowledge of the benthic fauna has developed from historical surveys, individual national projects and cooperative projects, such as the European Polarstern Study (EPOS), Ecology of the Antarctic Sea Ice Zone (EASIZ), Evolution in the Antarctic (EVOLANTA), Census of Antarctic Marine Life (CAML), Latitudinal Gradient Project (LGP), Food for Benthos on the Antarctic Continental Shelf (FOODBANCS), Antarctic Benthos (BENTANTAR), and the Antarctic benthic DEEP-sea biodiversity: colonization history and recent community patterns (ANDEEP), but regionally many gaps in survey data remain (Griffiths et al., 2009). Some 4,000 species have been described (White, 1984; Arntz et al., 1997; Clarke and Johnston, 2003), of an estimated total macrofauna of more than 17,000 species (Gutt et al., 2004); the deep benthos remains largely unsampled (Brandt et al., 2004).

Close to the shoreline, benthic communities are strongly affected by ice scouring. This phenomenon provokes a continuous recolonization of benthos. Iceberg impacts are catastrophic events eliminating up to 96 per cent of the biomass of the community (Smale et al., 2008), interfering with community development in those areas where ice scouring becomes chronic (Dayton et al., 1974; McCook and Chapman, 1993; Barnes, 1995; Pugh and Davenport, 1997). In essence, long-lived species are selected against by this process which results in widely different community structures among areas with different scouring histories.

Benthic communities are marked by the absence of crabs and sharks and by a limited diversity of skates and finfish; skeleton-breaking predation is limited. Slow-moving invertebrates are present at high trophic levels. These characteristics, together with dense ophiuroid and crinoid populations, resemble the worldwide Palaeozoic faunal assemblages (Aronson and Blake, 2001). Detritivores, feeding on deposited organic material, include the infauna (mainly mollusks) and vagrant deposit feeders such as holothurians (Gutt, 2007).

At regional and local levels, patchiness is high, due to differences in environmental conditions, food supply and disturbances; but at very coarse spatial resolution, benthic assemblages are typical of the Antarctic with circumpolar distributions (Turner et al. (eds.), 2009).

Below the depth scoured by drifting ice, the invertebrate benthic fauna typically comprise a dense community of sessile species (e.g., sponges, ascidians, gorgonians, anemones, corals, bryozoans, crinoids) in a three-dimensional pattern (Arntz et al., 1994, 1997; Gutt, 2000) with an associated mobile fauna (echinoids, pycnogonids,

isopods, amphipods, polychaetes, etc.) developing complex relations among different species (Figure 5).

Figure 5. From Mintenbeck et al. 2012. (A) *Trematomus cf. nicolai* hiding inside a sponge; (B) *Pogonophryne sp.* on top of a sponge (ANT XXVII-3 in 2011, western Weddell Sea). Photos: ©Tomas Lundälv, University of Gothenburg.

The highly seasonal primary production in the Antarctic results in a seasonal flux of organic material deposited in the sediment. This provides an abundant persistent food supply for detritivores which might be resuspended as a result of water mixing or ice scouring. This was identified as a “food bank” by Mincks et al. (2005) and Mincks and Smith (2007).

Macroalgae are common elements of nearshore hard-substratum communities in Antarctic and Sub Antarctic regions (Wulff et al., 2011). The areas with hard substrata (e.g., rocks and boulders) are particularly suitable for macroalgal colonization (Quartino et al., 2013). Macroalgae occur in a distinct vertical zonation, mainly between the intertidal and the subtidal zone, down to 30 m depth. The lower distribution is related to their capacity to survive under low light conditions. The South Atlantic Ocean is a nutrient-replete system where nutrients rarely become limiting for macroalgae (Zacher et al., 2009).

Macroalgal communities play a key role in the coastal ecosystem. They are important primary producers, constituting food supply for benthic organisms, such as amphipods, gastropods, annelids and fish (Barrera-Oro, 2002), and represent a significant contribution to the particulate and dissolved organic matter for the coastal food web (Iken et al., 2011). Furthermore, macroalgae provide habitat and structural refuges (Barrera-Oro, 2002; Huang et al., 2007). Macroalgal coastal carbon production seems to be an important food source for the benthic Antarctic communities. If not grazed, macroalgae die and decompose, returning particulate organic matter and mineral nutrients to the system (Quartino and Boraso, 2008).

The sublittoral rocky shores are colonized by macroalgae; the deeper macroalgal assemblages are dominated by canopies of large brown algae from the Order Desmarestiales (*Desmarestia anceps*, *D. menziessi* and *Himantothallus grandifolius*), which replace ecologically the role of the Order Laminariales (i.e., the kelp *Macrocystis pyrifera*) in temperate waters (Wulff et al., 2011).

The strong isolation of the benthic seaweed flora of the South Atlantic Ocean has resulted in a high degree of endemism in Antarctica. Thirty-five per cent of all seaweed species are endemic to the Antarctic region. Within the Heterokontophyta (brown and golden algae) 44 per cent of the species are endemic, within the Rhodophyta (red algae) 36 per cent and within the Chlorophyta (green algae) 18 per cent; and the number of endemic species is continuously increasing (Wiencke and Amsler, 2012). The northern distribution of endemic Antarctic species is often limited by the temperature demands for growth. The southern-most location of open water where macroalgae occur is the Ross Sea, Antarctica (Wiencke and Clayton 2002).

5. Fish

The Antarctic ichthyofauna is small in size and less diverse than might be expected, given the size and age of the Antarctic marine ecosystem (Eastman, 1995). The knowledge of Antarctic fish began in the nineteenth century through zoogeographic and taxonomic descriptions. Fish fauna in the Antarctic is dominated by the Suborder Notothenioidei; approximately 66 per cent of the Antarctic species and 95 per cent in numbers belong to this Suborder. They live from tide pools (genus *Harpagifer*) to great depths (genus *Bathyraco*). Conversely, Antarctic habitats dominate within the Suborder: from about 100 species of notothenioids, 92 are Antarctic, 12 are found in Patagonia, 4 in New Zealand, 2 in Tasmania and 1 from Saint Paul and Amsterdam Islands. In Antarctica, the Notothenioidei are represented by six families: Bovichtidae, Nototheniidae, Harpagiferidae, Artedidraconidae, Bathyracidae and Channichthyidae (Kock, 1992). The family Chaennichthyidae (ice-fish) is exceptional because it has a colorless blood due to lack of haemoglobin (Kock, 2005); only one species lives outside the Antarctic (*Champscephalus esox*, Calvo et al., 1999).

Notothenioids lack a swim bladder and have antifreeze glycoproteins in their blood (Matschiner et al., 2011). They have developed a wide range of feeding strategies, which allow them to utilize food resources in a variety of habitats (Gröhsler, 1994). This diversification has been supported by a trend towards pelagization of demersal species (Nybelin, 1947), which might be related to the abundance of available food in the water column, such as krill, in zones of the Southern Ocean. Thus, fish are main predators of benthos, zooplankton and nekton in the water column, including krill, copepods, hyperiid amphipods, squid and fish.

Besides the Notothenioids, demersal fish of the families Zoarcidae, Liparidae, Muraenolepidae, Macrouridae, Moridae, Achiropsettidae, etc. are represented with significant numbers of species endemic to the Southern Ocean. Chondrichthyes

(sharks and rays) are also found with bottom dwelling (e.g. *Somniosus antarcticus*, *Amblyraja spp.* and *Bathyraja spp.*) and mesopelagic species (e.g. *Lamna nasus*).

The Southern Ocean lacks the epipelagic fish typically found in surface waters of other oceans. The few species of mesopelagic fish, living in the open ocean down to depths of about 1000 m, are members of cosmopolitan families. Typically antarctic is the nototheniid *Pleurogramma antarctica*. Closely related with ice are the species *Trematomus borchgrevinki*,

T. amphitreta, and *Pagothenia brachysoma*. A recent revision of Southern Ocean fish, their diversity and biogeography can be found in Duhamel et al. 2014.

The environmental factors related to fish distribution can only be described in general terms. On the deep Antarctic shelves (500 m deep on average in the Antarctic, against some 200 m deep worldwide) lying in the area of seasonal ice and the islands in the Scotia arc, the fish fauna are dominated by the families Notothenidae and Channichthyidae. In the high Antarctic, although the biomass and numbers are smaller, the diversity and endemism are the highest (Kock, 1992) (e.g., genera *Trematomus*, *Pleuragramma*, *Aethotaxis* and *Pagothenia*).

Pelagic fish include occasional species like *Lampris spp.*, *Lamna nasus* and *Thunnus maccoyii*, and, in general, species also found in waters north of the Polar Front. About 85 per cent of the shelf fish fauna are endemic to the Antarctic against only 25 per cent of the deep sea fish. The vertical distribution of mesopelagic fish is related to the Antarctic surface water (Lubimova et al., 1983).

High energetic costs are associated with pelagic feeding, which may hamper the development of shark species in the southern basins. On the other hand, the benthos is a seasonally stable resource, but most of the benthic epifauna are not very suitable for utilization by fish (Kock, 1992).

The mesopelagic fish fauna are mainly composed of Myctophidae (the dominant group) and Gonostomatidae (Kozlov, 1995); the distribution is mainly circumpolar and always related to the Antarctic surface water (Lubimova et al., 1983). This water mass drifts northwards and sinks at the Polar Front. *Gymnoscopelus nicholsi*, found in surface waters down to 700 m near the subtropical convergence, reaches more than 2000 m depth; they are prey of other fish, squid, fur seals and penguins (Sabourenkov, 1991). *Pleuragramma antarcticum* is the nototheniid present in the mesopelagic over the shelves.

Inshore, the ecological role of demersal fish is more important than that of krill. There, demersal fish are major consumers of benthos and also feed on zooplankton (mainly krill in summer). They are links between lower and upper levels of the food web and are common prey of other fish, birds and seals. Offshore, pelagic fish (e.g., myctophids, *Pleuragramma antarcticum*) play an important role in the energy flow from macrozooplankton to higher trophic levels (Barrera-Oro, 2002). As krill predators, fish play an important role in the Southern Ocean ecosystems (Kock et al., 2012). Nototheniids and Channichthyids are relevant predators of krill and myctophids (Kock et al., 2012); the latter also prey on all development stages of krill.

6. Higher-order predators

Many sub-Antarctic species of birds, pinnipeds and cetaceans occur in northern ice-free waters of the Southern Ocean, and move south in the summer as the pack ice recedes (see chapter 36B). Oceanic fronts present sharp discontinuities in the properties of surface water and food availability; it is well known that predators associate with fronts where they find favourable feeding conditions and are critical for the distribution of seabirds and marine mammals (Bost et al., 2009).

Numerous species of seabirds have been recorded in the Southern Ocean; most are vagrant with only 16 of them nesting in the Antarctic continent (Clements, 2000; Woehler et al., 2001; Harris et al., 2011; Coria et al., 2011; Santora and Veit, 2013; Joiris and Dochy, 2013; Ropert-Coudert et al., 2014). Vagrant species forage within the productive Southern Ocean waters during summer and come mainly from sub-Antarctic islands, although some, such as the Arctic tern *Sterna paradisaea*, fly thousands of kilometres from very distant places (Egevang et al., 2010). A community of seabirds with very stable composition is found in the pack ice; it is probably the most unvarying of any seabird assemblage in the Southern Hemisphere (Ribic and Ainley, 1988). Penguins (Adélie and Emperor) are the typical species, together with snow and Antarctic petrels and, in summer, the South Polar skua and Wilson and storm petrels.

Penguins are the dominant component of the seabird communities in the Southern Ocean in terms both of biomass and prey consumption (Croxall and Lishman, 1987). Nine out of the 18 penguin species inhabit the Southern Ocean; their distributions are reflected in their diets and adaptations to the particular environmental conditions found in their respective ranges, as summarized by Ratcliffe and Trathan (2011):

- Emperor penguins (*Aptenodytes forsteri*) are inhabitants of the high Antarctic; this is the only species that breeds on the land-fast ice along the Antarctic coast during winter. When foraging during winter, emperor penguins have to travel to the edge of the fast ice to feed (Wienecke and Robertson 1997; Zimmer et al., 2008).
- King penguins (*Aptenodytes patagonicus*) feed close to the Polar Front in summer, predominantly on myctophids (*Krefflichthys anderssoni* and *Electrona carlsbergi*). In winter the birds move closer to the ice edge.
- Adélie penguins (*Pygoscelis adeliae*) breed on the Antarctic continent and nearby islands, but their breeding season is in summer, roughly from October to March, and their foraging activity is heavily dependent on sea-ice conditions (Ainley, 2002). Their diet is dominated by euphausiid crustaceans and fish (e.g., Coria et al., 1995; Libertelli et al., 2003). Foraging is mainly confined to pack ice, and seasonal variations in the distribution of this ice cause marked seasonal and spatial variations in foraging ranges, migration routes and wintering areas.
- Chinstrap penguins (*Pygoscelis antarctica*) have a diet comprised almost entirely of *Euphausia superba*; diet and reproductive success are dependent on ice conditions (Rombolá et al., 2003; 2006). Chinstrap penguins tend to forage in open water and avoid areas of pack ice (Ainley et al., 1992).

- Gentoo penguins (*Pygoscelis papua*) have a diet comprised of a wide range of crustacean and fish taxa, with crustaceans typically less important than for other *Pygoscelis* or *Eudyptes* spp. breeding at the same sites.

- Royal penguins (*Eudyptes schlegeli*) are found only on Macquarie Island and macaroni penguins (*Eudyptes chrysolophus*) are found at all other localities. Their diet comprises mostly euphausiid crustaceans and myctophid fish throughout their biogeographic range, with small contributions by amphipods and squid.

Among flying seabirds, the families that are best represented in the Antarctic marine avifauna are Procellariiformes, including albatrosses (Diomedidae), petrels, prions and shearwaters (Procellariidae), storm petrels (Hydrobatidae) and diving petrels (Pelecanoididae). The order Suliformes is represented by cormorants (Phalacrocoracidae) and the order Charadriiformes by skuas (Stercorariidae) and, to a lesser extent, the gulls and terns (Laridae). Most of the Procellariiformes travel hundreds or thousands of kilometres from the colony during the breeding season to feed on patchily distributed resources and they migrate even further during the non-breeding period (Phillips et al., 2008).

Antarctic marine mammals can be defined as those species whose populations rely on the Southern Ocean as a critical habitat for a part or all of their life history, either through the provision of habitat for breeding and/or through the provision of a major food source (Boyd, 2009). The Southern Ocean accounts for about 10 per cent of the world's oceans, but is estimated to support 80 per cent of the world's pinniped biomass (Laws, 1977) and is a critical feeding ground for several cetaceans, particularly the highly migratory baleen whales (Mackintosh, 1965). Many subfamilies and genera are missing in the Southern Ocean. In spite of the species richness of the family Otariidae (sea lions and fur seals) in the South Atlantic, Indian and Pacific Oceans, only Antarctic fur seals (*Arctocephalus gazella*) are found south of the Polar Front in island rookeries and open waters; sometimes they reach the boundary of the pack ice during the austral summer, and some 50 per cent of the population migrates north during winter. This species feeds mainly on krill, with fish and squid found in their diet in proportions that vary with area and season.

True seals (family Phocidae) are represented by five species. The elephant seal (*Mirounga leonina*), also found north of the Polar Front in open waters, is seldom found in the pack-ice area and also migrates to the north in winter. The remaining seal species are more or less associated with the pack ice: the leopard seal (*Hydrurga leptonyx*) preys on krill (about half of its diet), seabirds (mainly penguins), other seals and fish. The Weddell seal's (*Leptonychotes weddellii*) diet is practically all fish and a small proportion of krill. The crabeater seal is the most abundant marine mammal in the world (*Lobodon carcinophaga*) and is a pack-ice inhabitant feeding mostly on krill. Finally, the Ross seal (*Ommatophoca rossii*) is very scarce and little is known of its diet.

A main ecological distinction exists between seals: those breeding in shore colonies (fur and elephant seals) and those breeding on the pack ice (leopard, Weddell, crabeater and Ross seals). The difference is a key element in our ability to estimate population sizes: ice-breeding seals can only be studied through large-scale surveys and it is very difficult to sample the same population year after year; shore colonies

offer easier conditions (Southwell et al., 2012). Crabeater seal numbers were estimated from the Antarctic Pack Ice Seals (APIS) International Programme at 10 million individuals, albeit with large confidence intervals and this is likely to be an overestimate (Southwell et al., 2012). Populations of the other three species are much smaller.

Cetaceans in the Southern Ocean are represented by six species of baleen whale: blue (*Balaenoptera musculus*), fin (*Balaenoptera physalus*), sei (*Balaenoptera borealis*), humpback (*Megaptera novaeangliae*), Antarctic minke (*Balaenoptera bonaerensis*) and southern right whales (*Eubalaena australis*). Among these, the Antarctic blue whale was depleted close to extinction by the whaling industry (from 239,000 (95 per cent confidence interval; 202,000-311,000) to a low of 360 (150-840) in 1973) (Branch et al., 2004). Current estimates suggest that some populations are recovering, but that others are not (e.g., those seldom sighted in the Antarctic Peninsula region); others, such as the southern right whale and especially the humpback whale, are both increasing in numbers (Branch, 2011).

At least nine species of odontocetes are found: sperm whale (*Physeter macrocephalus*), southern bottlenose (*Hyperoodon planifrons*), Arnoux's (*Berardius arnuxii*), Cuvier's (*Ziphius cavirostris*) and strap-toothed (*Mesoplodon layardii*) beaked whales, long-finned pilot whale (*Globicephala melas*), orca (*Orcinus orca*), hourglass dolphin (*Lagenorhynchus cruciger*) and the spectacled porpoise (*Phocoena dioptrica*) (Brownell, 1974; Laws, 1977; Jefferson et al., 2008). Female sperm whales do not reach the Southern Ocean, and only large adult males reach the pack ice.

All in all, cetaceans in the Southern Ocean represent a little less than one-fifth of the world's cetacean species in spite of the large diversity of this family (86 species). Those species that sustain a large biomass are related to the direct plankton food chain (diatoms-krill-vertebrates) which has on average one trophic level less and is more efficient in terms of the transfer of energy and mass than those that include squid or fish as intermediate steps (Boyd, 2009).

7. Pressures and Trends

By-catch, habitat loss, introduced species, human disturbance, pollution and climate change pose severe, albeit of different intensity, threats for seabirds at sea and in colonies in the Southern Ocean and along the Antarctic continent (Micol and Jouventin, 2001; Croxall et al., 2002; Weimerskirch et al., 2003; Jenouvrier et al., 2005). Population trends are variable between species and colonies within a species (Woehler et al., 2001). Significant decreases in populations are evident for those species known to be caught on longline fisheries (albatrosses, Southern giant petrel and *Procellaria* spp.: Woehler et al., 2001; Tuck et al., 2003). Penguin population trends vary in terms of degree and direction among species and geographical areas (Forcada et al., 2006; Lynch et al., 2010; Trivelpiece et al., 2011; Coria et al., 2011). Burrowing petrel species are poorly known, in particular their abundance and trends (Woehler et al., 2001).

8. Harvesting of living resources

Early exploration of the Southern Ocean was driven by the potential of harvesting its nekton – first mammals, then finfish, and finally krill. The discovery of islands lying south of the Antarctic Polar Front rapidly led to the initiation of massive sealing expeditions from various nations during the early 1800s. The outcome of these intensive sealing activities was the near-extirpation of fur seals in Antarctic and Sub-Antarctic Islands by the mid-19th century. Combined with the hunting of fur seals, a rather less relentless pursuit of elephant seals (*Mirounga leonina*) followed for the production of an oil equivalent to whale oil (Bonner, 1984). In 1812, a new method to process seal skins was introduced in London factories, increasing the value of southern pelts. Despite efforts to regulate the catches, Patagonian seals were depleted below commercial levels by 1825, and the Antarctic exploration and harvesting finally resulted in severe depletion and loss of commercial value of seal colonies by 1840. Around 1870, technological improvements led to the growth of pelagic whaling with the development of faster, steam-powered catching vessels, and whaling in the Southern Ocean entered a new era in the early years of the 20th century, which saw the industrialization of whale exploitation. In 1904, the first shore station was built at Grytviken. In 1912, about 11,000 whales were killed annually to be processed at six Antarctic shore stations, a level deemed to be unsustainable (Suarez, 1927). Over the following decades (1904-1960s), more than 2 million large whales were caught, reducing their populations to less than 35 per cent of their initial numbers and 16 per cent of their original biomass (Laws, 1977; Clapham et al., 1999).

The ensuing extraction of other resources followed the same pattern as in other parts of the world; from the highest trophic levels down the trophic web (Kock, 2007; Ainley and Pauly, 2014). The impacts of the reduction to less than 20 per cent of their original size of several fish stocks by 1980, stocks which are not experiencing significant recovery despite management actions by the Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR) (Ainley and Blight, 2008; Marschoff et al., 2012) are still felt in spite of significant harvest reductions (including fisheries closures in large areas). Species' relationships might be altered by harvesting: for example, evidence exists that the decrease in demersal fish in the fishing area was followed by a long-term increase in populations of benthic octopods (Vecchione et al., 2009).

Although the targets and intensity of harvesting have shifted over the years, the ecosystem effects continue. Removal of large predators, such as seals and especially whales, reduces predation pressure on species in the mid-level of the food web, including fish and squid. Some of the large predators (e.g., baleen whales, fur and crabeater seals) feed directly on krill, whereas others (e.g., toothed whales) feed on krill predators. Therefore, the ecosystem effects of sealing, whaling and fishing are potentially complex and were initially related to the “whale reduction” or “krill surplus” hypothesis (Sladen, 1964), in which the outcome from the dramatic exploitation of whale stocks was a presumed excess of food (krill) which was being redistributed throughout the system. Although sealing has ceased and historical levels of whaling have been reduced (a reduced harvest of baleen whales continues),

impacts from the reduced levels of these top-level species arguably still reverberate through the pelagic ecosystem.

The reduction of whaling brought about increased harvesting of fish. Rapid reduction of the target fish stocks was a major reason for the adoption of the CCAMLR, which implemented international fisheries and ecosystem research and resulted in a moratorium on bottom fishing for notothenioids. Kock and Jones (2007) reviewed the fisheries data for the primary fishing area around the Antarctic Peninsula. They found that populations of several fish species declined as a result of the fishery primarily targeting mackerel icefish, *Champscephalus gunnari*, and marbled notothenia, *Notothenia rossii*. Since the CCAMLR moratorium was implemented in 1989-90 for the South Shetland area, populations of several fish species have recovered, but not of the two main target species. The observed recovery in *Notothenia rossii* in the South Shetland Islands shelf is taking longer than the objective set by CCAMLR of two or three decades and *Gobionotothen gibberifrons* remains at low levels (Barrera-Oro and Marschoff, 2007).

Finfish fishing was conducted by bottom trawling until 1985, when regulation of by-catch of depleted finfish species moved the *Champscephalus gunnari* fishery to introduce midwater trawls. Since 2008, fisheries where the fishing gear interacts with the bottom (e.g., longlining and demersal trawling) are subject to mitigation measures to protect Vulnerable Marine Ecosystems, for example the positions where substantial amounts of VME indicator species are encountered are closed to fishing (see CCAMLR – Conservation Measures at www.ccamlr.org). Further, marine reserves have been established by France and Australia (Welsford et al. 2011; Falguier and Marteau 2011) and in South Orkney Islands where fishing is restricted.

Antarctic fur seals may have recovered (and may even have become overpopulated on South Orkneys during the late 1990s (Hodgson et al., 1998)) after being severely depleted, but some breeding rookeries have reached carrying capacity well below historical records (Hucke-Gaete et al., 2004). Trends in the ice-breeding seals are difficult to establish (Southwell et al., 2012). In other circumstances it might become impossible to determine the causes behind the observed population trends. For example, it is difficult (if not impossible) to disentangle the effects of climate change, recovery of seals, and variations in krill availability on the population trends observed for pack-ice seals (Trathan et al., 2012). However, recent evidence suggests that climate change might actually be responsible for the declining trend in Antarctic fur seals, where food stress provoked by climate variation has significantly reduced female longevity, juvenile and adult survival, fecundity and pup birth weight, among other symptoms, since 2003, after a three-decade monitoring programme of biometric, life history and genetic aspects (Forcada and Hoffman, 2014).

A decrease in density of krill (*Euphausia superba*) and a correlated increase in salp abundance has been suggested from the analysis of net samples (Atkinson et al., 2004). Krill decrease has also been inferred by stable isotope studies in krill predators (e.g., Huang et al., 2011).

The regulation of Antarctic fisheries under CCAMLR operates in the framework of the Antarctic Treaty System. Since its inception (1980), CCAMLR requires the application

of the ecosystem approach, aiming to limit the changes induced by the fisheries to those reversible in two to three decades. Catch limits and *inter alia*, fishing methods and data collection requirements are established by a Commission, based on the assessments and advice provided by the Scientific Committee. To date, no methods of catch allocation among members are in place. Several of the 25 Commission Members and 11 acceding do not participate in harvesting. However, the management developed along 30 years has proved to be effective in the sense that this organization is highly regarded in terms of the achievement of conservation objectives (Cullis-Suzuki and Pauly, 2010).

The krill fishery is the largest in the Southern Ocean. Recent annual catch has exceeded 200,000 tons. The fishery developed on a relatively small scale in the 1970s, but rapidly increased during the 1980s to a peak of >500,000 tons/year (Nicol et al., 2012). This is actually much less than the precautionary catch limit set by CCAMLR at a total of over 8.6 million tons. Therefore, krill are considered to be “underexploited”, but the fishery is expanding and management methods to take into account ecosystem considerations are under development (e.g., CCAMLR, 2013, paragraph 5.5; SC-CAMLR, 2013, paragraphs 3.11 to 3.27). A trigger level (a level that cannot be exceeded until more advanced management procedures are in place) of 620,000 tons throughout the main fishing ground is being applied by CCAMLR. However, ecosystem effects of the removal of large numbers of krill remain to be determined, especially when considered in light of climate change.

9. Climate change

In addition to harvesting, the other major pressure on Antarctic biota is the changing climate. The Scientific Committee on Antarctic Research (SCAR) produced a comprehensive Antarctic Climate Impact Assessment (Turner et al. (eds.), 2009). The following discussion is largely based on this report.

For the past 50 years the Antarctic marine ecosystem has been affected by climate change, especially on the western side of the Peninsula, with its warming water and declining sea ice. Westerly winds around the continent have increased by 20 per cent since the 1970s and surface air temperature has increased over the Antarctic Peninsula. Information from ice cores suggest that warming started around 1800. The Antarctic Circumpolar Current temperature increased by approximately 0.5°C between 300 m to 1000 m. Böning et al. (2008) analyzed historical and recent data from drifting buoys, finding that the wind-driven Antarctic Circumpolar Current has not augmented its transport, but reported warming and freshening of the current on a hemispherical scale extending below 1000 m, meaning that transport and meridional overturning are insensitive to changes in wind stress. Although the response of the Antarctic Circumpolar Current and the carbon sink to wind-stress changes is under debate, it has been suggested (Hallberg and Gnanadesikan, 2006; Meredith and Hogg, 2006) that the Antarctic Circumpolar Current’s response to an increase in wind is a change in eddy activity rather than a change in transport. Given the importance of the Antarctic Circumpolar Current and its system of eddies in

structuring the pelagic ecosystem, the consequences of these changes cannot be foreseen.

Ship observations suggest that the extent of sea ice was greater in the first half of the twentieth century, but satellite measurements from 1979 to 2006 show a positive trend of around 1 per cent per decade. The greatest increase, at around 4.5 per cent per decade, occurred in the Ross Sea; the reduction in sea-ice cover affected the Bellingshausen sea.

The pelagic ecosystem was affected by the consequences of the regional sea-ice reduction. Krill population has not increased after the near-extinction of some whale stocks. Although predation by seals and birds increased, the total bird and seal biomass remains only a fraction of that of the former whale population (Flores et al., 2012). The krill stock, of which 150 million tons were being eaten by whales, would have been an estimated three times larger in the pre-whaling time. Commensurate primary production would be around that estimated for the North Sea, not leaving much for other grazers and copepods. This means that phytoplankton also decreased, but the details of the phenomenon are still unclear.

Sea bird monitoring in the Scotia Sea has shown a significant decline in the abundance of krill predators, such as the cape petrel, *Daption capense*, the southern fulmar, *Fulmarus glacialis*, and Wilson's storm petrel, *Oceanites oceanicus*; other species with generalist diets have increased their number: the Antarctic Prion, *Pachyptila desolata*, and the Black-browed Albatross, *Thalassarche melanophris* (Orgeira and Montalti, 1998). Other non-Antarctic species, such as the white-chinned petrel, *Procellaria aequinoctialis*, have extended their pelagic ranges further south, (Montalti et al., 1999).

At least a conceptual model of the structure and functioning of the ecosystem is necessary to understand these phenomena. *In-situ* iron fertilization experiments demonstrated that iron, as a micronutrient, may limit phytoplankton growth even in presence of large concentrations of nitrate and phosphate. In the whale feeding grounds, krill stocks were close to, if not at, the carrying capacity of the ecosystem prior to whaling; this is consistent with the frequent observations in the 1930s of krill swarms at the surface, an observation now seldom made from tourist or scientific vessels.

Estimates of krill abundance derived from the analysis of net samples indicate a decline of up to 81 per cent in the krill stock (Atkinson et al., 2004) and an increase in salp populations, suggesting the replacement of krill by salps and of the typical short food chain of diatoms-krill-higher predators by the longer food chain implied in the microbial food webs to which salps are better adapted. The actual dimension of these changes is currently under debate, because of the large difficulties associated with the analysis of the simultaneous effects of whale depletion, sea-ice retreat at one of the most important recruitment sites of krill (the western Antarctic Peninsula), iron-limited phytoplankton growth, and more complex ecological phenomena (Ainley et al., 2007; Nicol et al., 2007). The lower rate of recycling of iron in the microbial planktonic food web when compared to the short diatom-krill-predators "chain of the giants" may also contribute to the reduction in iron. Large

predators also contribute to iron recycling while accumulating blubber and excreting nutrients in surface waters; a significant proportion of plankton biomass is degraded below the euphotic zone. Thus the productive “chain of the giants” may have maintained itself via recycling the nutrients at a rate compatible with the growth of phytoplankton.

With the decline in sea ice, more phytoplankton blooms should be supplying food to benthic organisms on the shelf. A resulting increase in phytodetritus on the shelf may cause a decline in suspension feeders adapted to limited food supplies, and to their associated fauna. The positive correlation between the extent and duration of sea-ice cover over krill reproduction and survival (Loeb et al., 1997), the negative trends of sea-ice extent (Stammerjohn et al., 2008) and the overall decrease in krill biomass over the last decades (Siegel and Loeb 1995; Atkinson et al., 2004) would be expected to have profound implications for the Southern Ocean food web and is the most relevant issue affecting krill-dependent fauna particularly. When ice shelves collapse, the changes from a unique ice-shelf-covered ecosystem to a typical Antarctic shelf ecosystem, with high primary production during a short summer, are likely to be among the largest ecosystem changes on the planet, a process that seems to develop faster than was previously thought (Gutt et al., 2013).

Another expected impact of climate change is the change in pH levels, with seawater becoming more acid. It seems likely that the skeletons of planktonic pteropoda and of cold water corals will become thinner. Hatching rates of krill eggs are also demonstrated to be negatively affected by the level of ocean acidification projected for the end of the century and beyond (Kawaguchi et al., 2013). The Southern Ocean is at higher risk from this than other oceans, because it has low saturation levels of CaCO₃.

10. Invasive species

The slow rates of growth and endemism of Antarctic species may lead to the establishment of non-indigenous species, probably restricted by their own physiological limits. The incomplete taxonomic knowledge of the Antarctic biota will make it difficult to recognize whether a particular specimen is the result of a natural southern distribution limit or an invasive species. Examples include: the occasional findings of anomuran and brachyuran larvae in the South Shetland Islands (Thatje and Fuentes, 2003); *Euphausia superba* in Chilean fjords; Antarctic diatoms in Tasmania, etc. (Clarke et al., 2005).

There is concern that several factors associated with ocean warming and increased vessel activity (scientific expeditions, tourism, fisheries, etc.) in the Antarctic increase the risk of the introduction of alien species and even pathogens (Kerry and Riddle, 2009). In the crab-eater population of the Antarctic Peninsula, one-third of the population carries antibodies to the canine distemper (Bengtson et al., 1991), attributed to contagion from sled dogs, which were removed from the Antarctic Treaty Area. The introduction of non-native living organisms is banned, except in accordance with a permit.

11. Contamination

At the local level, contaminants from coastal stations are introduced through waste water, dump sites and particulates from the activity of stations and ships. Persistent organic pollutants (POPs) have been found in water, sediments and organisms in the vicinity of several stations (e.g., UNEP, 2002; Bargagli, 2005). Since 1991, the Protocol on Environmental Protection to the Antarctic Treaty¹ has imposed severe restrictions and regulations on disposal and treatment of wastes and emissions from stations and tourism vessels. Thus, locally originated contamination is not expected to become a significant problem.

Global contamination reaches Antarctica through the global circulation of the oceans. Persistent pollutants are transported and biomagnified, these include DDT (dichlorodiphenyltrichloroethane) and other organophosphates. While DDT has been little used since the 1970s a possible source of DDT maintaining high levels in penguin populations is glacier ablation (Geisz et al., 2008). Anthropogenic radionuclides stemming from above-ground nuclear bomb testing are also present throughout Antarctica, including evidence of the Chernobyl nuclear accident (Dibb et al., 1990), and have even been used to provide dating controls within long-lived biological systems (Clarke, 2008). Snow samples enabled the reconstruction of lead pollution of Antarctica that started as early as the 1880s, related to non-ferrous metal production activities in South America, South Africa and Australia and coal-powered ships that crossed Cape Horn en route between the Atlantic and Pacific Oceans. Lead pollution declined in the 1920s, correlated with the opening of the Panama Canal in 1914, and decreased from the mid-1980s because of lead-free modern cars. Antarctica is significantly contaminated with other metals, such as Cr, Cu, Zn, Ag, Bi and U, as a consequence of long-distance transport from the surrounding continents.

Chapter 37. Marine Mammals

Contributors: Tim D. Smith (Convenor), John Bannister, Ellen Hines, Randall Reeves, Lorenzo Rojas-Bracho, Peter Shaughnessy, Jake Rice (Lead Member and Editor for Part VI)

1. Introduction

Marine mammals occupy a wide range of marine and some freshwater habitats around the world. They have been used by humans for millennia for food and to obtain other products. Marine mammals consist of cetaceans (whales, dolphins and porpoises), pinnipeds (seals, sea lions and walruses), sirenians (dugongs and manatees), mustelids (sea otters and marine otters) and the polar bear – 130 or more species in total, including several that range into fresh water and some that exclusively occupy rivers and lakes. Human interactions, both direct and indirect, have negatively affected most marine mammal species at least to some degree. Historically, industrial harvesting greatly reduced the abundance of many populations. Although the intensity of such exploitation has declined in recent decades for many species, humans continue to use certain species of marine mammals in some places for food, skins, fur, ivory and increasingly as bait for fisheries. In addition, human activities continue to reduce the availability and quality of marine mammal habitats and cause substantial numbers of marine mammals to die incidentally as a result of entanglement or entrapment in fishing gear and from being struck by vessels. Mitigation of ongoing and future threats to marine mammals from human activities requires improved knowledge of those human activities and of the animals' ecology, behaviour and habitat use.

1.1 *Changes in Biological Diversity*

Globally, certain species of marine mammals have become extinct over the last several centuries, i.e., Steller's sea cow, the Japanese sea lion, the Caribbean monk seal. The Yangtze River dolphin (baiji) is also likely to have become extinct although there has been one unconfirmed sighting in 2005. In addition, many populations have been reduced to remnant status, such that they no longer play a significant role in the ecosystem, i.e., they are functionally extinct. For example, right whales have essentially disappeared from the eastern North Atlantic, and walruses are gone from their former strongholds in south-eastern Canada (Gulf of St. Lawrence and Sable Island). The loss of marine mammal diversity due to actual and functional extinctions has had significant effects on marine ecosystems at varying scales from local to ocean-basin-wide (Estes et al., 2006).

1.2 *Magnitude of changes*

Besides the above-mentioned extinctions and extirpations, the numerical abundance

(and biomass) of many other marine mammal populations has been greatly reduced. All of the commercially valuable great whales were depleted by whaling. A good example is the world's largest animal, the blue whale. Within the 20th century more than 360,000 Antarctic blue whales were taken, leaving a remnant population of only hundreds of animals and a current abundance of roughly 5 per cent of original numbers (Branch et al., 2007). Some populations of virtually all types of marine mammals have been depleted to low levels; for example, southern and northern hemisphere populations of fur seals and elephant seals were all depleted by harvesting for either their fur or their oil (Busch, 1985). Similarly, many populations of sirenians and sea otters have been reduced to small fractions of historic levels.

Although the abundance of almost all populations of marine mammals has been reduced by human activities, a number of them have recovered since they were protected from deliberate exploitation. Eastern Pacific gray whales, northern elephant seals, eastern Steller sea lions, humpback whales and some populations of right whales provide some of the most clear-cut examples. Certain populations of those species, however, have not recovered and remain at small fractions of historic levels (e.g., western Pacific gray whales, Arabian Sea humpback whales, western Steller sea lions, North Atlantic right whales, and southern right whales in some areas).

2. Population trends or conservation status

2.1. Aggregated at global scale

Because of the great diversity of marine mammal species and their habitats, it is difficult to characterize their conservation status and population trends in the aggregate or at a global scale. Many of the marine species suffered major declines over the past several hundred years as a result of commercial hunting. Massive changes in human demography and economy have unquestionably affected the environmental carrying capacity, particularly in coastal regions, and as a result less suitable habitat (including forage base) is available to support marine mammal populations. These changes make 'full' recovery unfeasible for some species.

2.2. Major taxonomic and/or geographic subdivisions

2.2.1. Large whales

Commercial exploitation began as long ago as the 10th century, and by the late 19th century intensive whaling had caused severe depletion, and even near-extinction, of some species and populations. Industrial mechanized whaling in the 20th century led to further major declines. Some populations of large whales have been recovering in recent decades: for example, humpback whales globally, blue whales in some regions and southern hemisphere right whales when treated as a single group (Figure 1, from IWC, 2013a). At the same time, many populations have failed to recover to anywhere near their original abundance. For example, right whales are effectively extirpated from the eastern North Atlantic, and are only barely surviving in the eastern North

Pacific the eastern South Pacific, and around New Zealand (Jackson et al., 2011).

2.2.2. *Pelagic dolphins and porpoises*

Pelagic (off-shore) dolphins are generally less susceptible to human interactions than many marine mammals because they are relatively small, of little commercial importance, wide-ranging (some species are also extremely numerous) and live far from most human activities. There are potential interactions with military activity, and clear interactions with fishing gear in the eastern tropical Pacific. Several dolphin species in that region have been significantly affected by humans because they have symbiotic relationships with other pelagic animals that are of commercial interest, notably yellowfin tuna. Purse seine fishermen learned to chase and encircle these dolphins to facilitate the capture of tuna, and in the past large numbers of dolphins drowned in the nets. This mortality greatly reduced the abundance of several dolphin species in the latter half of the 20th century. Due to international efforts, fishing methods have changed and the by-catch has been reduced significantly (Hedley, 2010, NMFS, undated).

2.2.3. *Coastal and Estuarine dolphins and porpoises*

Coastal dolphins and porpoises are hunted for food and bait by a number of States. Furthermore, they often die accidentally in fishing gear in coastal commercial and artisanal fisheries. This has contributed to declines in abundance, at times to critical levels. For example, vaquitas in the Gulf of California (Mexico) declined by 57 per cent from 1997-2008, and continue to decline (Gerrodette et al., 2011). In New Zealand, the Māui dolphin (a subspecies of Hector's dolphin) has declined to very low levels (Currey et al., 2012; Hamner et al., 2012). In both cases, there have been management interventions aimed at minimizing direct mortalities and entanglements. However, under current levels of direct mortalities and entanglements, these trends are expected to continue, with both the vaquita and the Māui dolphin at risk of becoming extinct within the next few decades (CIRVA 2014).

Several species of small cetaceans live in estuaries and in large rivers, often in close proximity to humans, and are threatened by artisanal fisheries, pollution, and coastal development. Two species of South American river dolphins are relatively widespread and at least locally common in Amazonia and Orinoquia: the tucuxi and the boto (Trujillo et al., 2010). The endemic blind river dolphins of the South Asian subcontinent still inhabit large portions of the Indus, Ganges, Brahmaputra and Karnaphuli rivers. Although they are locally common in a few places, their numbers and ranges have declined markedly over the past century. Three relict populations of 100 or fewer Irrawaddy dolphins persist in the Ayeyarwady (Irrawaddy) River of Myanmar, the Mahakam River of eastern Borneo, Indonesia, and the Mekong River of Cambodia and Laos. All three populations are at high risk of extirpation from a variety of human activities (Kreb et al., 2010). The baiji (*Lipotes vexillifer*), endemic to the Yangtze River, (China), is likely to have become extinct in the early 21st century (Turvey et al., 2007), and the Yangtze population of narrow-ridged finless porpoise (*Neophocaena phocaenoides asiaeorientalis*) is declining rapidly, probably due to mortality in fishing gear, vessel strikes and habitat degradation (Wang et al., 2013).

2.2.4. *Pinnipeds*

Populations of many species of commercially exploited pinnipeds were greatly reduced in abundance from the 18th to the 20th century. They were targeted mainly for the oil from their insulating blubber and for their fur. Some species, such as the Caribbean monk seal and the Japanese sea lion, were driven to extinction, and others, such as the Mediterranean monk seal, as well as fur seals in many areas, were reduced to very low numbers. The hooded seal in the Greenland Sea has been hunted down to 10-15 per cent of its original population. However, some regional and ocean-basin-wide pinniped populations have been recovering, such as the harp seal in Canada and grey and common seals in the United Kingdom of Great Britain and Northern Ireland. In some cases they have been recolonizing habitat where they had long been absent, for example, the New Zealand fur seal has expanded into former habitats in New Zealand and Australia (Shaughnessy et al., 2014). In other cases populations have increased to historical levels, such as the Antarctic krill-eating seals (Kovacs et al., 2012).

2.2.5. *Sirenians*

Manatees and dugongs are the only totally aquatic herbivorous mammals, feeding primarily on submerged vegetation. Sirenians have a global range in about 90 tropical and subtropical countries. They have been and continue to be hunted, trapped, and netted for food, and human activities of many kinds have modified or otherwise degraded their habitat. Overall, populations have been greatly reduced in terms of both abundance and range. One species discovered in 1741, Steller's sea cow, was hunted to extinction in less than a quarter of a century after its discovery. The present status varies regionally (Marsh et al. 2014, Hines et al. 2014).

2.2.6. *Mustelids*

Two species of mustelids are truly marine: the sea otter (*Enhydra lutris*), along the Pacific coast of North America and East Asia, and the marine otter (*Lontra felina*), along the Pacific coast of South America. Both species are very coastal and they have been extensively exploited for their pelts. The sea otter has recovered substantially in many areas of its original distribution, whereas the marine otter has not, as it continued to be harvested through much of the 20th century. Its contracted range is fragmented due to various kinds of human interaction (IUCN, 2015).

2.2.7. *Polar bears*

Polar bears are endemic to high latitudes of the northern hemisphere. They have a circumpolar distribution and depend on both sea ice (for hunting pinnipeds and for denning and reproduction in some areas) and land (for hunting hauled-out pinnipeds such as walruses, as well as for denning and reproduction). Most populations have been subjected to extensive killing, at least historically, mainly for meat, hides, and sport, and to protect human life and property. Commercial hunting is now prohibited, although substantial numbers of bears are killed every year (legally) by aboriginal people in Alaska (United States of America), Canada and Greenland (Denmark). The main long-term and range-wide threat to polar bears is the projected loss of sea ice habitat associated with climate change. Sea ice provides essential breeding habitat for ringed seals, the principal prey of polar bears, and the bears rely

on ice as a hunting platform to gain access to the seals. Limited access to food leads to mobilization of fat reserves and the release of hazardous substances stored in fat, which are transported by the blood circulation to vital organs such as liver and brain. High levels of contaminants have been associated with negative health effects (e.g. enzyme activation, hormonal disturbance and weakened immune systems) in polar bears in Svalbard (Norway), Greenland (Denmark), and Hudson Bay, Canada (Atkinsson et al 1996).

2.3 *Special Conservation Status Issues*

2.3.1 *Sources of conservation information*

International Whaling Commission: The conservation issues associated with large whales and, to a lesser extent, small cetaceans are addressed in the reports of the Scientific Committee of the International Whaling Commission. Besides directed hunting, these reports increasingly have addressed other topics of concern, including habitat degradation, ship strikes, climate change, fisheries by-catch, noise disturbance, and ecological interactions. The status of many of the great whales is summarized at www.iwc.int/status#species.

International Union for Conservation of Nature (IUCN): The IUCN Red List is an authoritative and regularly updated source of conservation information for all species and subspecies of marine mammals and for many threatened subpopulations. This information is easily accessible (www.redlist.org). The authority for listing determinations resides within the relevant Specialist Groups (SG) of the IUCN Species Survival Commission: the Pinniped SG, Cetacean SG, Sirenian SG, Otter SG and Polar Bear SG.

National and regional sources: In addition to the international sources of conservation information, some nations undertake research in support of management. Information obtained from such research is often available online. Major sources include Australia, Canada, New Zealand and the United States. The United States National Marine Fisheries Service and Fish and Wildlife Service provide updated Stock Assessment Reports on marine mammals under their respective jurisdictions (www.nmfs.noaa.gov/pr/sars; www.fws.gov/alaska/fisheries/mmm/stock/stock.htm). The United States Marine Mammal Commission also provides much information on marine mammal science and conservation (www.mmc.gov). In Canada, the Department of Fisheries and Oceans publishes information on population and ecosystem status (www.isdm-gdsi.gc.ca/csas-sccs). In addition, the Committee on the Status of Endangered Wildlife in Canada posts status reports on all marine mammal species of concern in Canada (www.sararegistry.gc.ca). Australia provides information on cetaceans, pinnipeds and dugongs that occur in areas within national jurisdiction (www.environment.gov.au/topics/marine/marine-species). New Zealand undertakes its own assessments (Hitchmough, 2010). In addition, a regional body in the North Atlantic, the North Atlantic Marine Mammal Commission, provides information on marine mammals in that region (www.nammco.no).

2.3.2 *Potential value of management methods*

Regulation of directed and indirect takes: The most obvious approach to management of human activities that result in the killing of marine mammals is to control directed (i.e. deliberate) takes. Numerous examples demonstrate the effectiveness of this approach, such as the strong recoveries of some severely depleted populations following protection from whaling, sealing, or other forms of deliberate exploitation. The status of marine mammal populations, especially in relation to the effects of directed takes, is usually measured in terms of the size of populations relative to historical levels. The likelihood of population recovery after takes are controlled depends on the survival of a viable nucleus of individuals in the population at the time of protection. Furthermore, suitable habitat, including food resources, needs to exist to support recovery.

In some cases, especially when a population has been reduced to low levels, it is also necessary to manage sources of incidental (i.e. unintentional) mortality, injury, and disturbance due to other human activities. This can include requiring the use of less wasteful fishing practices and less by-catch-prone fishing gear and the regulation of ship traffic to reduce the incidence of vessel strikes. Techniques to reduce by-catch include the use of acoustic deterrents, gear modifications, time-area closures, and gear switching, for example, from gillnets to hook-and-line or traps/pots (i.e., Knowlton and Kraus, 2001; Read et al., 2006). Some of these approaches have been the subject of considerable research (www.bycatch.org). Other anthropogenic threats may also need to be addressed, including reduction of noise from anthropogenic sources, and reduction of contamination by toxic substances (including oil) and of marine debris (including discarded or derelict fishing gear, and plastics of all sorts) (see chapter 25. The effects of tourism, for example whale and pinniped watching, in modifying behaviour through close approach, particularly to breeding and nursery areas, may also need to be addressed (Higham et al., 2014). In any event, successful marine mammal management requires selecting and implementing suitable methods of enforcement.

Marine Protected Areas: Protecting marine mammals in specific areas (e.g., feeding, breeding, and resting areas) can sometimes be effective for addressing certain threats (Gormley et al., 2012). Understanding the life history of the species, the degree of localization of the threats and the needs and interests of local human populations is critical to the design of area management. Effective protection depends on devising plans that consider local community needs, as well as establishing effective control and monitoring. Furthermore, marine mammals tend to be highly mobile, and some species migrate across multiple ecosystems and even entire ocean basins, so protection may be needed in more than one area. There is considerable interest in spatial management to protect and conserve marine mammals through the establishment of parks, reserves and sanctuaries (e.g., Reeves, 2000; Marsh and Morales-Vela, 2012; and see www.icmmpa.org).

3. Key pressures linked to trends

3.1. *Direct Removals*

There are various types of directed takes, including commercial harvests, scientific sampling, captive display, and subsistence. Some of these are under management while others are unauthorized and unmanaged. The nature of direct removals varies among major marine mammal groups.

There is a very long-standing, but relatively small (811 whales over four centuries), capture of northern bottle-nosed whales in the Faeroe Islands (Denmark), recorded from at least the sixteenth century (Bloch et al., 1996). Coastal dolphins continue to be taken not only in the Solomon Islands (Oremus et al., 2013), but also in a large-scale drive fishery in Japan. Dolphins are hunted with harpoons in various countries for human consumption or for bait, especially in shark fisheries (IWC, 2013b). The consumption of by-catch as well as deliberately taken cetaceans and sirenians is a growing concern in Africa, Asia, and some parts of Latin America (Clapham and Van Waerebeek, 2007). In the Arctic, narwhals and belugas continue to be hunted by aboriginal people in Canada, Greenland (Denmark), the Russian Federation and the United States. Marine mammals are also harassed and sometimes deliberately killed around aquaculture facilities in many parts of the world.

Whales are taken by several States for commercial, aboriginal and scientific purposes. The nature and regulation of these takes are described by the International Whaling Commission (www.iwc.int). Cetaceans occasionally strand on the shore in large groups: so-called mass strandings. The cause of this behaviour is poorly understood, but it has occurred for millions of years (Pyenson et al., 2014). Unless a population has been depleted by other causes, mass strandings are unlikely to be a major threat in themselves.

Pinnipeds – including walruses and numerous seal species – are hunted in large parts of the Arctic and sub-Arctic, primarily for subsistence. A few commercial hunts for pinnipeds continue, including those for Cape fur seals in Namibia, harp and hooded seals in Canada, and harp seals in Norway and the Russian Federation. Because pinnipeds often interact directly with fishing operations, sometimes fishermen and aquaculturists exert pressure to limit or reduce pinniped populations by commercial hunting or culling.

For manatees and dugongs, commercial hunting no longer occurs, but harvesting for meat and for dugong tusks continues in many areas. Although often illegal, there is little enforcement in most areas. The largest aboriginal hunts of dugongs persist in Australia and the western Pacific (Dobbs et al., 2012). In Australia, both Aboriginal and Torres Strait Islander people continue their traditional subsistence hunting of dugongs, but commercial hunting of dugong is prohibited.

3.2. *Fisheries Interactions*

While the effects of fisheries on marine mammals from entanglement and by-catch are well known (see section 2.3.2.1), the effects of marine mammals on fish

populations and the effects of fisheries on the prey base of marine mammals are less clear. The diet of most marine mammals includes fish and the possibility is often raised that some marine mammals are competing with fisheries or impeding the recovery of depleted fish stocks. Although some cetaceans, such as sperm whales, killer whales, pilot whales, and false killer whales, are known to depredate fishing operations, the significance of such depredation on fish populations and fish catches is not always clear.

Similarly, the effects of pinniped predation on valuable fish populations remain uncertain. For example, in the north-eastern Pacific sea lions feed on small populations of endangered salmon during spawning migration in rivers, especially in connection with dams (NMFS 1999). On the other hand, the significance of some other interactions is less clear (NMFS, 1999). Cape fur seals prey on two commercially fished species of hake off the west coast of South Africa (Punt et al., 1995) and grey seals prey on cod populations off the east coast of Canada (Fisheries and Oceans Canada, 2010). Population modelling studies of these fishery interactions suggest that seal culls are likely to have small if any effects on fish catch rates. Indeed, the effect of Cape fur seal predation may be overshadowed by predation of one hake species on the other. This suggests the need for further ecosystem-level research to clarify complex foraging relationships and interactions before conclusions are drawn, as discussed in section 4.1. (Yodzis, 2001; Gerber et al., 2009; Morissette et al., 2010). The biological and economic significance of marine mammal interactions varies with the fisheries and fish species involved. The areas of conflict are geographically limited and fishery interactions do not appear to be a global problem (Kaschner and Pauly, 2004).

3.3. *Habitat Alterations*

3.3.1 *Disturbance*

Many human activities generate underwater noise, including ship movements, military exercises involving the use of sonar or explosives, offshore oil and gas exploration and pile driving associated with construction of renewable energy facilities. Potential effects of such noise on marine mammals include direct acoustic injury, interference with foraging and communication, and food-web disruption. Disturbances are more likely to be significant for populations that have also been affected by other factors, such as harvesting or bycatch. Among the effects of disturbance that have been confirmed are the tendency of some whales to modify their movement patterns to avoid fixed-point noise sources, as for bowhead whales near an offshore oil production facility (McDonald et al., 2012), and the mortality of deep-diving cetaceans exposed to naval sonar (Cox et al., 2006; Fahlman et al., 2014; Ketten, 2014).

Offshore oil and gas development creates unique problems related to oil spills, whether at drill sites or during shipping. For depleted species, the additional mortality from ship strikes have been shown to be significant and vessel speed controls are demonstrably effective at reducing such strikes, as for right whales in the western North Atlantic (Laist et al., 2001; Laist et al., 2014).

3.3.2. *Coastal and riverine development*

Development in coastal and freshwater areas affects marine mammals in a variety of ways. Residential and urban development can make pinniped haul-out habitat inaccessible or hazardous. However, some species have shown remarkable adaptability to human-modified beach environments. For example, in the United States, California sea lions regularly haul out on piers and even on moored yachts in San Francisco. Although monk seals are extremely sensitive to disturbance in some areas, in Hawaii they sometimes rest and even nurse pups on crowded bathing beaches. In such cases, the animals seem capable of co-existing with the human presence as long as they are not molested.

Coastal habitats used by whales and dolphins make them vulnerable to increasingly intensive aquaculture operations of many types (Hucke-Gaete et al., 2013). A well-studied case is salmon farming in southern Chile, which operates in concentrated areas using open-cage net pens, moorings and anchoring, external supplementary feeding (rich in nutrients) and a significant quantity of chemical products (antimicrobials and pesticides) (Buschmann et al., 1996). However, there are differences globally in fish-farm design and operation, so general conclusions are difficult.

The construction of dams, barrages, and other structures in rivers and estuaries has led to fragmentation of dolphin and manatee populations in Asia and South America, making such populations more vulnerable to various threat factors, including entrapment in canals and mortality in flood-control gates. Runoff from agricultural fields, livestock feedlots, factories, and city streets contributes to chemical and biological contamination of freshwater, estuarine and coastal food webs, with often uncertain but likely negative effects on marine mammal health. For example, sea otter deaths in California (United States), have been linked to protozoan parasites known to breed in domestic cats (Johnson et al., 2009) and toxoplasmosis has been identified in Hector's dolphins (Roe et al. 2013).

3.3.3. *Climate change*

Climate change, both natural and human-induced, has the potential to affect the spatial distribution, reproductive success, foraging, and health of marine mammals (Leaper et al., 2006; Burek et al., 2008). The direction of such effects, negative or positive, is likely to be variable, with some species suffering from the loss of habitat and others able to take advantage of new habitat. MacLeod (2009) predicted that the ranges of most cetacean species (88 per cent) would be affected by changes in water temperature resulting from global climate change. This author predicted that the effects would be unfavourable for about half (47 per cent) of cetacean species. Little is known about the ability of most marine mammals to adapt to rapid environmental change. For example ice seals and polar bears, which are dependent on sea ice (Ferguson, et al. 2006), may be especially vulnerable to predicted climate change effects on ice habitat. Foraging habitat of right whales, which are dependent on small zooplankton, may change with increasing water temperature (Torres et al., 2013). Other species with more generalized diets and the ability to thrive in multiple types of habitat, such as bottlenose dolphins, may be more resilient (e.g., Heide-Jørgensen, 2009; Salvadeo et al., 2010). The overall effects of sea-level rise have been studied for northern elephant seals (Funayama et al., 2012) and Hawaiian monk seals (Baker, Littman and Johnston, 2006).

4. Major ecosystem services provided by marine mammals

4.1. Services to the ecosystem

Marine mammals can affect their ecosystems in several ways. Some species, such as sea otters, dugongs and walruses, structure their foraging habitat (e.g. Estes and Duggins, 1995). Depletion of these animals can result in major habitat changes; for example, kelp beds thrive when sea urchins are suppressed by sea otter predation. Other species, such as killer whales and leopard seals, play key roles as high-order predators, and their absence can affect prey resources of other marine mammal, bird or fish populations (Estes et al., 1998; Williams et al., 2004). Additionally, some species, such as sperm whales and blue whales, may have a large effect on nutrient recycling, with nutrient transport from deep ocean feeding areas to the surface (Lavery et al., 2010; Lavery et al., 2014). These ecosystem-level effects are understood for only a few species, but they can be critical for maintaining diverse and productive ecosystems (Bowen, 1997; Roman and McCarthy, 2010).

4.2. Direct services to humans including economic and livelihood services

The economic value of products obtained from marine mammals – meat, oil, ivory, fur, and many others – has been large, and this has contributed to these animals' extreme depletion and in a few instances led to their extinction (Steller's sea cow, Caribbean monk seal). Many groups of people continue to benefit from hunting marine mammals, including in some instances from selling products in international markets (e.g., narwhal and walrus ivory and seal skins). Aboriginal people in the Arctic and sub-Arctic continue to consume products from cetaceans and pinnipeds on a regular basis. Local people in Amazonia, northern Australia, and West Africa continue to harvest sirenians for food. In Nunavut and the Northwest Territories in Canada, regulated polar bear sport hunts provide income to Inuit who serve as guides and are required to use dog teams and sleds to pursue the animals.

In contrast, many people benefit from non-consumptive or low-consumptive uses of marine mammals, especially through whale-, dolphin-, and seal-watching tourism (see chapter 27). In addition, many people enjoy seeing marine mammals in the wild on their own. However, such activities can negatively affect small localized populations, for example bottlenose dolphins in Shark Bay, Australia (Bejder et al. 2006). Additionally, public display of captive marine mammals can make people more aware and appreciative of them, but it is extremely controversial, in part because the capture of marine mammals from the wild for display in captivity could threaten small wild populations (Fisher and Reeves, 2005).

5. Conservation responses and factors for sustainability

Like most large animals, marine mammals have limited capacity to reproduce and increase their numbers. Therefore, factors that can result in either low recruitment (e.g. impairment of reproduction by chemical contaminants such as organochlorines in food webs; (Dierauf and Gulland, 2001) or human-induced mortality rates higher than replacement (e.g. hunting or by-catch) need to be addressed to achieve conservation goals. Harmful algal blooms, ocean acidification, and expansion of hypoxia zones are among the most intractable factors affecting marine mammal populations. Conservation requires understanding of the organisms and their habitat requirements, and a balancing of human needs and desires with the natural productivity and the carrying capacity of the environment. The identification of key limiting factors is a first step toward developing management measures that can help populations to recover.

For the most part, population recoveries are regarded as successes, although in some cases they have led to unanticipated conflicts. One such conflict is with fishermen who have become accustomed to low levels of marine mammal abundance. For example, the recovery of numbers and range of sea otters has increased competition with fisheries for high-value molluscs in Alaska (United States) and the eastern North Pacific. Similarly, as mentioned above, sea lions prey on endangered fish, such as salmon and sturgeon, and recovering grey seals in Europe have had negative effects on seabird nesting habitat. Growing pinniped populations have also led to increased interactions with recreational fishers, vessel owners, and marina managers.

The conservation of marine mammals, like conservation more generally, should be understood as a dynamic and continuing process. Consequences of management actions need to be anticipated and unforeseen consequences addressed as they arise. Especially in the case of animals like marine mammals, that are widely distributed and rarely occur within the jurisdiction of only one State, multilateral approaches are essential. For example, the global ban on large-scale pelagic drift net fishing on the high seas imposed by the United Nations in 1994 was a major step in limiting the by-catch of several marine mammal (and seabird) species that were especially vulnerable to entanglement. Other international instruments, such as Convention on the International Trade in Endangered Species (CITES) and the International Convention for the Regulation of Whaling, have helped limit the damage caused by over-exploitation of the great whales.

With a broad understanding of the many aspects of both conservation and use of marine mammals and their roles in marine ecosystems, it should be possible to address at least some of the issues arising from human interactions.

Figure 1. Catches (solid dark line) and estimated population size for southern right whales from 1770 to 2010, assuming a maximum annual net rate of increase of 6 per cent (grey line) and 7 percent (dotted line), culminating in an estimated population size of 13,600 in 2010 (IWC, 2013a).

Chapter 38. Seabirds

Contributors: Ben Lascelles (Convenor), Jake Rice (Lead Member and Editor of Part VI), Mayumi Sato, Marguerite Tarzia, Ross McLeod Wanless¹

1. Introduction

Seabirds are the most threatened bird group and their status has deteriorated faster over recent decades. Globally 28 per cent are threatened (5 per cent are in the highest category of Critically Endangered) and a further 10 per cent are Near Threatened. Of particular concern are those species whose small range or population is combined with decline (64 species). Pelagic species are disproportionately represented in comparison with coastal species; those listed under the Agreement on the Conservation of Albatross and Petrels² have fared worst of all.

Declines have been caused by ten primary pressures. At sea these include: incidental bycatch (in longline, gillnet and trawl fisheries); pollution (oil spills, marine debris); overfishing; energy production and mining. On land, invasive alien species, problematic native species (e.g. those that have become super-abundant), human disturbance, infrastructural, commercial and residential development, hunting and trapping have driven declines. Climate change and severe weather affect seabirds on land and at sea.

Given their imperilled conservation status, many seabirds have been highlighted for special conservation status and action under a range of international, regional and national agreements and mechanisms. Data on distribution, abundance, behaviour and pressures can be used to inform the design of effective management regimes for seabirds. Management decisions can be guided by: (1) where the key areas are, (2) when these areas are used, (3) what variables explain seabird presence in a given area, (4) the threat status of species in a given area, (5) what pressures may be adversely affecting the species, associated habitats and processes, (6) what management actions are needed to address these threats, and (7) how any management intervention can best be monitored to assess its effectiveness.

Seabirds provide many ecosystems services and their role as potential indicators of marine conditions is widely acknowledged. Many studies use aspects of seabird biology and ecology, especially productivity and population trends, to infer relationships with and/or effects on and/or correlate with aspects of the marine environment, particularly food availability.

2. Population trends or conservation status

2.1 Aggregated at global scale

Croxall et al. (2012) reviewed 346 seabird species and found that overall, seabirds are more threatened than other comparable groups of birds and their status has deteriorated faster over recent decades. In terms of the categories used in the International Union for the Conservation of Nature (IUCN) Red List, globally 97 species (28 per cent) are threatened, with 17 species (5 per cent) in the highest category of Critically Endangered) and a further 10 per cent Near Threatened. Only four species, all storm petrels, are regarded as Data Deficient; three species are considered Extinct, and two other species are Possibly Extinct. Of the 132 threatened and Near Threatened seabird species 70 (53 per cent) qualify by virtue of their very small population and/or range. 66 species (50 per cent) qualify by virtue of having undergone rapid population decline. Of particular concern are those with both small range and/or population as well as having undergone decline (64 species; 48 per cent); this includes six species of penguins, 17 of gadfly petrels and eight of cormorants. Pelagic species are disproportionately represented in all categories in comparison with coastal species (Figure 1). 57 species (17 per cent) are increasing; for many, such as the 17 gull species, this is doubtless due to their abilities to exploit close links with human activities.

Figure 1. Proportion of species in each IUCN Red List category for pelagic species, coastal residents and coastal non-breeding visitors. Figures give number of species (for totals >5). Source: Croxall et al., 2012.

A broader, but less sensitive, measure of overall trends is provided by the Red List Index (Butchart et al., 2004; 2007), which measures trends in extinction risk (based on the movement of species through IUCN Red List categories owing to genuine improvement or deterioration in status) and is virtually the only trend indicator currently available for seabirds on a worldwide and/or regional basis. It shows (Figure 2) that, over the last 20 years, seabirds have had a substantially poorer

conservation status than non-seabirds and that they have deteriorated faster over this period. Pelagic species are more threatened and have deteriorated faster than coastal species, and this difference is particularly pronounced for the albatrosses and large petrels that are covered by the 2004 Agreement on the Conservation of Albatross and Petrels ([ACAP] BirdLife International, 2012).

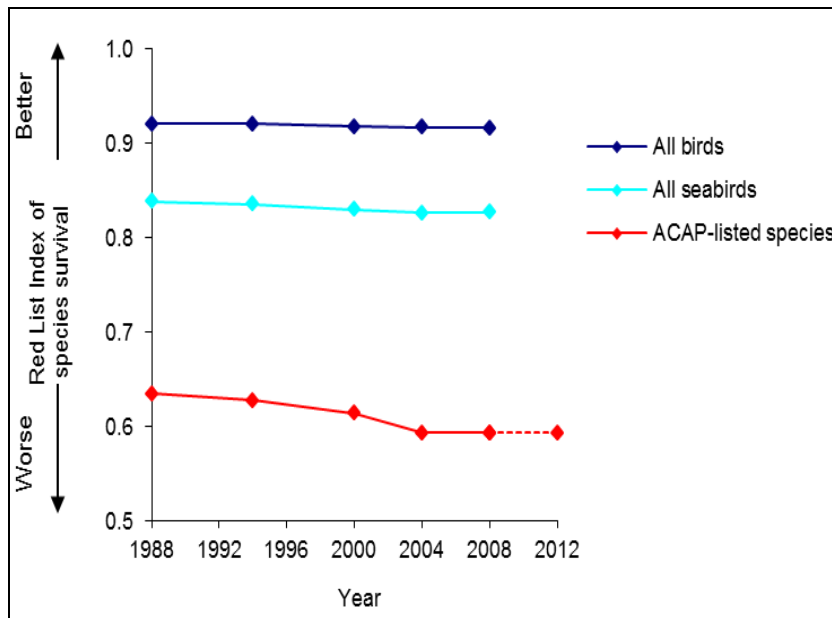

Figure 2. Red List Index of species survival for all bird species (n=9,853 non-Data Deficient species extant in 1988), all seabirds (n=339) and ACAP (Agreement on Conservation of Albatross and Petrels)-listed species (n=29). Values for the latter are projected to 2012 based on data from the 2012 IUCN Red List to be published later this year. RLI values relate to the proportion of species expected to remain extant in the near future without additional conservation action. An RLI value of 1.0 equates to all species being categorized as of Least Concern, and hence that none are expected to become extinct in the near future. An RLI value of zero indicates that all species have become Extinct. See Butchart et al 2004 for further explanation. Source: BirdLife International 2012.

For major taxonomic and/or geographic subdivisions

Figure 3. Percentage of species in each IUCN Red List category for the major seabird families. Figures give number of species. Source: Croxall et al., 2012.

Reviewing the pattern taxonomically (Figure 3) reveals that, of the main families (which together account for 87 per cent of species), the most threatened are the albatrosses/petrels (Diomedidae/Procellariiformes and penguins (Sphenisciformes). Together these represent nearly one half (43 per cent) of all seabirds and contain many pelagic species. Conservation of Diomedidae benefits considerably from ACAP. Within Procellariiformes the genera *Pterodroma* and *Pseudobulweria* are the next most threatened and a special internet forum has recently been established to promote priority conservation action for them: Gadfly Petrel Conservation Group; www.gadflypetrel.ning.com.

2.2 *Special conservation status issues*

Given their imperilled conservation status, many seabirds have been highlighted for special conservation status and action under a range of international, regional and national agreements and mechanisms. However, because seabirds are highly mobile and migrate, they are exposed to vagaries of differing levels of protection across international (and non-governmental) regions. Those agreements and mechanisms currently most actively undertaking work include ACAP (30 species), EU Birds Directive (all seabirds in the EU), the Convention for the Protection of the Marine Environment of the North-East Atlantic³ (OSPAR Convention) (9 species), the Agreement on the Conservation of African-Eurasian Migratory Waterbirds⁴ (82 species), East Asian-Australasian Flyway Partnership (39 species), the [Convention for the Protection of the Mediterranean Sea Against Pollution⁵ \(Barcelona Convention\)](#) (14 species), Convention on the Conservation of Migratory Species of Wild Animals⁶ (CMS; 20 seabird species are listed on Annex I; 50 on Annex II), the Convention on the conservation of European wildlife and natural habitats⁷ (Bern Convention) (over 30 species), Helsinki Commission (HELCOM; 11 species), the Convention on the Protection of the Black Sea Against Pollution⁸ (Bucharest Convention) (2 species), Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR; 7 species), Convention for Arctic Flora and Fauna (3 species), Migratory Bird Treaty Act (139 species), North American Agreement on Environmental Cooperation (1 species), Trilateral Committee for Wildlife and Ecosystem Conservation and Management (1 species), and the Convention on International Trade in Endangered Species of Wild Fauna and Flora⁹ (CITES) (6 species). Other agreements that have this remit but are not yet active include the Nairobi Convention for the Protection, Management and Development of the Marine and Coastal Environment of the Eastern African Region¹⁰ (Nairobi Convention) (47 species), the Regional Convention for the Conservation of

the Red Sea and Gulf of Aden Environment¹¹ (Jeddah Convention) (lists not yet provided by contracting parties), the Convention for Cooperation in the Protection, Management and Development of the Marine and Coastal Environment of the Atlantic Coast of the West, Central and Southern Africa Region¹² (Abidjan Convention) (considering adding a species list), and the Convention for the Protection and Development of the Marine Environment in the Wider Caribbean Region (WCR)¹³ (Cartagena Convention) (5 species). In addition to the above agreements, Regional Fisheries Management Organisations (RFMOs) have also begun to adopt strategies that address incidental seabird bycatch. Level of regulation varies across RFMOs but includes combinations of the use of one or more bycatch mitigation measures in certain areas, data collection through observer programmes and use of monitoring, surveillance and compliance measures.

3. Key pressures linked to trends

The majority of seabirds are highly migratory species that require a variety of marine and terrestrial habitats during different seasons and life stages (Lascelles et al, 2014). Many seabirds are long-lived and slow reproducing. These characteristics make them particularly vulnerable to a wide range of pressures, where even quite small increases in mortality can lead to significant population declines. In addition, many seabirds have highly specialised diets, being reliant on just a few prey species, the abundance and distribution of which can alter dramatically in response to abrupt environmental changes.

Croxall et al. (2012) found that globally, of the top 10 pressures on threatened seabirds (Figure 4), invasive species typically acting at the breeding site potentially affect 73 species (75 per cent) of all threatened seabird species and nearly twice as many as any other single threat, although in some cases the threat is of a potential future impact. The remaining pressures are fairly evenly divided between: (a) those acting mainly at the breeding site, namely problematic native species (e.g. those that have become superabundant - 31 species, 32 per cent), human disturbance (26 species, 27 per cent), infrastructural, commercial, and residential development (14 species, 14 per cent) and (b) those acting mainly at sea in relation to foraging, moulting or migration areas/aggregations, namely, bycatch in longline, gillnet and trawl fisheries (40 species, 41 per cent), pollution (30 species, 31 per cent), overfishing and/or inappropriate spatial management of fisheries (10 species, 10 per cent). Hunting and trapping (23 species, 24 per cent) and energy production and mining (10 species, 10 per cent) affect both domains, the former more at breeding sites, the latter more in relation to foraging areas, flight paths and flyways. Climate change and severe weather (39 species, 40 per cent), as currently assessed, largely reflect adverse weather and flooding at breeding sites. However, the impact of sea

¹³ United Nations, *Treaty Series*, vol. 1506, No. 25974.

level rise is clearly an important driver of change that is increasingly affecting seabirds in many ways, albeit mainly in the medium to long term (i.e., at time frames mostly outside those of relevance to IUCN Red List criteria). The relative importance of threats is largely similar when only those of high impact are considered, although bycatch becomes almost as significant as the effects of invasive alien species (Croxall et al., 2012).

Figure 4: threats to threatened (a) seabirds (n=346 species); (b) pelagic seabirds (n=197 species); (c) coastal seabirds (n=146 species). Source: Croxall et al., 2012.

Commercial fisheries are the most serious at-sea pressure facing the world's seabirds, affecting both adult and juvenile birds. Despite data gaps, each year incidental bycatch in longline fisheries is estimated to kill 160,000-320,000 seabirds from 70 species, although there is evidence of substantially reduced bycatch in some

key fisheries where the pressure has been managed (Anderson et al., 2011). Several papers have reviewed seabird bycatch rates in both demersal (bottom) and pelagic (upper water column) longline fisheries in various regions (e.g., Brothers, 1991; Dunn and Steel, 2001; BirdLife International, 2007; Steven et al., 2007; Bugoni et al., 2008; Rivera et al., 2008; Waugh et al., 2008; Kirby et al., 2009, Waugh et al., 2012), and two assessments have been made on a global scale (Nel and Taylor, 2003; Anderson et al., 2011). The fleets identified as having the highest levels of seabird bycatch include the Spanish hake fleet in the Gran Sol area, the Japanese pelagic tuna fleet in the North Pacific, the Namibian hake fleet and the Nordic demersal fleets (Anderson et al., 2011). The impacts of illegal, unreported, and unregulated fishing (IUU) on seabirds have been estimated in the thousands of individuals each year south of 30° S but are inherently difficult to assess here and elsewhere (Anderson et al., 2011).

Since 1992 a global moratorium has been imposed on the use of all large-scale pelagic drift-net fishing on the high seas, including enclosed and semi-enclosed seas (General Assembly resolution 46/215). Gillnet fisheries (both set and drift nets) are, however, still permitted to operate within a State's Exclusive Economic Zone (EEZ). Although many data gaps remain, hampering assessment, a review of existing data shows that gillnets are responsible for the incidental capture of large numbers of birds, sharks and marine mammals (e.g., Northridge, 1991; Hall, 1998; Tasker et al., 2000; Johnson et al., 2005; Rogan and Mackey, 2007; Žydelis et al., 2013). Amongst birds, the pursuit-diving species, such as divers (loons), grebes, seaducks, auks and cormorants, are the most vulnerable to entanglement (Piatt and Nettleship, 1987; Žydelis et al., 2009). The most recent global review estimated incidental bycatch in gillnet fisheries at 400,000 seabirds from 150 coastal and diving species each year (Žydelis et al., 2013). The highest bycatch has been reported in the Northwest Pacific, Iceland and the Baltic Sea (Žydelis et al., 2013).

Although seabird bycatch in long-line fishing has been known since the 1980s, the threat posed by trawl fisheries has also become apparent in recent years (Bartle, 1991; Weimerskirch et al., 2000; Sullivan et al., 2006). No global review of the impact of trawl fishing on seabirds has been undertaken, but a number of regional and national levels studies highlight the significance of the problem (Gonzalez-Zevallos et al., 2007; Petersen et al., 2008; Yorio et al., 2010) with tens of thousands of 40 larger species of seabird thought to be killed each year. Trawling can also alter benthic habitats which may have indirect impacts on seabirds via the effect this has on forage fish species (see, for example, Chapter 36A).

Fisheries may compete with seabirds for their prey items, and overfishing of both forage species and predatory species that help aggregate food sources for seabirds have been cited as a reason for the decline in several species (e.g., Becker and Beissinger, 2006; Camphuysen, 2005). Cury et al. (2011) assessed prey abundance and breeding success for 14 bird species within the Atlantic, Pacific, and Southern Oceans and found that when less than one third of the maximum prey biomass was available to seabirds, their productivity was adversely affected.

Climate change and severe weather driven by habitat shifts and alterations, storms and flooding, and temperature extremes are already affecting some seabird species. Species' sensitivity and adaptive capacity depend on a suite of taxon-specific biological and ecological traits; as well as the degree to which they are exposed to changes in climate (Foden et al. 2013). Known negative impacts may include loss of habitat, decreased marine productivity causing shifts in location of prey, and shifts in range and migration routes due to changes in winds, ocean currents and sea surface temperature (e.g. Forcada and Trathan, 2009; Hazen et al., 2012; Sydeman et al., 2012).

Pollution in various forms is a widespread problem adversely affecting many seabirds. Oil spills, from both offshore facilities and shipping tankers, can cause mortalities that lead to population-level impacts, particularly when they occur within the most sensitive sites. Single spills have been recorded as killing up to a quarter of a million birds (García et al., 2003) and causing the loss of 7 per cent of regional populations of certain species (Piatt and Ford, 1996). Since its advent, plastic in the form of solid waste materials has become ubiquitous in all oceans of the world and entanglement and ingestion of this material by seabirds is now a widespread problem, affecting at least 100 species (Laist, 1997, Provencher et al. 2014).

Attraction to artificial sources of light has been recorded in at least 21 species of Procellariiformes, as well as in several other seabird groups, and has a detrimental effect on some globally threatened populations (Reed et al., 1985), notably shearwater (e.g. Day et al. 2003) and *Pterodroma* (e.g. Ainley et al. 1997; Le Corre et al. 2002;) species around their breeding colonies. Light-induced seabird collisions at sea, either with fishing vessels (such as those emitting light to catch squid) or with marine oil platforms, are difficult to quantify, occurring episodically particularly in low-visibility conditions and probably exacerbated by seabirds' attraction to bright lights and flares (Ronconi et al 2014). However, up to tens of thousands of seabirds have been observed in a single collision event (Montevecchi, 2006).

Impacts from shipping may include water and air pollution, disturbance, and collision. The level of impact may increase in the future as ship traffic increases, particularly in sensitive areas such as the Arctic, where key seabird habitats and potential shipping routes may overlap, and further exacerbate impacts from predicted climate change (Humphries and Huettman 2014).

4. Major ecosystem services provided by the species group and impacts of pressures on provision of these services

4.1 Services to ecosystems

The role of seabirds as potential indicators of marine conditions is widely acknowledged (e.g., Boyd et al., 2006; Piatt et al., 2007; Parsons et al., 2008). Many studies use aspects of seabird biology and ecology, especially productivity and population trends, to infer relationships with and/or effects on and/or correlate with aspects of the marine environment, particularly food availability.

Seabirds play a key role in nutrient cycling via the shaping of the plant community in their terrestrial and coastal breeding habitat. Seabirds transport allochthonous nutrients (i.e., fixed nitrogen, phosphorus, and trace elements), mainly via their guano, to seabird colonies (i.e., cross-ecosystem subsidies). They also shape plant communities in their breeding habitat by creating physical disturbance, dispersing seeds, and bioturbating the soil with their burrowing (Ellis, 2005; Bancroft et al., 2005). These functions provided by seabirds increase productivity and diversity in terrestrial and coastal ecosystems surrounding seabird colonies (Powell et al., 1991; Bosman et al., 1986; Brimble et al., 2009).

4.2 *Direct services to humans including economic and livelihood services*

Seabirds contribute several provisioning (e.g., protein, guano) services, play an important cultural role in many countries (e.g., for the Maori of New Zealand and the Tsimshian of Alaska), and feature in Greek, Hawaiian and Christian mythology. Seabird breeding colonies are increasingly used as a means to generate tourism income.

Seabird guano has excellent properties as a natural fertilizer enriching both terrestrial (Havik et al. 2014) and marine (Gagnon et al. 2013) environments. It consists of nitrogen-rich ammonium oxalate and urate, phosphates, as well as some earth salts and impurities. It typically contains 8 to 16 per cent nitrogen (the majority of which is uric acid), 8 to 12 per cent equivalent phosphoric acid, and 2 to 3 per cent equivalent potash. Archaeological evidence suggests that Andean peoples have collected seabird guano for well over 1,500 years (Collar et al., 2007). A harvest boom in the nineteenth century, called the “white gold rush”, saw tens of thousands of workers extracting guano from the Peruvian seabird breeding islands and loading thousands of tons onto each ship. Other harvested guano islands were located in the Caribbean, atolls in the Central Pacific, and off the coast of Namibia, South Africa, Oman, Patagonia, and Baja California (Skaggs, 1994). This unsustainable harvest resulted in massive deposits of guano, in some cases more than 50 m deep, being severely depleted. Many areas of the industry collapsed, although some Peruvian islands are still managed for guano on a rotational system (Méndez, 1987).

Harvesting of seabird adults, chicks, eggs, and feathers have been important activities for some coastal communities for many centuries, but have also driven seabird declines. Bones were used to make fishing hooks and musical instruments and to engrave tattoos; feathers featured prominently in the millinery trade and are still used in some countries for local arts and handicrafts, e.g., to make cloaks and hair adornments (Spennemann, 1998). The meat and eggs still form key sources of protein. Harvest methods have changed over time to include more efficient tools, making the seabirds more exposed to excessive harvesting. Declines in a number of species have been attributed to over-exploitation. Harvesting quotas exist in some areas, such as in the Seychelles (limited to 20 per cent of Sooty Tern eggs each year), New Zealand (limited to 13 per cent of Sooty Shearwater chicks each year (Newman et al., 2009), and the United Kingdom (limited to 2,000 Northern Gannet each year).

However, unregulated harvesting is a substantial problem in the entire Arctic region (2 million adults and countless eggs of several species of Alcidae are taken each year (Merkel, 2008)), the Tuamotus and the Marquesas (egg collection), Peru (Waved Albatross and Humboldt Penguin), Madagascar (egg collection), Jamaica (egg collection (Haynes, 1987)) and Indonesia.

For centuries fishers have used seabirds as a visual guide to locate fishing areas. They remain important for artisanal operations (such as in Hawaii, Comoros, Madagascar and Tanzania), which search for flocks of seabirds in order to find fish. Without seabirds, these livelihoods (e.g., catching small skipjack and juvenile yellow-fin tuna) could disappear or be substantially adversely affected.

Viewing seabirds is an increasingly popular pastime for many tourists; many spectacular breeding colonies are accessible to visitors and revenues generated contribute substantially to local economies (Steven et al., 2013). For example, in Australia, the Phillip Island Little Penguin colony receives half a million visitors a year, spending 35 million Australian dollars (Marsden Jacob Associates, 2008). A single African Penguin colony in South Africa generates United States dollars 2 million/yr in tourist revenue (Lewis et al., 2012). In New Zealand, nature-based tourism relying primarily on the Yellow-eyed Penguin returned 100 million dollars annually to the Dunedin economy, hence a single breeding pair could be worth 60,000 dollars/yr (Tisdell, 2008). The Royal Society for the Protection of Birds (RSPB) estimated that four of its seabird reserves in the UK (one each in England, Northern Ireland, Scotland and Wales) together generated around 1.5million dollars/yr for the local economies (RSPB 2010). Tourism in the Galapagos is thought to generate over 62 million dollars each year; seabirds are a prime reason for visiting. Pelagic trips to view seabirds at sea have also become popular, particularly in Europe, North America and the Southern Ocean. The value of these trips has not been quantified to any degree, but is likely to be significant; for example, 80,000 dollars was spent on a single pelagic trip off South Africa (Turpie and Ryan, 1999).

5. Conservation responses and factors for sustainability

Data on seabird distribution, abundance, behaviour and pressures can be used to inform the design of effective management regimes (Lascelles et al 2012). Management decisions can be guided by: (1) where the key areas are, (2) when these areas are used, (3) what variables explain seabird presence in a given area, (4) the threat status of species in a given area, (5) what pressures may be adversely affecting the species, associated habitats and processes, (6) what management actions are needed to address these threats, and (7) how any management intervention can best be monitored to assess its effectiveness.

Depending on the species, the priority actions needed may involve: (a) formal and effective protection of the most important sites. For site protection to be effective, it should ensure that areas are large enough to capture critical behaviour (such as key breeding sites, the marine areas around them used for maintenance and more

distant feeding and aggregation sites), consider temporal and spatial variations, and have adequate regulation to minimise effects of any pressures. Where national, regional and global networks of Marine Protected Areas (MPAs) are being developed, inclusion of key sites in those networks would contribute substantially to the necessary site protection; (b) removal or control of invasive, and especially predatory, alien species from areas used for seabird breeding, feeding and/or aggregation, as part of habitat and species recovery initiatives; and (c) reduction of bycatch to levels that do not pose a threat of species decline. For many uncommon species or species of low productivity, this likely can only be achieved when bycatch is reduced to near zero. Other, more generic actions, such as education and awareness-raising and accompanying stakeholder involvement, are also high priorities, as are some more species-specific activities, such as harvest management, species reintroductions and species recovery. Although it is relatively straightforward to derive these generic recommendations for conservation action, it can be costly and difficult to implement them effectively and at a sufficient scale to make a difference to the conservation status of seabird species. However, progress has been achieved in recent years in terms of the three highest priority actions, but despite these successes, problems will continue without further action.

Where simple seabird mitigation measures have been implemented, there is evidence of substantially reduced bycatch in some key fisheries where the pressure has been managed (e.g. Anderson et al., 2011), including a greater than 95 per cent reduction in some areas (Maree et al., 2014). The main tuna RFMOs now have voluntary or binding regulations in place that require the use of a combination of mitigation techniques in different geographies, though their effectiveness may be hampered by a lack of monitoring and/or enforcement.

Key sites for seabirds have begun to be protected in several countries, primarily covering selected breeding sites on land, though marine designation for seabirds has also advanced, with new MPAs in Europe, the Antarctic and the Americas in recent years. Where eradications and/or controls of invasive alien species have been undertaken, recoveries of seabird populations have been rapid and dramatic (e.g. Pitman et al., 2005), and a great number of larger islands are now being tackled. Translocations of some species to new locations have also proved an effective conservation strategy for several species (e.g. Carlile et al., 2003; Madeiros 2004).

Actions that are implementing an ecosystem approach to capture fisheries management are discussed in Part IV of this assessment; many of those measures, including better management of selectivity of fishing gear and including ecosystem feeding requirements in setting fishery harvest limits, will contribute to improving the conservation status of seabirds if implemented effectively.

Chapter 39. Marine Reptiles

Contributors: Bryan P. Wallace (convenor), Peter H. Dutton, Maria Angela Marcovaldi, Vimoksalehi Lukoschek, Jake Rice (Lead Member and Editor Part VI Biodiversity)

1. Assessment Frameworks

Although several other frameworks assess marine turtle status at global and sub-global scales, in this chapter we focus on results from the International Union for the Conservation of Nature (IUCN) Red List assessments and the IUCN Marine Turtle Specialist Group's conservation priorities portfolio (Wallace et al., 2011) because these are the most comprehensive and widely recognized assessment frameworks at present. For a comprehensive summary of other assessment frameworks for marine turtles, please see Chapter 35. In this chapter, we provide an overview of the two above-mentioned IUCN assessments with regard to marine turtles, and we also present available information on the conservation status of sea snakes and marine iguanas.

2. Status Assessments

2.1 *IUCN Red List*

The primary global assessment framework for marine turtle species is the IUCN *Red List of Threatened Species*TM (www.iucnredlist.org). The universally applicable criteria and guidelines of the Red List make it the most widely used and accepted framework for assessing the conservation status of species worldwide.

The IUCN Marine Turtle Specialist Group (MTSG), one of the IUCN/Species Survival Commission's specialist groups, is responsible for conducting regular Red List assessments of each marine turtle species on a global scale. However, because marine turtle population traits and trajectories can vary geographically, the global extinction risk assessment framework represented by the Red List does not adequately assess the conservation status of spatially and biologically distinct marine turtle populations (see Seminoff and Shanker, 2008 for review).

2.2 *Subpopulation or regional assessments*

To address the challenges presented by the mismatched scales of global Red List assessments and regional/population-level variation in status, the MTSG developed an alternative assessment framework and a new approach to Red List assessments that better characterize variation in status and trends of individual populations (Wallace et al., 2010; Wallace et al., 2011; see next section). This new approach centres on assessing

marine turtle subpopulations, as well as the global population (i.e., species), using Red List guidelines, which results in official Red List categories for subpopulations in addition to the single global listing. This working group first developed regional management units (RMUs) (i.e., spatially explicit population segments defined by biogeographical data of marine turtle species) as the framework for defining biologically meaningful population segments for assessments (Wallace et al., 2010). RMUs are functionally equivalent to IUCN subpopulations, thus providing the appropriate demographic unit for Red List assessments. Next, the group developed a flexible yet robust framework for assessing population viability and degree of threats that could be applied to any subpopulation in any region (Wallace et al., 2011). Population viability criteria included abundance, recent and long-term trends, rookery vulnerability, as well as genetic diversity, and threats included by-catch (i.e., incidental capture in fishing gear), human consumption of turtles or turtle products, coastal development, pollution and pathogens, and climate change. The final product was a “conservation priorities portfolio” for all subpopulations globally. It includes identification of critical data needs, as well as risk and threats criteria by subpopulation, and reflects the wide variety of conservation objectives held by different stakeholders, depending on institutional or regional priorities.

3. Conservation Status of Marine Reptiles

3.1 Marine Turtles

Currently, global Red List categories for marine turtle species are: Vulnerable (leatherback, *Dermochelys coriacea*; olive ridley, *Lepidochelys olivacea*), Endangered (loggerhead, *Caretta caretta*; green turtle, *Chelonia mydas*), Critically Endangered (Kemp’s ridley, *Lepidochelys kempii*; hawksbill, *Eretmochelys imbricata*), and DataDeficient (flatback, *Natator depressus*).

However, as mentioned above, the MTSG is actively appraising Red List assessments to include all subpopulations, as well as the global listing for each marine turtle species. In 2013, the MTSG completed the first complete suite of subpopulation assessments—in addition to the global listing—for any marine turtle species (Wallace et al., 2013a). The updated Red List assessments for leatherback turtles changed the global status for this species from Critically Endangered to Vulnerable—due to new data becoming available and to one large and increasing subpopulation (Northwest Atlantic Ocean)—and added new listings for each of the seven leatherback subpopulations, which ranged from Critically Endangered (East Pacific Ocean; West Pacific Ocean; Southwest Atlantic Ocean; Southwest Indian Ocean) to Least Concern (Northwest Atlantic Ocean) to Data-Deficient (Southeast Atlantic Ocean; Northeast Indian Ocean) (Wallace et al., 2013a). Updated global and subpopulation assessments are expected to be completed in 2016-2018.

3.2 MTSG's conservation priorities portfolio

Marine turtle Red List assessments have been and will continue to be informed by the MTSG's conservation priorities portfolio (Wallace et al., 2011), the results of which are presented briefly here.

Average values of population risk and threats criteria across marine turtle subpopulations assessed by Wallace et al. (2011) are presented in Table 1. Globally, long-term population trends are declining on average across marine turtle subpopulations, but are stable or perhaps even increasing in recent years (Table 1). In general, population viability criteria tend to cluster around moderate values across subpopulations.

At ocean-basin scales (i.e., Atlantic Ocean and Mediterranean Sea, Indian Ocean, Pacific Ocean), subpopulations in the Pacific Ocean had the highest average risk (i.e., population viability) score, whereas subpopulations in the Atlantic Ocean (as well as in the Mediterranean Sea) had the highest average risk and threats score (Table 2). Indian Ocean subpopulations had the highest average data uncertainty scores for both risk and threats (Table 1), as well as the most populations assessed as "critical data needs" (Table 3).

One-third of all marine turtle subpopulations were assessed as "high risk-high threats"—i.e. low, declining abundance and low diversity simultaneously under high threats—which could be considered as the world's most endangered populations (Wallace et al., 2011). Between 20 and 30 per cent of subpopulations in each ocean basin were "high risk-high threats" (Table 3). More than half of *E. imbricata* subpopulations and roughly 40 per cent of *C. caretta* and *D. coriacea* subpopulations were categorized as High Risk-High Threats (Fig. 1).

One-fifth of marine turtle subpopulations globally were categorized as "low risk-low threats"—i.e., high and stable or increasing abundance, high diversity while experiencing low to moderate threats—a pattern that was reflected at the ocean-basin scale as well (Table 2). These included five *C. mydas* subpopulations, three *E. imbricata* subpopulations, two *D. coriacea* subpopulations, and one each for *C. caretta* and *L. olivacea* (Fig. 1).

These results illustrate both the large degree of variation and level of uncertainty in the conservation status of marine turtles within and among species and regions, as well as the importance of flexible assessment frameworks capable of reflecting these sources of variation.

3.3 Sea snakes

Elapid sea snakes comprise two evolutionary lineages: live-bearing true sea snakes (at least 63 species) and egg-laying amphibious sea kraits (genus *Laticauda* - 8 species). True sea snakes are further divided into two monophyletic groups, the *Aipysurus* group (> 10 species in two genera, predominantly associated with coral reefs) and the

Hydrophis group (> 50 species in ten nominal genera, mostly associated with inter-reefal habitats) (Lukoschek and Keogh, 2006). Marine elapids are found throughout the Indian and Pacific Oceans, but do not occur in the Atlantic Ocean, Mediterranean or Caribbean Seas. Highest species richness occurs in Southeast Asia and northern Australia (Elfes et al., 2013). Marine snakes are poorly studied: new species continue to be described, and revisions to taxonomic status and geographic ranges are not uncommon, resulting in changes in the numbers of recognized species and complicating assessments of their conservation status.

In 2009, the first Red List global marine assessment of extinction risk was conducted for 67 of the 71 elapid sea snake species recognized at the time (Elfes et al., 2013). Six species were classified in one of the threatened categories (Critically Endangered, Endangered or Vulnerable) and four species were classified as Near Threatened. The three most threatened species were *Aipysurus* congeners, two of which were Critically Endangered (*A. apraefrontalis* and *A. foliosquama*) and one Endangered (*A. fuscus*). At the time of the Red List Assessments, these three species were regarded as being endemic to a small number of reefs in the Timor Sea, where they had undergone catastrophic population declines since the mid-1990s (Lukoschek et al., 2013). However, recent sightings of at least one of these three species on coastal reefs in Western Australia suggest that further research is needed to confirm their true geographic ranges (Lukoschek et al., 2013). Of the eight species of *Laticauda*, two were classified as Vulnerable and three as Near Threatened (Elfes et al., 2013). Both Vulnerable species of *Laticauda* were small-range endemics (*L. crockeri* restricted to Lake Te-Nggano in the Solomon Islands; *L. schistorhyncha* to Niue), as were two of the three Near Threatened species (*L. frontalis* occurring only in Vanuatu and the Loyalty Islands; *L. guineai* restricted to Southern New Guinea). The third Near Threatened species, *L. semifasciata*, had undergone significant historical declines in the Philippines due to harvest for skin and food. *Hydrophis semperi* (endemic to Lake Taal in the Philippines, was classified as Vulnerable, and *Hydrophis pacificus* (endemic to North-east Australian waters) was classified Near Threatened. Of the remaining 57 species, 34 were classified as of Least Concern and 23 as Data-Deficient (Elfes et al., 2013). Several species classified as Data-Deficient are known only from a few museum specimens collected many years ago and may not be valid species. At the same time, some species listed as Data-Deficient may, in fact, be threatened and clarification of threat status for Data-Deficient species is needed (Elfes et al., 2013).

3.4 Marine iguanas

Marine iguanas (*Amblyrhynchus cristatus*) are the world's only marine lizard species, and are endemic to the Galápagos Islands (Ecuador). Ten subpopulations occur on separate islands within the archipelago, but the status of most of these subpopulations is unknown. Marine iguanas occupy rocky coastal areas and intertidal areas, and forage on marine algae in nearshore waters (Nelson et al. 2004). Although abundance estimates are unavailable for seven of the subpopulations, abundance estimates of

three subpopulations range between 1,000-2,000 individuals (Rabida Island), 4,000-10,000 (Marchena Island), and 15,000-30,000 (Santa Fe Island) (Nelson et al. 2004). Due to their restricted distribution and area of occupancy, marine iguanas are classified as Vulnerable according to the IUCN Red List (Nelson et al. 2004).

4. Threats to Marine Reptiles Globally

4.1 Marine Turtles

Dutton and Squires (2011) highlight the need for a holistic conservation approach that addresses all sources of mortality and deals with the trans-boundary nature of these multiple threats. Decades of over-harvest of eggs on nesting beaches have driven historic declines of some breeding populations, rendering them more vulnerable to impacts from fisheries by-catch and other threats. According to Wallace et al. (2011), fisheries by-catch was scored as the highest threat across marine turtle subpopulations, followed by human consumption and coastal development (Table 1). Climate change was scored as Data-Deficient in two-thirds of all RMUs, whereas pollution and pathogens were scored as Data-Deficient in more than half of all RMUs (Table 1).

A recent global assessment of fisheries by-catch impacts documented the Mediterranean Sea, Northwest and Southwest Atlantic, and East Pacific Oceans as regions with particularly high by-catch threats to marine turtle subpopulations (Wallace et al., 2013b). This assessment also highlighted the disproportionately large impact that by-catch in small-scale fisheries in coastal areas can have on marine turtle populations. Efforts to reduce turtle by-catch have included changes in gear configuration and/or fishing method, time-area closures, and enforcement of by-catch quotas, but by-catch reduction has only been successful when tailored to local environmental factors and characteristics of fishing gear and methods (Lewison et al., 2013). At a global scale, the FAO has adopted guidelines to reduce sea turtle mortality in fishing operations and encourages States to adopt and implement sea turtle by-catch reduction measures according to the those guidelines. Human consumption of marine turtles and turtle products has occurred as traditional and subsistence use, as well as commercially, around the world for centuries. The full magnitude of the effects of this human consumption on marine turtle populations has not been quantified, but unsustainable rates of consumption have contributed to declines in abundance in several places (e.g., *C. mydas*, *D. coriacea*, *L. olivacea* in the East Pacific Ocean, Abreu-Grobois et al., 2008; Seminoff and Wallace, 2012; *E. imbricata* in the Wider Caribbean, Southeast Asia, West Pacific; Mortimer and Donnelly, 2008). Consumption of turtles and turtle products has been reduced in recent decades due to top-down enforcement of national and international regulations against trade and use of turtle products (e.g., Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), national endangered species laws), but both legal and illegal turtle harvest continues in many countries (Humber et al., 2014).

Although climate change has been suggested as a major potential threat to marine turtles globally—e.g., possible skewing of sex ratios (which are controlled by temperature), habitat alteration related to increased frequency and severity of storms affecting nesting beaches, among other effects (Hamann et al. 2013)—specific impacts have not been quantified widely to date (Wallace et al., 2011). Increased beach sand and air temperatures and decreased precipitation might negatively affect hatchling production from nesting beaches, and fluctuating oceanographic conditions might alter migratory routes and foraging areas (Hawkes et al., 2009). More quantitative analyses of potential impacts to marine turtles related to climate change are warranted.

4.2 *Sea Snakes*

Sea snakes are a diverse group of meso-predators with varying habitat and prey requirements that range on a spectrum from being generalists to highly specialised. Some species of true sea snakes occur predominantly in inter-tidal and estuarine habitats, others are restricted to coral reefs, and others occur in reefal, inter-reefal and estuarine habitats. Egg-laying amphibious sea kraits require intact coral reefs for feeding, as well as intertidal and terrestrial sites for nesting and resting. In terms of diet, generalist species feed on a variety of small fish, eels, squid, and crustaceans, whereas dietary specialists, such as *Emydocephalus* spp., exclusively forage on eggs of small reef fish, and most sea kraits forage exclusively on eels. Range extents also vary enormously, with some species having extensive ranges (Persian Gulf to Australia), and others being restricted to a single island or inland lake, or a handful of coral reefs. The differing ecologies, diets and geographic ranges mean that potential threatening processes vary among species and among geographically disparate populations of the same species.

Globally sea snakes are taken as by-catch, particularly in trawl fisheries in inter-reefal and/or estuarine habitats. Most information about the nature and extent of sea snake by-catch comes from northern and eastern Australia, and indicates that species composition and abundance vary spatially, temporally and between fisheries (Courtney et al., 2009). For example, trawl fisheries on Queensland's east coast catch > 100,000 sea snakes from 12 species annually, of which approximately 25 per cent die; however, 59 per cent of all sea snake catches and ~85 per cent of deaths occur in just one fishery, due to the spatial overlap of habitats between the red-spot king prawns, *Melicertus longistylus*, being harvested and reef-associated sea snakes (Courtney et al., 2009). Nonetheless, risk assessments for Australia's Northern Trawl Fishery indicated that no sea snake species was at risk under the existing fishing effort (Milton et al., 2008). While the use of by-catch reduction devices (BRDs), which are placed the regulation 120 meshes from the codend drawstring, did not reduce sea snake by-catch (Milton et al., 2008), the use of some BRDs placed closer to the drawstring (<70 meshes) has been shown to reduce the number of snakes taken by 40-85 per cent without significant prawn loss (Milton et al., 2008).

In Southeast Asia, many reptile species are heavily harvested for the commercial food, medicine and leather trades; however, very limited information exists about the extent to which marine snakes are targeted and about potential impacts (Auliya, 2011). To some extent, this lack of information probably reflects the fact that to date no sea snake species has been CITES-listed. One anecdotal account of a tannery in West Malaysia indicates that over 6,000 spine-bellied sea snakes (*Lapemis curtus*) were harvested per month (Auliya, 2011), suggesting that the impact might be high if this account is representative of other locations. Nonetheless, *L. curtus* has a large geographic range, is a voracious generalist predator (feeding on a variety of small fish, eels, squid, crustaceans) and typically occurs in large numbers in many habitat types, so it may be able to sustain heavy harvests (Auliya, 2011).

The three most threatened sea snake species are endemic to coral reefs in the Timor Sea, including Ashmore Reef, a renowned sea snake biodiversity hotspot. Species diversity at Ashmore Reef has declined from at least nine species in 1973 and 1994 to just two species in 2010 (Lukoschek et al., 2013) and abundances have declined > 90 per cent from the estimated standing stock of > 40,000 snakes in the mid-1990s (Guinea and Whiting, 2005; Lukoschek et al., 2013). In addition to the three threatened species from the genus *Aipysurus*, two species that disappeared (*Aipysurus duboisii*, endemic to Australasia, and *Emydocephalus annulatus*, also in the *Aipysurus* group), typically occur on coral reefs, suggesting that their declines might be due to loss or degradation of reef habitats. Reef-associated sea snakes shelter and forage under ledges and within the reef matrix, where they might be affected by reductions in coral cover, diversity and habitat complexity following coral bleaching events. A mass bleaching event in 2003 caused widespread coral mortality at Ashmore Reef; however, the most pronounced sea snake declines occurred between the mid-1990s and 2002 (Lukoschek et al., 2013), preceding the 2003 coral loss. The cause of these declines is unknown (Lukoschek et al., 2013). Widespread bleaching associated with the 1998 El Niño event affected many Australian reefs, including Scott Reef in the Timor Sea, but Ashmore Reef experienced minimal coral loss in 1998 (Lukoschek et al., 2013). Moreover, two additional species that disappeared from Ashmore Reef (*Hydrophis coggeri* and *Acalyptophis peroni*) were predominantly associated with soft-sediment habitats. Illegal harvesting on Timor Sea reefs targets invertebrates and sharks, but there is no evidence that sea snakes have ever been taken (Lukoschek et al., 2013). Moreover, Ashmore Reef was declared a National Nature Reserve (IUCN Category 1a) in 1983 and a National Parks or Customs presence, maintained for much of the year since 1986, has limited illegal fishing at Ashmore Reef (Lukoschek et al., 2013). Similar declines of *Aipysurus* group species have occurred on protected reefs in New Caledonia (Goiran and Shine, 2013) and the southern Great Barrier Reef (Lukoschek et al., 2007a). Possible reasons for these apparently enigmatic declines of sea snakes include reproductive failure due to the sub-lethal or lethal effects of increased sea surface temperatures, disease, and pollution; however, compared with other marine vertebrates, limited research has been conducted quantifying the extent to which these processes affect sea snakes. There has been no research into the effects of ocean acidification on sea snakes.

Sea snakes tend to have highly patchy or aggregated distributions throughout their ranges. Genetics research on species from the *Aipysurus* group (Lukoschek et al., 2007b; Lukoschek et al., 2008; Lukoschek and Shine, 2012) suggests that dispersal (gene flow) between geographically disparate populations is limited and that local population declines or extinctions are unlikely to be reversed by dispersal over ecological time-scales relevant for conservation (Lukoschek et al., 2013).

4.3 *Marine Iguanas*

Periods of extremely high water temperatures and poor nutrient availability associated with El Niño events cause declines in food resources available to marine iguanas; dramatic (60-90 per cent) population declines related to El Niño have been documented (Vitousek et al. 2007). Introduced predators could also negatively affect marine iguana populations on some islands (Nelson et al. 2004). Increased stress responses and related changes in immune function have been documented in marine iguanas subject to consistent presence of tourists, which could pose a significant sub-lethal threat, particularly when compounded by periods of low resource availability (French et al. 2010).

5. Assessment and Conservation Needs

In general, an urgent need remains for enhanced monitoring and reporting of marine reptile population status and trends, as well as of threats to marine reptiles globally. For example, insufficient information was available to assess recent and long-term trends for roughly 25-30 per cent of all subpopulations, and threats such as climate change also remain poorly quantified (Wallace et al., 2011). Significant efforts to quantify fundamental marine reptile demographic rates and processes (NRC, 2010) are still required to improve assessments of marine reptile status at global, regional, and local scales. Understanding biogeographical factors that influence the biology and ecology of marine reptiles, as well as the anthropogenic pressures on marine reptile species and populations, will improve status assessments and inform conservation strategies.

Table 1. Average values of population risk and threats criteria across marine turtle subpopulations. Scores range from 1 (high abundance, increasing trends, high diversity, low threats) to 3 (low abundance, declining trends, low diversity, high threats).

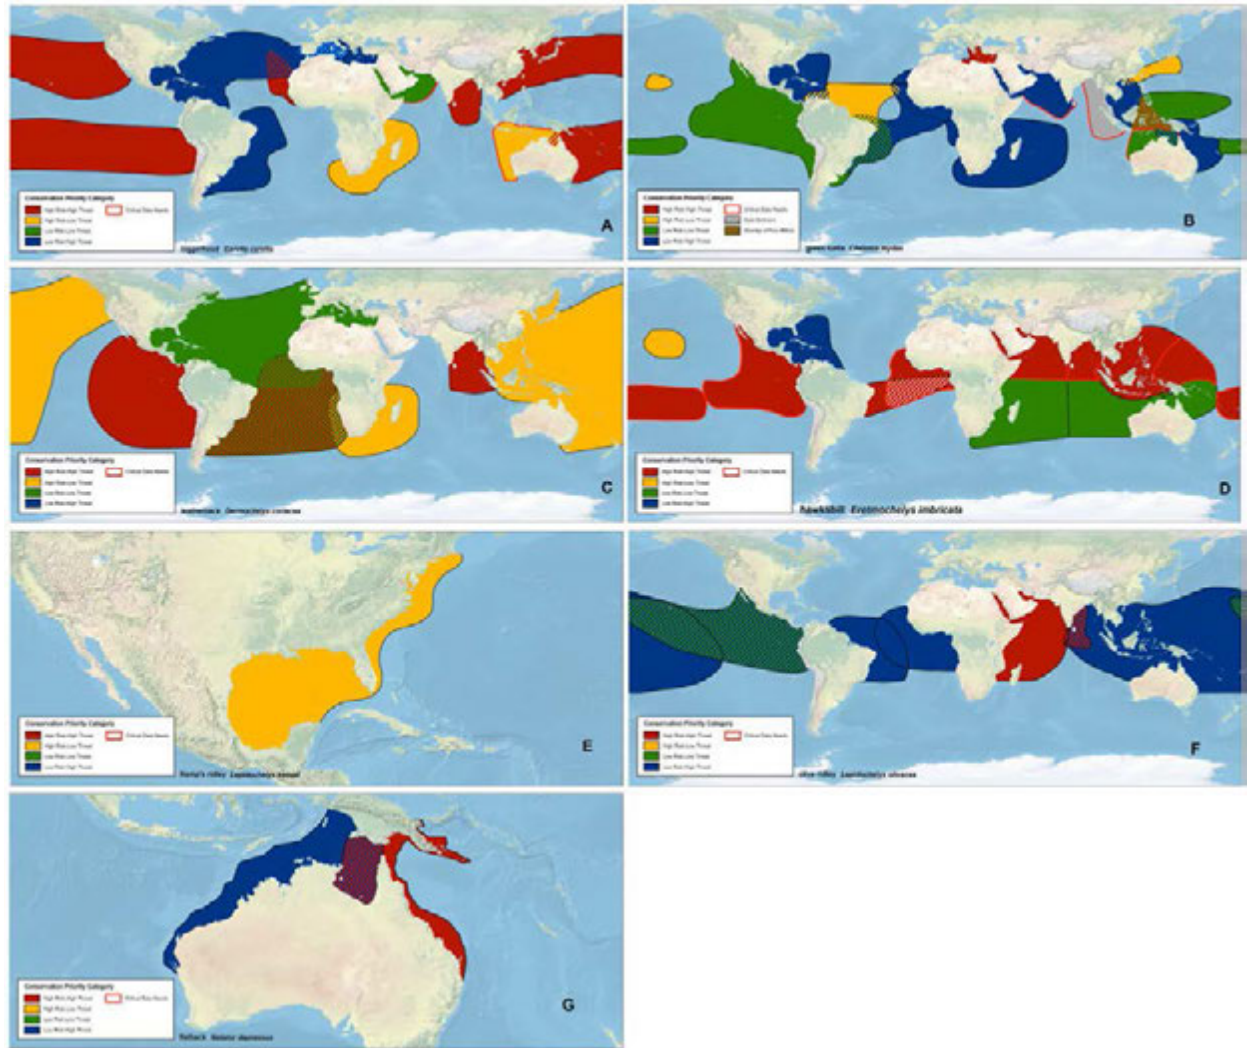

RISK SCORES					
	population size	recent trend	long-term trend	rookery vulnerability	genetic diversity
mean	1.95	1.81	2.47	1.72	1.90
No. subpop'ns scored	58	43	38	57	58
THREATS SCORES					
	fisheries by-catch	human consumption	coastal development	pollution and pathogens	climate change
mean	2.21	2.08	1.93	1.70	2.20
No. subpop'ns scored	56	57	53	25	20

Table 2. Average risk and threats scores (and accompanying data uncertainty indices) of subpopulations that occur in each ocean basin.

ocean basin	average risk score	average risk score data uncertainty	average threats score	average threats score data uncertainty
Atlantic/Med (n=19)	1.81	0.26	2.16	0.35
Indian (n=18)	1.92	0.78	2.08	0.68
Pacific (n=21)	2.03	0.32	1.96	0.48

Table 3. Categories in which RMUs occurred in each basin (including critical data needs RMUs). Categories: HR-HT=High Risk-High Threats; HR-LT=High Risk-Low Threats; LR-LT=Low Risk-Low Threats; LR-HT=Low Risk-High Threats. * One RMU (*C. mydas*, northeast Indian Ocean) was scored critical data needs only.

ocean basin	Categories					Total
	critical data needs	HR-HT	HR-LT	LR-LT	LR-HT	
Atlantic/Med (n=19)	1	5	2	3	9	19
Indian (n=18) *	8	6	3	4	4	17*
Pacific (n=21)	3	8	4	5	4	21
Total	12	21	9	12	15	57*

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Conservation status of marine turtles: Four conservation priority categories are displayed: (red) high risk – high threat, (yellow) high risk – low threat, (green) low risk – low threat, (blue) low risk – high threat. Panels: (A) loggerheads (*Caretta caretta*), (B) green turtles (*Chelonia mydas*), (C) leatherbacks (*Dermochelys coriacea*), (D) hawksbills (*Eretmochelys imbricata*), (E) Kemp’s ridleys (*Lepidochelys kempii*), (F) olive ridleys (*Lepidochelys olivacea*), (G) flatbacks (*Natator depressus*). Subpopulations were classified as having critical data needs (outlined in red) if the data uncertainty indices for both risk and threats ≥ 1 (denoting high uncertainty). Hatched areas represent spatial overlaps between subpopulations. The brown area in panel B highlights an overlap of four subpopulations, and the grey area in panel B represents the *C. mydas* Northeast Indian Ocean subpopulation, which had excessive data-deficient scores and was not included in overall calculations and categorization. Figure from Wallace et al. (2011) PLoS ONE 6(9): e24510. doi:10.1371/journal.pone.0024510.

Chapter 40. Sharks and Other Elasmobranchs

Contributors: Steven E. Campana and Francesco Ferretti, Andrew Rosenberg (Lead member)

Sharks and rays are among the most endangered group of marine animals and include many species for which there is little information on abundance and distribution. There are no global abundance trends for elasmobranchs as a group, and very few robust regional trend indicators. Population-level stock assessments, which provide the most reliable index of abundance, are available for only about 10 per cent of 1,088 chondrichthyan species (FAO 2012; Worm et al., 2013; Dulvy et al., 2014; Cortés et al. 2012). Almost all of these assessments report a depleted and/or over-exploited population. In light of the scarcity of time series of absolute abundance indicators, the conservation status of elasmobranchs as a group is most commonly based on trends in reported landings, trajectories of standardized catch rates or indices of current status.

1. Global catches and trends

Global landings of sharks, rays and chimaeras (chondrichthyans) as reported to the Food and Agriculture Organization of the United Nations (FAO) have increased steadily since the 1950s, peaking at about 888,000 mt in 2000 before declining (Figure 1). In 2012, landings were 14 per cent lower than in 2000. The increasing trend in global catches reflected a combination of fisheries expansions into previously-unexploited regions, changes in the species composition of catches, and changes in the way countries reported landed catch for sharks and rays (e.g. changes in the taxonomic resolution of the reported landings; Ferretti et al. 2010). Historically, many species of sharks and rays had low commercial value, and were not regularly recorded in fisheries statistics. Since the 1980s, sharks became an alternative resource for some fisheries as many fish stocks collapsed and demand for shark fins in Asian markets strongly increased. The resulting increased fishing pressure on elasmobranchs and reports of severely depleted populations attracted the attention of management agencies, which increasingly reported shark statistics.

Although it has been assumed that the recent decline in reported landings may reflect better management for the species (FAO 2010), a recent analysis of the FAO chondrichthyan landings disaggregated by countries (Davidson et al. 2015) evaluated the importance of direct and indirect indices of fishing exploitation and measures of fisheries management performance, revealing that the decline is more closely related to fishing pressure and population declines (Eriksson and Clarke 2015, Davidson et al. 2015). Yet reported landings continue to be a gross underestimation of actual catches (Dulvy et al. 2014). Catches estimated from the volume of the shark-fin trade suggest

global shark catches are on the order of 1.7 million mt in recent years (Clarke et al., 2006). More recently, Worm et al. (2013), using various assumptions about reporting rate, discarding and post-release mortality, derived a similar global estimate of 1.41 million mt in 2010, which is twice the figure reported from FAO statistics. Not included in that value would be any post-release mortality of discarded, unfinned catch. Thus, actual trends in shark catch and landings are unknown. Similar reporting issues confound shark catch statistics reported by other regional fisheries management organizations (RFMOs), such as is the case with blue sharks reported by International Commission for the Conservation of Atlantic Tunas (Campana et al., 2006).

Figure 1. Trends in reported landings of elasmobranchs as reported to FAO. The trend line for the Atlantic includes the Mediterranean.

Regional differences in the status of shark and ray populations might reflect different histories of fishing exploitation (Figure 1). The North-West Pacific, North-East Atlantic and Mediterranean were the areas where industrial fisheries began before the 1950s. These three areas, in decreasing order, recorded the highest initial catches per unit shelf area. The North Atlantic, Mediterranean, around Australia and New Zealand, and the North Pacific are the regions with the longest history of intensive fishing, but are also among the best-monitored sectors of the world's oceans, with stock assessments available for some species. The analysis of International Union for the Conservation of Nature (IUCN) Red List species indicated that these regions (as a group) were somewhat less likely to have a higher proportion of threatened species (<20 per cent) than were the less populated Indian, central Pacific and south and central Atlantic Oceans (>20 per cent) (Dulvy et al., 2014). Unassessed fisheries in the central Pacific and central and southern Atlantic were also likeliest to be characterized by low relative biomass on the

basis of time series of catch and fisheries development, and species life histories traits (Costello et al., 2012); this is indicative of overfishing.

1.1 Conservation status

A comprehensive analysis of 1,041 chondrichthyan species on the IUCN Red List (www.redlist.org) reported that 17 per cent of the species were considered threatened with extinction (Critically Endangered, Endangered or Vulnerable, Dulvy et al., 2014). Moreover, just 241 species (23 per cent of the total) were considered to be safe from extinction threats (categorized as Least Concern according to IUCN criteria), which is the lowest fraction of safe species among all vertebrate groups studied by IUCN to date. Assessed shark and ray species with large body sizes were considered to be in the most danger, especially those living in shallow waters that were accessible to fisheries. Almost half of the examined species (47 per cent) were considered data-deficient, meaning that their conservation could not be assessed for lack of adequate data on abundance and distribution. However, in an independent study, Costello et al. (2012) used a multivariate regression analysis of assessed finfish species to estimate the current population biomass relative to maximum sustainable yield (MSY) in 1,793 unassessed marine fisheries around the world. Chondrichthyans had the lowest relative biomass values (40 per cent of the MSY (optimal) level) of any fish species or group; this was considered indicative of considerable over-exploitation (Costello et al., 2012).

2. Drivers of shark decline

2.1 Sharks are intrinsically vulnerable

Most sharks and rays are characterized as having low productivity associated with low fecundity, a slow growth rate, and a late age at sexual maturation (Musick, 1999). These life history characteristics are more similar to those of marine mammals than of the more productive bony fishes (Myers and Worm, 2005), which make them particularly susceptible to fishing pressure (Walker, 1998). Deep-sea sharks appear to be particularly susceptible, due to their very low productivity (Clarke et al., 2003; Forrest and Walters, 2009).

However, the similarity of their environmental preferences to several commercially valuable teleost species can also increase the likelihood of their capture in some fisheries. For example, blue shark catch rates and seasonal distributions tend to co-vary with those of swordfish, making the blue sharks difficult to avoid in a swordfish fishery (Bigelow et al., 1999). Similarly, many skates and rays are captured in bottom trawling for groundfishes such as flounders, and subsequently discarded dead (Enever et al., 2009; Damalas and Vassilopoulou 2011; Graham et al., 2001).

2.2 *Fishing*

Mortality due to fishing is almost entirely responsible for the world-wide declines in shark and ray abundance. Although directed shark fishing is still practised in some countries, a much larger proportion of overall shark mortality is associated with by-catch in non-shark fisheries (Lewison et al., 2004).

2.2.1 *By-catch*

Sharks have typically been exploited as a by-catch of commercial fisheries targeting more valuable bony fishes, especially tuna and billfish (ICCAT, 2005) and in trawl fisheries exploiting groundfishes and shrimps (Shepherd and Myers, 2005). In many countries, shark by-catch is partially or primarily retained for the fin and/or food trade. But even where living sharks are released at sea because they are considered unwanted catch, post-release mortality rates can exceed 18 per cent for some species (Campana et al., 2009; Musyl et al., 2011). In the North-West Atlantic, blue shark by-catch from an international pelagic longline fleet outnumbers the target swordfish catch by about 3:1, resulting in an annual post-release blue shark mortality of ~20,000 mt (Campana et al., 2009). Similar calculations of capture and post-release mortality of released sharks, using conservative mortality estimates for all shark species, suggest total shark mortalities of non-landed sharks of about 34,000 mt per year (Worm et al., 2013). Discarded skate and ray by-catch of bottom trawl fisheries are ubiquitous and poorly documented, but appear to be responsible for steep declines in abundance, and even risk of extinction, in some areas (Shepherd and Myers, 2005; McPhie and Campana, 2009).

Elasmobranch species living in the high seas appear to be particularly susceptible to undocumented and/or illegal catches.

2.2.2 *Historical shark fisheries*

At local scales, targeted shark fisheries have developed in multiple regions of the world. In the Mediterranean Sea, for example, fishing for sharks constituted an important off-season activity for fishing communities relying on harvests of tuna or small pelagic species, such as sardines and anchovies (Ferretti et al., 2008). In the Adriatic Sea, at the beginning of the last century, there were elasmobranch fisheries for angel sharks, skates and dogfishes; some have persisted into recent times (Ferretti et al., 2013; Costantini et al., 2000). In Monterey Bay, United States, between the 1930s and the 1940s, large numbers of basking sharks stimulated the development of a directed fishery used for the production of liver oil and other pharmaceutical products (Castro et al., 1999). Similar fisheries developed in the northeast Atlantic for basking and porbeagle sharks (Fowler et al., 2004; Sims, 2008). Directed fisheries for the meat of porbeagle shark and/or spiny dogfish still persist in both the North-West Atlantic and the North-East Pacific Oceans (Campana et al., 2008; Rago and Sosebee, 2009).

2.2.3 Shark fishing for fins

In recent decades, an increasing demand for shark fins from the Asian market stimulated the conversion of many industrial fisheries from bony fishes to sharks (Amorim et al., 1998; Aires-da-Silva et al., 2008). For countries in central America and in southeastern Asia, shark finning has become an important source of income (Dell’Apa et al., 2014).

The commercial trade in shark fins has been a primary driver of shark mortality. With prices of up to 2,000 United States dollars per kg, and a total estimated market value of about 350 million dollars, the fin trade is a strong motivator for retaining shark by-catch (Worm et al., 2013). The fin trade (which also includes fins of landed sharks) has been linked to a median annual estimate of 38 (CI: 26 – 73) million sharks landed, resulting in fishing mortality rates which are unsustainable for some species (Clarke et al., 2006, 2013).

Some elasmobranch species are also the target of a lucrative international trade of body parts, above and beyond that of shark fins, leading to unsustainable mortality rates for some species. The jaws and teeth of white sharks have been sold for as much as 50,000 US dollars (Fergusson et al. 2009), resulting in the intentional killing of many accidentally caught sharks that might otherwise be released. Sawfishes are critically endangered in most parts of the world, in part because of the high value of their toothed rostra (Harrison and Dulvy, 2014, Dulvy et al. 2014).

2.2.4 Recreational fisheries

Recreational shark fisheries provide an economic value to local communities greatly exceeding the value of commercial fisheries for the same species (Babcock, 2008). Although some recreational shark fisheries have been converted to no-kill, catch-and-release fisheries, recreational shark fishing remains a significant source of fishing mortality in regions such as the southeastern United States. Shark tournaments (a specific type of recreational shark fishing) have been conducted for decades in several countries (Campana et al., 2006; Pradervand et al., 2007), but even shark tournaments have converted to catch-and-release in some regions, with rewards given for sharks that are tagged and released (NOAA, 2013).

2.3 Habitat destruction

Population declines have been linked to habitat destruction in some regions and for some species, but the linkage is often indirect. Habitat destruction is considered an issue for elasmobranch species living in estuarine or mangrove habitats and in demersal communities exploited by trawl fisheries. For example, in the Adriatic Sea, elasmobranch catch rates in an aggregate of five trawl surveys declined by 94 per cent between 1948 and 2005. Exploitation history and spatial gradients in trawl fishing pressure, one of the most destructive forms of fishing in use (Walting and Norse, 1998),

explained most of the declining patterns in abundance and diversity (Ferretti et al., 2013).

2.4 *Pollution*

Persistent bioaccumulation of toxins and heavy metals have been documented in sharks feeding at high trophic levels, at concentrations which can be toxic to human consumers, but their effect on the host shark remains unclear (Storelli and Marcotrigiano, 2001; Mull et al., 2012).

3. Ecosystem effects of shark depletion

3.1 *Community changes through predator or competitor release*

Sharks are very abundant and diverse in unperturbed ecosystems (Nadon et al., 2012; Ferretti et al., 2010). However, because of their slow population productivity low levels of fishing mortality may rapidly deplete these communities, with consequent pervasive effects on the structure and functioning of marine ecosystems. The overfishing of sharks can trigger community changes because of changing interspecific interactions among shark species and between sharks and other marine animals. The overfishing of large sharks triggered range expansions of more prolific broad-ranging competitors in coastal and offshore areas (Baum and Myers, 2004; Dudley and Simpfendorfer, 2006; Myers et al., 2007), and increases in small elasmobranchs released from shark predation (van der Elst, 1979; Myers et al., 2007; Ferretti et al., 2010). Sharks are often the sole consumers of small meso-predators, such as small sharks and rays, and of other long-lived marine organisms like turtles, tuna, billfish, and marine mammals, especially during their juvenile stages. Hence when large predatory sharks are removed, a rapid increase in the numbers of dogfishes, skates and rays or the recovery of historically depleted megafauna populations has been observed in some areas (Ferretti et al., 2010).

Changes in community structure due to shark depletion can also have indirect effects on community structure. Green turtles and dugongs affected by the presence of tiger sharks influence the distribution and species composition of seagrass beds through foraging and excavation (Heithaus et al., 2008; Preen, 1995; Aragonés, 2000). In the North Atlantic, decades of overfishing on large sharks along the United States east coast coincided with a generalized increase in small shark and ray populations, and a substantial increase in one of these species (the cownose ray) adversely affected the abundance of bay scallops (Myers et al., 2007). Similarly, 50 years of shark netting along the KwaZulu Natal shore in South Africa triggered a trophic cascade involving smaller sharks and bony fishes (Ferretti et al., 2010).

3.2 *Effect on stability*

In addition to inducing trophic cascades, overfishing of sharks can make communities more prone to perturbations through a reduction in omnivory (Bascompte et al., 2005). In the Caribbean ecosystem, the observed change of many coral reefs from coral- to seaweed-dominated reefs was attributed to the depletion of shark populations and a consequent increase in fish consumers, which ultimately depressed herbivore density. Analyses of long-term time series of cost per unit effort (CPUE) in the Mediterranean Sea demonstrated that the removal of large predatory sharks from coastal ecosystems destabilized the community by reducing resistance, resilience and reactivity (Britten et al., 2014).

4. Shark management

Historically, shark species have been a low management priority for RFMOs and national management bodies (Ferretti et al. 2010; Dulvy et al., 2014). However, this trend is changing as shark and ray species are increasingly representing a larger proportion of protected species relative to other fishes. Regional fisheries management organizations such as the Northwest Atlantic Fisheries Organization (NAFO) and ICCAT now require all countries to report all shark catches, while the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) prohibits directed fishing on any shark species, other than for scientific research. The Bahamas, Maldives and Palau have enacted legislation to prohibit shark fishing within areas under national jurisdiction (Dell’Apa et al., 2014; Techera and Klein, 2014), and the great white shark has become a protected species in all four countries where it is abundant (Australia, New Zealand, South Africa and the United States).

Although sustainable shark fisheries are theoretically possible, most industrial fisheries targeting elasmobranch resources have been characterized by a “boom and bust” trajectory of landings, culminating with a strong depletion of exploited populations (Castro et al., 1999; Campana et al. 2008). A few such fisheries that are apparently sustainable are now in place, but they require more conservative benchmarks and perhaps a higher level of enforcement (Walker, 1998; Gedamke et al., 2007).

4.1 *Seafood certification*

Certification of the sustainability of a fishery (e.g., the Marine Stewardship Council) is intended to provide an indirect economic incentive towards ensuring that the fished population is not threatened, and certification has been granted for a small number of shark fisheries, such as northwest Atlantic spiny dogfish. However, such certification is usually only possible for directed fisheries; in by-catch fisheries (such as is the case for most elasmobranchs), alternate conservation and/or recovery actions would have to be taken.

4.2 *By-catch mitigation options*

Reduced by-catch of sharks is usually the preferred option, since it results in both reduced shark mortality and reduced loss of fishing gear and bait (and therefore increased profits) by fishermen.

4.3 *Spatial or seasonal closures*

In principle, by-catch can be reduced by restricting access to “by-catch hotspots” through spatial or seasonal closures, although this approach is complicated by the similar habitat preferences of the target species and the shark by-catch. To this point, there is still little evidence of the effectiveness of large sanctuaries for sharks (mainly because of the absence of empirical data), although analyses of shark abundance and distribution along spatial gradients suggest that these might be effective management options (Ferretti et al., 2013).

Closure of shark mating and pupping grounds to fishing increases the protection of sensitive life-history stages (i.e., Campana et al., 2008). By-catch can also be reduced through modifications to fishing gear; for example, the introduction of the circle hook has reduced shark hooking mortality relative to the traditional J hook (Kaplan et al., 2007). However, other attempts to reduce shark catchability through use of rare earth metals and electrical fields have largely been disappointing (Godin et al., 2013).

4.4 *Catch and release*

Recreational shark fishing is a relatively small source of fishing mortality, despite its public visibility (Campana et al., 2006). Nevertheless, the introduction of catch-and-release fishing tournaments has reduced the mortality of some species.

4.5 *Better monitoring*

Ensuring the survival of a shark population is very challenging if the status of the population is unknown. Improved reporting of all catches and discards, the introduction (or expansion) of scientific observer programmes on commercial fishing vessels, and the inclusion of dead discards and estimates of post-release mortality rates in stock assessments, would all lead to improved assessments of population status, and thus simplify recovery efforts.

4.6 *Fin trade bans and restrictions on finning*

The fin trade has been one of the primary drivers of global shark mortality. Bans on fin sales have been adopted by some cities and in some states of the United States on the presumption that sales would decline in the absence of a legal market. Customer education in some Asian markets is also reducing the demand for wedding soup, and

thus fin sales (Eilperin, 2011). Fisheries regulations requiring that the entire shark carcass be landed, and not just the fins, would also reduce shark mortality, as boat capacity is much more limited by the presence of entire sharks than by the much smaller fins. In some countries there is a fin-to-carcass ratio regulation which requires fishers to land no more than a given percentage of fin weight relative to total landings (Davidson et al., 2015).

4.7 *Implementation of international policies*

In response to the perception that many of the world's elasmobranch species are severely depleted, several international organizations have moved to actively conserve some shark and ray species. The Food and Agriculture Organization of the United Nations (FAO) released an *International Plan of Action for the Conservation and Management of Sharks* urging immediate action to better document and conserve shark and ray species (FAO 1998). The Convention on the Conservation of Migratory Species of Wild Animals¹ (CMS) has listed eight shark species for international conservation and protection (CMS 2014; <http://www.cms.int/en/species>). Finally, the Shark Specialist Group of the International Union for Conservation of Nature (IUCN) provides information and guidance to governments and non-governmental organizations associated with the conservation of threatened shark species and populations. The SSG released their report on the Global Status of Oceanic Pelagic Sharks and Rays in 2009. As a final step of protection, the international Convention on International Trade in Endangered Species of Wild Fauna and Flora² (CITES) attempts to protect endangered species through international trade regulations, such as restrictions on import and export. To this point, CITES has listed 18 shark and ray species under their Appendices I and II trade restrictions (CITES 2014; <http://checklist.cites.org>), which will remain in place until it can be demonstrated that the population is being managed sustainably. CITES trade restrictions appear to have tangible effects on the trade of listed shark species, and thus reduce the demand (Wells and Barzdo, 1991). However, it is yet to be seen if CITES listings can be implemented in time to protect species, which have already reached the brink of extinction (e.g., sawfish).

5. Ecotourism

Ecotourism in the form of shark diving has become a burgeoning industry generating millions of dollars for local economies worldwide (Musick and Bonfil, 2005; Gallagher and Hammerschlag, 2011). One estimate suggests that shark ecotourism currently generates more than 314 million US dollars per year and supports about 10,000 jobs. Projections suggest that this figure could double in the next 20 years and thus surpass

¹ United Nations *Treaty Series*, vol. 1651, No. 28395.

² United Nations *Treaty Series*, vol. 993, No. 14537.

the landed value of global shark fisheries (Cisneros-Montemayor et al., 2013). Indeed, in terms of individual value, sharks in some localities may be worth more alive than if landed and marketed. In the Maldives, it has been estimated that an individual free-swimming grey reef shark is worth 33,500 dollars per year compared to 32 dollars for the same individual sold dead by local fishermen. In the Bahamas, shark diving generates annual revenues of 78 million dollars (Gallagher and Hammerschlag, 2011). In the Maldives (where shark fishing has been banned), ecotourism contributed >30 per cent of the Maldivian GDP (Gallagher and Hammerschlag, 2011).

Chapter 41. Tunas and Billfishes

Contributors: Victor Restrepo, Maria José Juan-Jordá, Bruce B. Collette, Flávia Lucena Frédou, Andrew Rosenberg (Lead member)

1. Introduction

Tunas and billfishes are epipelagic marine fishes that live primarily in the upper 200 metres of the ocean and are widely distributed throughout the tropical, subtropical and temperate waters of the world's oceans (Collette and Nauen 1983; Nakamura 1985). Tunas (Tribe Thunnini, family Scombridae) include five genera (*Thunnus*, *Katsuwonus*, *Euthynnus*, *Auxis* and *Allothunnus*) with 15 species altogether (Collette et al., 2001). Seven of the 15 species of tunas are commonly known as “principal market tunas” due to their economic importance in the global markets (Majkowski 2007). These include albacore (*Thunnus alalunga*), bigeye tuna (*T. obesus*), Atlantic bluefin tuna (*T. thynnus*), Pacific bluefin tuna (*T. orientalis*), southern bluefin tuna (*T. maccoyii*), yellowfin tuna (*T. albacares*) and skipjack tuna (*Katsuwonus pelamis*). The principal market tunas have extensive oceanic distributions and are highly migratory. They sustain diverse fisheries worldwide, from highly industrialized commercial fisheries, to small and medium scale artisanal fisheries, and also lucrative recreational fisheries. The non-principal market tuna species including longtail tuna (*Thunnus tonggol*), blackfin tuna (*Thunnus atlanticus*), kawakawa (*Euthynnus affinis*), little tunny (*E. alletteratus*), black skipjack (*E. lineatus*), bullet tuna (*Auxis rochei*), frigate tuna (*A. thazard*) and slender tuna (*Allothunnus fallai*) have in general more coastal distributions, except for the slender tuna which is found worldwide in the Southern Ocean. These species also sustain important small to medium industrial and artisanal fisheries throughout their distributions (Collette and Nauen, 1983; Majkowski, 2007).

Billfishes are highly migratory fishes that live also primarily in the upper 200 metres of the ocean and have widespread oceanic distributions. They are distinguished by their elongate spears or swords on their snouts. Some billfish species are targeted by commercial and recreational fisheries world-wide, but generally billfish species are caught as a by-product of the tuna fisheries (Kitchell et al., 2006). Billfishes include ten species in two families (Xiphiidae and Istiophoridae); the monotypic Xiphiidae (swordfish, *Xiphias gladius*) and Istiophoridae containing five genera and nine species: blue marlin (*Makaira nigricans*), sailfish (*Istiophorus platypterus*), black marlin (*Istiompax indica*), striped marlin (*Kajikia audax*), white marlin (*Kajikia albida*), and four spearfishes, shortbill spearfish (*Tetrapturus angustirostris*), roundscale spearfish (*Tetrapturus georgii*), longbill spearfish (*Tetrapturus pfluegeri*), and Mediterranean spearfish (*Tetrapturus belone*) (Collette et al., 2006)

Due to the highly migratory nature, widespread distributions, and global economic

importance of tunas and billfishes, five Regional Fisheries Management Organizations (RFMOs) are in charge of their management and conservation (hereinafter referred to as tuna RFMOs). The five tuna RFMOs are the International Commission for the Conservation of Atlantic Tunas (ICCAT, Atlantic Ocean), the Indian Ocean Tuna Commission (IOTC, Indian Ocean), the Inter-American Tropical Tuna Commission (IATTC, Eastern Pacific Ocean), the Western and Central Pacific Fisheries Commission (WCPFC, Western Pacific Ocean), and the Commission for the Conservation of Southern Bluefin Tuna (CCSBT, Southern Ocean).

2. Population trends or conservation status

2.1 Aggregated at global scale

Annual catches of tunas and billfishes have risen continuously since the 1950s, reaching at least 6 million tons in 2012 (Figure 1A). In 2012, the total catches of tunas and billfish species combined contributed up to 9.3 per cent of the annual total marine fish catch (FAO, 2014). Although the global increase in catches of all marine fishes reached a peak at the end of the 1980s and has since then stabilized, tuna and billfish catches have not reached a plateau yet. However, a plateau will likely be reached in the short term as many of the world's most important tuna and billfish fisheries are considered fully exploited now with limited room for sustainable growth (Miyake et al., 2010; Juan-Jordá et al., 2011; ISSF, 2013a). The current exploitation status of principal-market tuna and billfish populations is summarized according to the latest fisheries stock assessments and biological reference points¹ carried out by the five tuna RFMOs. Currently the tuna RFMOs have formally assessed a total of 44 stocks (13 species) of tuna and billfish species, including 23 principal market tuna stocks (7 species) and 21 billfish stocks (6 species) (Appendix 1). Hereinafter, the term “population” is used instead of “stock”. Each tuna RFMO has its own convention objectives ranging from ensuring the long term conservation and sustainable use of tuna and tuna-like species to, in some cases, ensuring the optimum utilization of stocks.² Scientific advisory groups or science providers within these tuna RFMOs routinely carry out stock assessments and estimate two common standard biological reference points, B/B_{MSY} and F/F_{MSY} , which are used to determine the current exploitation status of the populations. B/B_{MSY} is the ratio of the

¹ Definitions of the term “reference points” are available at the FAO Term Portal (<http://www.fao.org/faoterm/en/>) and in ISSF (2013b).

² See Agreement for the Establishment of the Indian Ocean Tuna Commission (United Nations, *Treaty Series*, vol. 1927, No. 32888); Convention between the United States of America and the Republic of Costa Rica for the establishment of an Inter-American Tropical Tuna Commission (United Nations, *Treaty Series*, vol. 80, No. 1041); Convention for the Conservation of Southern Bluefin Tuna (United Nations, *Treaty Series*, vol. 1819, No. 31155); Convention for the strengthening of the Inter-American Tropical Tuna Commission established by the 1949 Convention between the United States of America and the Republic of Costa Rica; Convention on the Conservation and Management of Highly Migratory Fish Stocks in the Western and Central Pacific Ocean (United Nations, *Treaty Series*, vol. 2275, No. 40532); International Convention for the Conservation of Atlantic Tunas (United Nations, *Treaty Series*, vol. 673, No. 9587).

current biomass (often measured only for the spawning fraction of the population) relative to the biomass that would provide the maximum sustainable yield (MSY). A population whose biomass has fallen below B_{MSY} (i.e., $B/B_{MSY} < 1$) is considered to be “overfished” with regards to this target. F/F_{MSY} is the ratio of current fishing mortality relative to the fishing mortality rate that produces MSY. Overfishing is occurring for a population whose fishing mortality exceeds F_{MSY} (i.e., $F/F_{MSY} > 1$).

According to the most recent fisheries stock assessments (2010-2014, Appendix 1), 51.2 per cent of the tuna and billfish populations are not overfished and are not experiencing overfishing (21 populations), 14.6 per cent of populations are not overfished but are experiencing overfishing (6 populations), 22 per cent of populations are overfished and are experiencing overfishing (9 populations), and 12.2 per cent of populations are overfished but are not experiencing overfishing anymore (5 populations) (Figure 2A). However, the total catches and abundance differ markedly among tuna and billfish species and populations, around 3 orders of magnitude between the population with the smallest catches (eastern Pacific sailfish ~300 tons/annually) and the population with the largest catches (western and central Pacific skipjack ~1,700,000 tons annually). When accounting for their relative contributions to their total global catches, a different global picture of the status of these species emerges (Figure 2B). In terms of their relative contributions to the total catches, 86.2 per cent of the global catch of tuna and billfish comes from healthy populations, for which the biomass is not overfished and whose populations are not experiencing overfishing, 4.5 per cent of the catch comes from populations that are not overfished but are experiencing overfishing, 1.4 per cent of the catch comes from populations that are overfished and are experiencing overfishing, and 8 per cent of the catch comes from populations that are overfished and are not experiencing overfishing anymore (Figure 2B). This distinct pattern of global exploitation status is mostly driven in part by the fact that tropical skipjack and yellowfin tuna populations contribute 68 per cent of the global tuna catches and their populations are largely at healthy levels and not experiencing overfishing. In contrast, most of the populations that are overfished and experiencing overfishing are mostly temperate bluefin tuna and billfish populations, whose combined catches make up a relatively small fraction of the total catch.

Although the current exploitation status for the principal market tunas is relatively well known globally, knowledge of the exploitation status for the non-principal market tuna and billfish populations and species is fragmentary and uncertain. Currently, all the populations for all seven species of principal market tunas are formally assessed on a regular basis (every 2-4 years depending on the population) by the scientific staff or scientific committees in the five tuna RFMOs, and have management and conservation measures in place. Not all billfish populations and species have been formally assessed yet, therefore the global picture of their current exploitation status may be biased towards the most commercially productive and resilient species of billfish. Furthermore, tuna RFMOs have not yet conducted formal fisheries stock assessments or adopted management and conservation measures for any of the eight non-principal market tuna species. Therefore their current exploitation status is unknown or highly uncertain

throughout their neritic distributions. There are some exceptions and some species of non-principal market tunas have been assessed locally by national government fisheries agencies or recently by IOTC. For the South Atlantic Ocean off the coast of Brazil, *Thunnus atlanticus* was assessed in the year 2000, concluding the population was as at healthy levels and not experiencing overfishing (Freire, 2009). In the Indian Ocean, *Thunnus tonggol* was assessed for the first time in the year 2013 and 2014 by the IOTC Working Party on neritic tunas. The assessments concluded that *Thunnus tonggol* was likely subject to overfishing in recent years while not being in an overfished state (IOTC-SC17, 2014). Therefore the exploitation status for the majority of non-principal market tuna populations and species is mostly unknown throughout their ranges, despite the importance of their commercial fisheries for many coastal fishing communities in many developed and developing countries around the world.

2.2 Four major taxonomic and/or geographic subdivisions

Since the 1950s, principal market tunas have made up the majority of the global catches of tunas and billfish combined (Figure 1A). In 2012, the catch of principal market tunas accounted for 80 per cent of the total catch, the catch of non-principal market tunas accounted for 16 per cent and billfish catch accounted for 4 per cent. Among principal market tunas, skipjack tuna and yellowfin tuna make up 46 per cent and 22 per cent of the global catch in 2012, followed by bigeye tuna (7 per cent), albacore tuna (4 per cent) and the three bluefin tuna species (1 per cent). The increasing trend in the total catch of principal market tunas is mainly due to the increase in catches in tropical tuna species since the 1950s until today, a trend driven by skipjack tuna, followed by yellowfin tuna and then bigeye tuna. By contrast, temperate principal market tuna species, including albacore tuna and the three bluefin tuna species, show an increasing trend in catch up to the 1970s, and since then the trend has stabilized or shown a decrease. Over two-thirds of the world's tunas and billfishes catches currently come from the Pacific Ocean (69 per cent), 22 per cent come from the Indian Ocean and 9 per cent from the Atlantic Ocean (Figure 1B). Although catches in the Atlantic Ocean have increased only until the early 1980s and since then have declined slightly, in the Pacific and Indian Oceans catches have increased continuously since the 1950s.

Among the non-principal market tuna species, frigate and bullet tunas combined (*Auxis rochei* and *A. thazard*) make up 40 per cent of the catch and kawakawa (*Euthynnus affinis*) makes up 33 per cent of the catch. Among billfishes, swordfish (*Xiphias gladius*) makes up 51 per cent of the catch and Atlantic blue marlin (*Makaira nigricans*) makes up 17 per cent of the catch. Global catches for non-principal market tunas and billfish have also shown a continuous increase since the 1950s, accelerating in the 1980s, a result that is likely to be derived from better reporting of the catch for these species. However, it is generally agreed that catch estimates for non-principal market tunas and billfish have been and still are underestimated as the majority of these species are

caught by small scale fisheries or as a by-catch³ of principal market tuna fisheries. Small-scale coastal fisheries targeting both principal market tunas and the smaller non-principal market tunas are poorly reported. Similarly, billfish catches, of which the majority come from industrial tuna fisheries as bycatch, have also been commonly poorly reported and monitored (Miyake et al., 2010).

According to the latest tuna RFMO fisheries stock assessments (Appendix 1), the global picture of the exploitation status of tunas and billfishes indicates that principal market tuna populations are relatively better managed than billfish populations (Figure 2C). Although 37 per cent of billfish populations (7 of 19 populations) are currently overfished and experiencing overfishing, 9 per cent of the principal market tunas (2 of 22 populations) are considered to be overfished and experiencing overfishing. The majority of principal market tunas are at healthy levels with 64 per cent of the populations not overfished and not experiencing overfishing, and 18 per cent of the populations, although overfished, are no longer experiencing overfishing and therefore are on the path to recovery, if fishing mortality continues to be controlled. The exploitation status of tunas and billfishes also differs among the three major oceans (Figure 2C). In the Atlantic Ocean, the status of only 47 per cent of the populations is currently healthy (not overfished and not experiencing overfishing), in the Indian Ocean the status of half of the populations (50 per cent) is healthy, and in the Pacific Ocean over half of the populations (~56 per cent) is currently healthy and within sustainable levels.

When accounting for the relative contributions of their catches, principal market tuna populations provide the majority of the catches from healthy populations when compared with billfish species. Although 87 per cent of the total catches of principal market tunas come from healthy populations (not overfished and not experiencing overfishing) and only 0.9 per cent come from unhealthy populations (overfished and experiencing overfishing), 60.8 per cent of the total catches of billfish populations come from healthy populations and 16.1 per cent come from unhealthy populations. Healthy populations of skipjack in every ocean make up a large portion of the total tuna catches, whereas healthy swordfish populations make up the largest portion of the total billfish catches. As previously mentioned, the exploitation status remains unknown for some billfish species and populations, and therefore this global picture might be biased towards the most commercially data-rich billfish species. Among the three oceans, the large majority of tuna and billfish catches in the Indian and Pacific Oceans come from healthy populations (92.3 and 87.5 per cent, respectively), and in the Atlantic Ocean 66.4 per cent of the catches come from healthy populations. In the Atlantic, currently 7.9 per cent of the tuna and billfish catches come from unhealthy populations (overfished and experiencing overfishing) and 25.7 per cent of catches come from overfished populations for which overfishing is no longer occurring and therefore might be on their path to recovery.

³ Definitions of the term “by-catch” are available at the FAO Term Portal and in Gilman et al. (2014).

3. Special conservation status issues (CITES, national listing or priority for Marine Protected Area)

In 2011, the International Union for Conservation of Nature (IUCN) assessed for the first time the global conservation status for all tuna and billfish species using the IUCN criteria (Collette et al. 2011). The IUCN conservation assessments provide a complementary tool to existing fisheries stock assessment for setting conservation priorities at the global levels for this group of species and a platform for identifying species with long-term sustainability issues. The IUCN assessments utilize the IUCN Red List Criteria and all the available species information, including their global distribution, ecology, landing trends, biomass trends (mostly derived from fisheries stock assessments), and impacts of major threats, in order to classify species into the IUCN Red List categories. These categories range from Least Concern and Near Threatened, to the three threatened categories (Vulnerable, Endangered, Critically Endangered), providing a species ranking in terms of their relative risk of global extinction and conservation needs.

There is also a Data Deficient category where species with insufficient information to be evaluated are placed. Nonetheless, the information used to categorize tuna and billfishes in the IUCN Red List categories vary greatly among species; whereas some species such as *Allothunnus fallai* and *Tetrapturus angustirostris* are data poor due to scarce and incomplete landing and biological data against which to apply the IUCN criteria, some species such as the majority of the principal market tuna species are data rich with relatively extensive and highly detailed biological studies and fisheries stock assessment models for multiple populations throughout their distribution, which makes applying the IUCN criteria relatively easy. The IUCN Red List evaluation for the 25 species of tunas and billfishes resulted in 48 per cent (12 of 25 spp.) of species being listed under the Least Concern category, 12 per cent of tunas and billfishes listed in the Near Threatened category (*Thunnus alalunga*, *T. albacares* and *Kajikia audax*), and 24 per cent (6 spp.) had declined sufficiently in biomass to trigger listing under the Threatened categories. *Thunnus maccoyii* is listed as Critically Endangered, *T. thynnus* is Endangered, and *T. obesus*, *T. orientalis*, *Kajikia albida* and *Makaira nigricans* are Vulnerable. Lastly, 16 per cent (4 spp.) of tunas and billfish were listed as Data Deficient (Collette et al., 2011; Collette et al., 2014).

It should be noted that the IUCN criteria sometimes conflict with fisheries management objectives (Davies and Baum, 2012). For example, a species whose abundance declines from the unfished level by one-half in a given period of time may be classified in a threatened category in the IUCN Red List, but it might be well managed (i.e., not overfished and not experiencing overfishing) from an RFMO perspective. Conversely, a species that remains severely overfished for a period of time may be of grave concern to an RFMO but not classified in a threatened category in the IUCN Red List. Nevertheless, from a global conservation perspective, the latest IUCN assessments and derived

conservation status were largely consistent with the current knowledge about the exploitation status of tuna and billfish populations derived from the RFMO fisheries stock assessments, in that the three longer-lived bluefin tuna species with geographically restricted spawning sites are more vulnerable to overfishing and are in need of more stringent management and conservation measures than the shorter-lived and more resilient tropical tuna species such as skipjack tuna for which spawning occurs in multiple broad spawning grounds throughout the tropics (Reglero et al., 2014).

More importantly, the IUCN conservation assessments are a useful tool particularly for those tuna and billfish species which are commercially exploited but lack formal fisheries population assessment, whose exploitation status is unknown and highly uncertain, and which do not have any management and conservation measures in place to ensure their long-term sustainability. According to the latest IUCN assessments, the following four IUCN Data Deficient species, *Thunnus tonggol*, *Tetrapturus angustirostris*, *Tetrapturus georgii* and *Istiompax indica*, should be the focus of future management and conservation efforts to ensure that their current fishing exploitation, and absence of fishery population assessments and management plans, do not jeopardize the long-term sustainability of these species.

A proposal to list Atlantic bluefin tuna on the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) was introduced at the fifteenth meeting of the Conference of the Parties in March 2010 by Monaco and supported by the United States and several European countries, but the proposal failed. There have also been several attempts to list several tuna and billfish species under National Listings. In the United States, the Center for Biological Diversity petitioned the United States Department of Commerce National Marine Fisheries Service to list both the eastern and western Atlantic populations of the bluefin tuna as endangered under the United States Endangered Species Act (ESA) (Center for Biological Diversity, 2010) but the Department rejected the petition, although declaring the Atlantic bluefin to be “a species of interest” after a review (Atlantic Bluefin Tuna Status Review Team, 2011). A petition from the Biodiversity Legal Foundation requesting listing of the Atlantic white marlin (*Kajikia albida*) as a threatened or endangered species under the ESA was found to be not warranted at that time by the National Marine Fisheries Service (White Marlin Biological Review Team, 2007). In Canada, the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) determined in 2011 that the western Atlantic bluefin tuna was Endangered (Maguire, 2012). In Brazil, a number of specialists, coordinated by the Brazilian Ministry of Environment (MMA) through the Instituto Chico Mendes de Conservação da Biodiversidade (ICMBIO), evaluated the risk of extinction of marine species following IUCN Red list of Threatened Species. Most species have been listed in the same category as the global list, however *Xiphias gladius* was categorized as Near Threatened, *Makaira nigricans* as Endangered, *Thunnus alalunga* and *T. albacares* as Least Concern and *Auxis rochei* and *A. thazard* as Data Deficient, differently from the global list (ICMBIO. In press).

Marine protected areas (MPAs), or time-area closures, a term mostly used by fisheries managers, are one of the many tools available to fishery managers to reduce fishing mortality or redistribute fishing effort to protect a segment of a fish population (e.g. spawning adults) or vulnerable fish habitats, among many other applications. Marine protected areas or time-area closures can vary from complete prohibition on fishing or other forms of exploitation “no-take zone” to a continuum of spatial, temporal and user restrictions allowing numerous options and applications. Currently, the role of pelagic MPAs or time-area closures for the conservation and management of tunas and billfishes is a major topic of discussion, given their high mobility, their wide distributions, the dynamic physical nature of pelagic habitats, as well as the small number of empirical and theoretical studies showing their effectiveness (Davies et al., 2012; Dueri and Maury 2012). In the last decade, tuna RFMOs have tested and implemented several types of time-area closures, always in combination with other tools to control catch and effort, to reduce fishing effort and reduce by-catch of non-target species (Sibert et al. 2012). Past experiences indicate that time-area closures, if used alone, might be ineffective and inefficient to manage tuna species (ISSF, 2012). However, if time-area closures are used in combination with other fishery management tools, closures could have substantial benefits when the objectives are clearly defined and their implementation is accompanied by close evaluation, monitoring and enforcement (ISSF, 2012).

The future success of pelagic MPAs or time-area closures as a fisheries, conservation and management tool for tuna and billfish species relies on more theoretical modelling and long-term empirical studies to compare and contrast their effectiveness with other fishery management tools and in combination with these tools.

4. Key pressures linked to trends

Commercial fishing has been identified as the primary pressure driving tuna and billfish population declines and causing the overexploitation of some populations (Collette et al., 2011). Over the last century, industrial fisheries targeting tuna and billfish species have sequentially expanded from coastal areas to the high seas and now their fisheries cover the majority of the world’s oceans (Miyake et al., 2004). Globally tuna and billfish catches and fishing effort have risen consistently since the 1950s and may not have yet reached a plateau (Juan-Jordá et al., 2011). Currently the global demand for tuna meat is still increasing, and fishing capacity, with the construction of new fishing vessels, especially purse seiners, and improved technology, is also increasing (Justel-Rubio and Restrepo, 2014). As concluded by Allen (2010), managing capacity and eliminating overcapacity where it exists has been identified as one of the major challenges jeopardizing the long-term sustainability of tuna and billfish species.

Climate change is another potential pressure that needs to be accounted for in the biology, economics and management of tuna and billfish species (McIlgorm, 2010). It is projected that by increasing ocean water temperatures, and altering oceanic circulation

patterns and the vertical stratification of the water column, climate change will lead to a decrease in primary productivity in the tropics and a likely increase in higher latitudes (Intergovernmental Panel on Climate Change (IPCC, 2007)). Climate change, and the resultant increase in ocean temperatures, is also increasing the extension of areas with hypoxic waters and oxygen-depleted dead zones (Altieri and Gedan, 2015).

The extension of deep hypoxic bodies of water limits the distribution of tunas and billfishes by compressing their preferred habitat into a narrow surface layer, making this species more vulnerable to over-exploitation by surface gears (Prince and Goodyear, 2006). Thus, climate change might have an effect on tuna and billfish species by changing their physiologies, temporal and spatial horizontal and vertical distributions and abundances within the water column. A growing number of studies are evaluating the current and future impacts of climate change on the physiology, distribution, abundance and reproductive and feeding migrations of these species (Dufour et al., 2010; McIlgorm, 2010; Muhling et al., 2011; Bell et al., 2013; Dueri et al., 2014).

A study modelling the impacts of climate change on skipjack tuna in the tropical world's oceans suggests that the spatial distribution and abundance of skipjack tuna may change substantially with current suitable tropical habitats deteriorating and habitat suitability improving at higher latitudes (Dueri et al., 2014). In the Western and Central Pacific, another modelling study evaluated the effect of climate change on the food webs, habitat and main fish resources of the region, and found that distribution of skipjack tuna, the major tuna resource of the area, may move further east across the region. This eastward movement of skipjack tuna could benefit some nations by increasing their access to tuna resources and adversely affect other nations which would lose access to optimum tuna fishing grounds (Bell et al., 2013).

In the Atlantic Ocean, it has been documented that each year North Atlantic albacore tuna and East Atlantic bluefin tuna have arrived progressively earlier in the Bay of Biscay area, a major feeding ground, indicating that these species may be progressively adapting the timing of their feeding migrations and latitudinal distributions in response to climate change (Dufour et al., 2010). Another modelling study has also suggested that climate change might alter the temporal and spatial spawning and migratory activity of the West Atlantic bluefin tuna in the Gulf of Mexico with subsequent effects on population sizes and fisheries (Muhling et al. 2011). The impacts of climate change on tuna and billfish species are raising increasing concerns and need to be further understood, in order that governments and tuna RFMOs can respond rapidly to climate change by developing mitigation and adaptation programs.

5. Major ecosystem services provided by the species group and impacts of pressures on provision of these services

5.1 Ecosystem services

The impacts of fishing on the abundance of fishes and food web dynamics can have consequences on the structure, functioning and resilience of marine ecosystems (Heithaus et al., 2008; Baum and Worm, 2009). Consequently, population declines in tuna and billfish species and changes in their food web dynamics may be impairing the ocean's capacity to generate basic ecosystem processes which are vital to enable the maintenance and delivery of other ecosystem services benefiting human health, welfare and economic activities. To what extent widespread declines in tuna and billfish populations have altered the capacity of the ocean to support vital ecosystem processes, functions and services by altering species interactions and food web dynamics is poorly known (Kitchell et al., 2006; Hunsicker, 2012; IATTC, 2014a).

Tuna and billfish species are large predatory fishes, acting as apex and mesopredators and occupying high trophic levels in the marine food web; their removal could have ecological consequences for predator-prey interactions through trophic cascading effects (Baum and Worm, 2009). To fully understand the effects of removing tunas and billfishes from marine ecosystems, and their value in maintaining key ecosystem processes and services, requires better understanding of their unique role as predators and prey, and their interactions and dynamics using modelling and empirical approaches. This requires the collection of accurate information on trophic links and biomass flows through the food web in open marine ecosystems and accounting for environmental forcing (IATTC, 2014a).

To date, tuna RFMOs have conducted limited research and have a limited track record for incorporating food-web and ecosystem considerations into the management of tuna and billfish fisheries because traditionally their management has focused on achieving MSY for each of their targeted species individually. Consequently, according to de Bruyn et al., (2013), tuna RFMOs have implemented limited conservation measures to address the wide ecological effects of fishing. However, in the last decade tuna RFMOs, and especially IATTC and WCPFC, have increased their research activities to ensure that ecosystem considerations are part of their agendas (IATTC 2014a). These actions have mostly focused on monitoring, quantifying and mitigating incidental by-catch, increasing the coverage of the observing programmes and modifying fishing gear technology (Gilman et al., 2014; IATTC, 2014a).

5.2 Direct services to humans including economic and livelihood services

Tuna and billfish species provide a wide variety of direct ecosystem services to humans by supporting food production and creating vital coastal livelihoods, economies and recreational opportunities such as sport fisheries (Gilman et al., 2014). At present more

than 80 countries have tuna fisheries, thousands of tuna fishing vessels operate in all the oceans, and tuna fishery capacity is still growing in the Indian and Pacific Oceans (ISSF, 2010). The popularity of tuna meat has increased remarkably around the globe and now tuna meat is considered to be a relatively low-cost source of protein, which is traded as a global “commodity” product (i.e. high volume, low value, low margins) (Hamilton et al., 2011). The canning and sashimi industries are the major players in the global trade of tuna, particularly focused on the principal market tuna species.

At the other extreme, in some regions of the world tuna and billfish species still contribute substantially to the subsistence of many fishing communities by providing the great majority of dietary animal protein (Bell et al., 2009). The global economic activity that tuna fisheries can generate directly and indirectly is remarkable. Every year at least 2.5 million tons of the global tuna catch is destined for the canning industry and globally around 256 million cases are consumed (3.2 million tons whole round equivalent), valued at 7.5 billion United States dollars (Hamilton et al., 2011). Therefore, ensuring the long-term sustainability of the world’s tuna and billfish fisheries is intrinsically linked with providing food security, vital livelihoods and economic benefits in many regions of the world.

The dependency on healthy and sustainable tuna populations and the direct ecosystem services they provide is particularly strong for countries in the tropical western and central Pacific Ocean which is the most important tuna fishing area in the world. The tuna catch in the West Pacific Ocean is greater than that of the Atlantic, Indian and East Pacific Oceans combined (Miyake et al., 2010). Countries in the tropical west Pacific Ocean depend heavily on tuna resources for their nutrition, food security, economic development, employment, government revenue, livelihoods, culture and recreation (Gillett et al., 2001; Gillett, 2004; Gillett, 2009). Pacific States and territories in the west Pacific Ocean derive a large share of their taxes (up to 40 per cent) and Gross Domestic Product (up to 20 per cent) from fishing licenses sold to distant-water fishing nations and fish processors (Gillett, 2009; Bell et al., 2013).

Tuna and billfish also provide valuable recreational services; these fishes are considered to be valuable sportfishes, which gives them an important status in recreational fisheries in many regions of the world. Although the global picture of the recreational catch, effort and economic data for this industry is very fragmentary or unknown, for those countries with better records, the aggregate impact of the recreational tuna and billfish industry in terms of revenue and employment can be substantial for the local economies. For example, the total annual aggregate value of the recreational billfish industry in Costa Rica, Mexico, the United States Atlantic coast and Puerto Rico (United States) combined ranges between 203 and 340 million United States dollars, creating vital economic development, employment and recreation in the region (Ditton and Stoll, 2003).

6. Conservation responses and factors for sustainability

Tuna RFMOs face several challenges to ensure the long-term sustainability of tunas and billfishes and associated ecosystems within their Convention areas. Some of the main challenges have been considered to be:

- (a) the existing overcapacity of fishing fleets;
- (b) the equitable allocation of fishing rights among fishing nations;
- (c) the possible implementation of the precautionary approach⁴ and ecosystem approach;
- (d) the monitoring of by-catch of vulnerable species; and
- (e) the adequacy of financial resources to eliminate illegal, unreported and unregulated fishing and implement effective Monitoring, Control and Surveillance.

Tuna RFMOs have increasingly adopted a series of conservation and management measures to specifically address each of these challenges although their success and implementation have been mixed, and more time is needed to fully evaluate their success.

Tuna RFMOs control the amount of fishing of each stock through a variety of tools including catch limits, time-area closures and other input or output controls. Nevertheless, management of fleet capacity remains an issue of special concern, especially in the long term, because it tends to increase pressure on resources and management. The open access nature of fisheries, particularly in the high seas, has led to overcapacity of fleets in every tuna RFMO convention area (Allen, 2010; Miyake et al., 2010). Once overcapacity develops, it is difficult to reduce it because the fishing industry will continue operating as long as profits exceed costs (ISSF, 2010b). The IATTC has adopted a closed vessel registry for its purse seine fleet, a first and key step in managing overcapacity. However, overcapacity in the region remains well above the target (IATTC, 2014b). ICCAT, IOTC and WCPFC also have measures to limit capacity for some of their fisheries, but the problem of overcapacity has not been addressed in the RFMOs as a whole. It has been proposed that the establishment of exclusive rights to fish can be a formula to prevent overfishing, reduce overcapacity, achieve maximum economic benefits and sustainability in tuna and billfish fisheries, but its application is currently being debated (Allen, 2010; ISSF, 2010b; Squires et al., 2013). Ultimately, the global nature of tuna and billfish fisheries and industries might need cooperation among tuna RFMOs to manage fleet capacity successfully.

The equitable allocation of fishing rights is another challenge, given that allocating

⁴ Definitions of the term “precautionary approach” are available at the FAO Term Portal and in ISSF (2013b).

fishing access or catch quotas among the different member countries continues to be one of the most contentious matters in the RFMOs decision-making progress, impeding other more timely relevant conservation and management measures from moving forward, according to the International Seafood Sustainability Foundation (ISSF, 2013c). Nowadays, tuna RFMO allocation negotiations occur in a decision-making climate that is basically consensus-driven, which can result in overall catch levels being higher than scientifically-recommended levels. Identifying solutions requires recognizing the complexity and heterogeneity of tuna fisheries and the diverse objectives of RFMO member countries (ISSF, 2011).

Endorsing the precautionary and ecosystem approach requires the adoption of harvest control rules including limit and target reference points for tunas and billfishes and associated species, a long-standing recommendation of several international FAO Agreements and Guidelines over the past 15 years (Caddy and Mahon, 1995) and part of the Agreement for the Implementation of the Provisions of the United Nations Convention on the Law of the Sea of 10 December 1982 relating to the Conservation and Management of Straddling Fish Stocks and Highly Migratory Fish Stocks.⁵ This is also part of the more modern RFMO Conventions, such as the WCPFC and IATTC. The CCSBT has adopted a formal management procedure⁶ for deciding on Total Allowable Catch levels to rebuild the southern bluefin tuna population to 20 per cent of the unfished abundance level by 2035. The other RFMOs have not adopted such formulaic approaches to decision-making, but all are making progress in adopting population-specific limit and target reference points and discussing the use of harvest control rules. The adoption of harvest control rules and limit and target reference points is also a common requirement of several eco-label certifications, such as the Marine Stewardship Council Management Program.

The fifth aforementioned challenge reflects the paucity of knowledge about the impacts of tuna and billfish fisheries on other less productive species such as sharks, on species interactions and food web dynamics, and on the greater marine ecosystems (Dulvy et al., 2008; Gerrodette et al., 2012; de Bruyn et al. 2013; Gilman et al., 2014; IATTC, 2014a). One issue of concern is the widespread use of Fish Aggregating Devices (FADs) by industrial purse seine tuna fisheries and its potential impacts on tuna populations (especially on very small bigeye), higher levels of bycatch relative to setting nets on free-swimming schools, and possible ecosystem impacts (Dagorn et al., 2012; Fonteneau et al., 2013).

RFMOs have increasingly adopted several measures to monitor and regulate the use of FADs, and to increase data reporting requirements specific to FADs. Moreover, new research initiatives have also been emerging that aim to identify best practices in FAD fishing, as well as modification of gears, and new technology to reduce the catch of non-target species by FAD fisheries. For example, IATTC, IOTC and ICCAT have adopted

⁵ United Nations, *Treaty Series*, vol. 2167, No. 37924.

⁶ See CCSBT (2011).

measures to require a transition to non-entangling FADs that would reduce unobserved mortality of sharks and other species. Pelagic longline tuna and swordfish fisheries have higher levels of bycatch of sensitive species such as sharks, turtles and seabirds (Gilman, 2011). In addition, mitigation measures in longline fisheries targeting tunas and swordfishes have been developed and adopted by the RFMOs to reduce the by-catch of species like sea birds and sea turtles, although their successful implementation and effectiveness in reducing by-catch levels vary greatly among tuna RFMOs (Small, 2005; Gilman, 2011).

The last challenge encompasses the difficulty of eliminating illegal, unreported and unregulated fishing (IUU) and implementing effective monitoring, control and surveillance (MCS) measures in a context of insufficient financial resources (ISSF, 2013c). Effective MCS is required to successfully implement any conservation and management measure in place and combat IUU fishing. MCS measures can be very diverse, from operating transparent catch documentation schemes, implementing effective at-sea observer programs, requiring vessels to acquire unique vessel identifiers, maintaining comprehensive IUU vessel lists, and operating regular reports of transshipments. The extent to which tuna RFMOs have successfully adopted MCS measures varies greatly (ISSF, 2013c). The compliance mechanisms used by the different tuna RFMOs vary considerably (Koehler, 2013). The identification of best practices, successful measures and incentives to promote best practices is a first step forward, which would require global collaboration among all tuna RFMOs.

Chapter 42. Cold-Water Corals

Contributors: Erik Cordes (Convenor and Lead Author), Sophie Arnaud-Haond, Odd-Aksel Bergstad, Ana Paula da Costa Falcão, Andre Freiwald, J. Murray Roberts, Patricio Bernal (Lead Member)

Commentators: Peter Harris (Group of Experts)

1. Inventory and Ecosystem Functions

Globally viewed, cold-water corals cover a wide range of depths (39 - 2000 m) and latitude (70°N – 60°S). In this Chapter, we will focus on the corals found below 200 m, the average depth below which photosynthesis does not occur, to avoid overlap with other chapters. The term “corals” refers to a diverse group of species in the Phylum Cnidaria, including the scleractinian hard corals, octocorals including the sea fans and soft corals, antipatharian black corals, and stylasterid lace corals. Although the majority of the species-level diversity of scleractinians is in the solitary corals (Cairns, 2007), some of the scleractinian corals may form extensive reef structures, occasionally accumulating into large carbonate mounds, or bioherms. Many of the ecological patterns discussed in this chapter are derived from the study of these structures, simply because they have been the focus of the most extensive research in this developing field. However, other types of cold-water corals can also form highly significant structural habitat and these are also discussed. The most representative cold-water, framework-building, scleractinian corals are *Enallopsammia rostrata*, *Goniocorella dumosa*, *Lophelia pertusa* (Figure 1) *Madrepora oculata*, *Oculina varicosa* and *Solenosmilia variabilis* (Roberts et al., 2006). The most common and widespread of the large, structure-forming octocorals are found in the genera *Corallium*, *Isidella*, *Paragorgia*, *Paramuricea*, and *Primnoa* (Watling et al., 2011) (Figure 2).

Cold-water corals (CWC) most commonly occur in continental slope settings, on deep shelves and along the flanks of oceanic banks and seamounts. The majority of CWC occur between the depths of 200 to 1000 m, with the bathymetric ranges becoming shallower towards the poles (Roberts et al., 2009). However, there are numerous, dense coral gardens (primarily octocorals and black corals) found on the slopes of seamounts and the base of the continental slope to over 3000 m, and some soft corals and sea pens are found on soft substrata down to abyssal depths (Yesson et al., 2012). The shallowest occurrences of typically deep-water species are in high latitudes associated with the rocky slopes and sills of fjords (*L. pertusa* off of Norway at 37 m depth, Wilson, 1979) or narrow passes between islands (the octocorals *Paragorgia arborea* and *Plumarella* spp. at 27 m depth in Alaska, (Stone, 2006)). Continental slopes exhibit a variety of specific topographic irregularities that provide suitable substrate for cold-water coral larvae to

settle. In many parts of the world ocean, the shelf edge is incised by gullies and submarine canyons (Harris and Whiteway, 2011; Harris et al., 2014). Some prominent examples are located at the canyon-rich slope of the Gulf of Lion off the coast of France (Fabri et al., 2014), the Bay of Biscay under the national jurisdiction of France and Spain (De Mol et al., 2011; Sánchez et al., 2014), the Gully off the coast of Nova Scotia (Mortensen and Buhl-Mortensen, 2005), and the canyons off the eastern United States (Watling and Auster, 2005; Brooke and Ross, 2014). Narrow straits between land-masses may also provide suitable substrate, such as the Straits of Florida (Correa et al., 2012), Gibraltar (De Mol et al., 2012), Sicily (Freiwald et al., 2009), and the Yucatan (Hebbeln et al., 2014). Open-slope CWC mounds are known from the large reefs off the Norwegian coast (Mortensen et al., 2001; Buhl-Mortensen et al., 2014), the Northeast Atlantic along the Rockall and Porcupine Banks (Van der Land et al., 2014), the Southeast coast of the United States (Stetson et al., 1962; Reed et al., 2006), the Gulf of Mexico (Reed et al., 2006; Cordes et al., 2008), Southwestern Atlantic Ocean (Viana et al., 1998; Sumida et al., 2004; Pires, 2007; Carranza et al., 2012), and off Mauritania (Colman et al., 2005). These mounds are not randomly distributed over the slope but show a strong affinity with distinct water mass boundaries passing along the slope (Mienis et al., 2007; Arantes et al., 2009; White and Dorschel, 2010). Open-slope coral gardens appear to be common along most of the continental margins of the world (Figure 3, Yesson et al., 2012). Oceanic seamounts represent another important cold-water coral-rich environment (see Chapter 51), such as the Tasmanian seamounts off South Australia (Thresher et al., 2011), the seamount speckled Chatham Rise off the coast of New Zealand (Tracey et al., 2011), seamounts of the central Pacific (Rogers et al., 2007), and seamounts of the Mid-Atlantic Ridge system (Mortensen et al., 2008). A compilation of framework-forming cold-water coral occurrences is displayed in Figure 4 based on the UNEP-WCMC database (Freiwald et al., 2005) and more recent findings. The current information on deep-water octocorals suggests that they are ubiquitous along continental margins and seamounts on hard substrata, as well as occasionally on soft-bottom in the case of the sea pens and a few species of bamboo corals. A combination of octocorals collections and observations along with a predictive habitat suitability model is displayed in Figure 3 (Yesson et al., 2012).

Cold-water corals have been known since the first descriptions in the 18th century and the first deep-water research expeditions of the 19th century (Roberts et al., 2006). The presence of large reef structures in deep water was not broadly appreciated by the scientific community until the first submersibles were available in the late 20th century (Cairns, 2007). Using these new tools, a more complete set of distribution records and characterization of the habitat requirements of CWC were developed. Based on these recent data, the use of habitat modelling has led to the discovery of numerous cold-water coral sites and habitats. As an example, scleractinians were discovered on steep submarine cliffs after modelling (Huvenne et al., 2011) and field observation in the Mediterranean (Naumann et al., 2013) and the Bay of Biscay (De Mol et al., 2011; Reveillaud et al., 2008). Similarly, an extensive screening of newly available mapping and visualization technology in the Mediterranean revealed additional and more extensive

coral formations than anticipated hitherto (Freiwald et al., 2009). Habitat modelling has thus far mostly been applied to a few of the most common species at a global and regional scale (Rengstorf et al., 2013; Yesson et al., 2012) at a coarse spatial resolution (Ross and Howell, 2013). However, models are now being applied at finer resolution levels in order to guide surveys with the visual tools of remotely-operated and manned submersibles (Georgian et al., 2014). Additional fine-grained and broad-scale habitat modelling, specifically incorporating the best available taxonomic identifications (Henry and Roberts, 2014) is still needed to discover additional habitats, and to forecast the fate of CWC facing both direct (fisheries) and indirect (environmental) impacts (Guinotte et al., 2006; Clark and Tittensor, 2010).

Cold-water coral reefs, mounds, and gardens support a highly diverse community, comprising faunal biomass that is orders of magnitude above that of the surrounding seafloor (Mortensen et al., 1995; Henry and Roberts, 2007; Cordes et al., 2008; Roberts et al., 2008; Rowden et al., 2010). In addition to this tightly-associated community, cold-water corals may also serve as important spawning, nursery, breeding and feeding areas for a multitude of fishes and invertebrates (Koslow et al., 2001; Fossa et al., 2002; Husebo et al., 2002; Colman et al., 2005; Stone, 2006; Ross and Quattrini, 2009; Baillon et al., 2012; Henry et al., 2013), and habitat for transient diel vertical migrators (Davies et al., 2010). The ability to construct massive calcium carbonate frameworks, which makes both shallow and deep-water coral reefs unique, provides an important biogeochemical function in both the carbonate system (Doney et al., 2009) and in calcium balance (Moberg and Folke, 1999). CWC skeletons also provide an information function (*sensu de Groot et al., 2002*) through their archiving of paleoclimate signals (Adkins et al., 1998; Williams et al., 2006). Besides this, CWC ecosystems possess an inherent aesthetic value (*sensu de Groot et al., 2002*) demonstrated through countless films, photographs, and paintings of reefs or reef organisms.

Cold-water corals and the communities they support rely on surface productivity as their primary source of nutrition; either through the slow, relatively steady deposition of particulate organic carbon (POC) in the form of marine snow, which may be enhanced by hydrographic mechanisms (e.g. Davies et al., 2009; Kiriakoulakis et al., 2007), or through more active transport of carbon provided by vertical migrators (Mienis et al., 2012). However, *L. pertusa* has been shown to incorporate everything from dissolved organic carbon (DOC) to POC to algal biomass to small zooplankton (van Oevelen et al., 2009). As in shallow-water systems, corals and sponges of the deep reefs recycle these nutrients and form both the structural and trophic foundation of the ecosystem. In addition to these ties from shallow to deep water, the transport of nutrients from deep to shallow water is accomplished both by the diel vertical migrations of plankton and small fishes (Davies et al., 2010) as well as by periodic down- and upwelling that can occur near some of the reefs (Mienis et al., 2007; Davies et al., 2009). Although the mechanisms for deep-to-shallow water transport are well established, the input of deep-water secondary productivity to shallow ecosystems remains unquantified.

2. Features and Trends

All geological structures mentioned share some environmental factors that facilitate coral settlement and subsequent growth: provision of current-swept hard substrate, and often topographically-guided hydrodynamic settings. It has been suggested that corals are preferably confined to narrow seawater density ($\Sigma\text{-}\theta$) envelopes (Dullo et al., 2008) in which along-slope larval dispersal propagation may be facilitated. Survival and growth may be most closely associated with specific hydrodynamic settings including tidal-driven internal-wave fronts hitting continental slopes and seamounts (Mienis et al., 2007; Henry et al., 2014), specific up- and downwelling currents affecting the summits of shallow-water seamounts (Ramirez-Llodra et al., 2010), and tidal-driven downwelling phenomena on inner shelf settings (Davies et al., 2009; Findlay et al., 2013). These hydrographic transfer processes tend to concentrate or prolong the retention time of nutrients and food that sustain the metabolic demands of the suspension-feeding community.

Another perspective on the occurrence of coral habitat is a combined biogeophysical and hydrochemical analysis of the ambient seawater, a very recent endeavour in the still young research history of cold-water coral systems (e.g., Findlay et al., 2014; Flögel et al., 2014; Henry et al., 2014; Lunden et al., 2013). These forms of data along with species presence data were incorporated into global habitat suitability study by Davies and Guinotte (2011) that was conducted on the six major cold-water framework-building corals (*Enallopsammia rostrata*, *Goniocorella dumosa*, *Lophelia pertusa*, *Madrepora oculata*, *Oculina varicosa* and *Solenosmilia variabilis*) using the Maximum Entropy modelling approach (MAXENT). This approach uses species-presence data, global bathymetry 30-arc second grids (1 km² resolution) and incorporates environmental data from several global databases. Viewed on such a global scale, these corals generally thrive in waters that: (1) are supersaturated with respect to aragonite, (2) occur shallower than 1500 m water depth, (3) contain dissolved oxygen concentrations of >4 ml l⁻¹, (4) have a salinity range between 34 and 37 ppt, and (5) show a temperature range between 5 and 10°C. Laboratory experiments have confirmed many of these ranges, with *L. pertusa* being the most commonly studied species. Mediterranean *L. pertusa* and *M. oculata* colonies survived and grew at 12°C for three weeks, with *M. oculata* showing a greater sensitivity to high temperature (Naumann et al., 2014). Gulf of Mexico *L. pertusa* colonies survived and grew at up to 12°C, but died when exposed to 14°C for 8 days (Lunden et al., 2014). Studies of *L. pertusa* from west of Scotland, United Kingdom of Great Britain and Northern Ireland, demonstrated that this species can maintain respiratory independence and even survive periods of reduced oxygen (Dodds et al., 2007).

However, some remarkable outliers to these trends exist in the Red Sea and the Gulf of Mexico. The Red Sea represents the warmest and most saline deep-sea basin on Earth, with temperatures >20°C throughout the water column and salinity in excess of 40 ppt.

Recent findings of typically deep-dwelling corals in these habitats shed new light on the persistence of corals in deep waters (Roder et al., 2013; Qurban et al., 2014). Although none of the coral species found in the Red Sea are among the most common globally (see above for list), limited framework growth is recorded mainly by *Eguchipsammia fistula* under food- and oxygen deprived conditions (1.02 – 2.04 ml l⁻¹). Coral survival under such extreme environmental conditions may follow the strategy of metabolic depression (*sensu* Guppy and Withers, 1999), including depressed aerobic respiration and calcification rates. However, the high temperatures in combination with high aragonite saturation values of 3.44-3.61 in the Red Sea may facilitate calcification under these otherwise adverse conditions (Roder et al., 2013). The cold-water coral communities in the northern Gulf of Mexico belong to the most intensively studied sites in waters of the United States (e.g., Cordes et al., 2008). The major framework-constructer is *L. pertusa* and most environmental variables (i.e., temperature, salinity and aragonite saturation state) reflect the ranges known from Atlantic *Lophelia* sites (Davies et al., 2010; Lunden et al., 2013). However, dissolved oxygen values appear to be low, 2.7–2.8 ml l⁻¹ are typically observed (Davies et al., 2010) and values as low as 1.5 ml l⁻¹ have been recorded adjacent to coral mounds (Georgian et al., 2014). Coral nubbins from these Gulf of Mexico populations survived and grew in the lab at oxygen levels as low as 2.9 ml l⁻¹, but eight-day incubations at lower oxygen concentrations (1.5 ml l⁻¹) caused complete mortality, suggesting that these conditions are short-lived *in situ* (Lunden et al., 2014). Similarly, low oxygenation levels were found in the newly discovered *Lophelia-Enallopsammia* coral mounds in the Campeche Bank coral mound province, in the southern Gulf of Mexico (Hebbeln et al., 2014). It is possible that the low oxygen concentrations of the Gulf of Mexico result in lower growth rates observed for *L. pertusa* on natural (Brooke and Young, 2009) and man-made substrata (Larcom et al., 2014), although this remains to be examined empirically.

There have been numerous recent advances in our knowledge of the oceanographic variables describing coral habitat in the deep sea. However, knowledge gaps still remain when up-scaling from local to regional to global scales. Furthermore, limited capacity to carry out long-term *in situ* measurements with benthic landers and cabled observatories persists. This knowledge is of utmost importance to understand the consequences of already perceptible environmental change, such as ocean acidification, spread of oxygen minimum zones, and rising temperatures, on deep-sea ecosystems.

3. Major Pressures Linked to the Trends

Numerous anthropogenic threats to cold-water coral communities exist, the most significant of which include fisheries, hydrocarbon exploration and extraction, and mining, as well as global ocean change including warming and acidification. An improved understanding of the function of cold-water corals as habitat, feeding grounds and nurseries for many fishes including certain deep-sea fisheries targets has emerged along with concerns as to the impact of fisheries on these ecosystems (Costello et al., 2005;

Grehan et al., 2005; Stone, 2006; Hourigan, 2009; Maynou and Cartes, 2012). Physical impacts from both trawl fisheries and long-lining, now being conducted as deep as 1500-2000 m, are likely to be significant anywhere deep-water fisheries are active, but have been well-demonstrated in the North Atlantic and Norwegian Seas (Roberts et al., 2000; Fossa et al., 2002; Hall-Spencer et al., 2002, Reed, 2002), on the Australian seamounts (Koslow et al., 2001), off the coast of New Zealand (Probert et al., 1997, Clark and Rowden, 2009), and Southwestern Atlantic slope (Kitahara, 2009). Trawl fisheries have the most severe impacts, by removal of large volumes of organisms and of cold-water coral framework from the seafloor and the concomitant destruction of the habitat, but long-lining impacts have also been observed (Heifetz et al., 2009). Recovery times from these types of disturbance are likely to require settlement and regrowth of the corals, which based on radiometric dating of cold-water coral species, can require decades to centuries (Andrews et al., 2002; Prouty et al., 2014) or in the case of the black corals, could require millennia (Roark et al., 2009). Direct evidence of recovery times is consistent with these estimates, indicating that there was no apparent recovery 5-10 years after the closure of seamount fisheries on the Tasmanian seamounts (Althaus et al., 2009). These impacts have also been the most recognized in terms of management efforts, thus far (see below).

Installation of oil and gas offshore facilities and drilling activities (see Chapter 21) have a great potential to impact cold-water coral communities. The potential impact should be higher in areas where much of the available substrate is from authigenic carbonates related to natural oil and gas seepage, such as the Gulf of Mexico (Cordes et al., 2008), some locations on the Norwegian margin (Hovland, 2005), and the New Zealand margin (Baco et al., 2010). Most of the typical impacts would be from infrastructure installation and the deposition of drill tailings that can include high concentrations in barium, among other potential toxins (Continental Shelf Associates, 2006). These impacts are typically confined to a few hundred metres, but can have been shown to extend over 2 kilometres in some cases (Continental Shelf Associates, 2006). The most glaring example of oil and gas industry impacts in the deep sea is the Deepwater Horizon disaster in 2010 in the Gulf of Mexico. Material conclusively linked to the spill was discovered on octocoral colonies (primarily *Paramuricea biscaya*) approximately 11 km away from the site of the drilling rig (White et al., 2012a). These colonies suffered tissue loss and many have continued to decline in health since the spill (Hsing et al., 2013). Subsequent surveys detected at least two additional sites, extending the impacts to 26 km from the site of the well, and from 1,370 m to 1,950 m water depth (Fisher et al., 2014). One of the primary lessons learned from this tragic incident is that there is an urgent need for improved baseline surveys in deep waters prior to industrial activity. Offshore energy industry activity in the form of wind and wave energy is also increasing (see Chapter 22), and physical structure placed on the seafloor, including pipelines and cables, could have an impact on cold-water corals if the appropriate surveys are not completed prior to installation.

Mining activities have increased in the deep sea in recent years. This activity has mainly focused on massive seafloor sulphide deposits near hydrothermal vents, cobalt-rich

crusts on seamounts, and also on polymetallic nodules on the abyssal plain (Ramirez-Llodra et al., 2011). These forms of mining would involve removal of a large area of the seafloor surface, and complete removal of any associated communities, along with the generation of large sediment and tailing plumes that may impact filter feeding communities at a distance from the mining activity (Ramirez-Llodra et al., 2011). On the seamounts of the Kermadec Arc, some which have already been leased for mining, cold-water coral communities consisted of scleractinian, schizopathid, stylasterid, primnoid, and isidid corals primarily associated with inactive areas away from hydrothermal venting (Boschen et al., 2015). Deep-sea corals are often found on the hard substrata in inactive vent fields, and may be subject to significant impacts from their removal due to their long life spans and low recruitment rates.

Global climate change is affecting every community type on Earth, and its effects are already being felt in the deep sea. Ocean warming has been recorded in numerous deep-water habitats, but is particularly significant in marginal seas, which are home to many of the world's cold-water coral reefs. In particular, there is evidence that the Mediterranean has warmed by at least 0.1°C between 1950 and 2000 (Rixen et al., 2005), and this change has been shown to impact the deep-sea communities there (Danovaro et al., 2004). Cold-water corals are highly sensitive to warming waters because of their upper thermal limits, and the temperature excursions around this general upward trend are likely to be much higher.

Ocean acidification is another pervasive threat (see Chapter 5). Continued additions of CO₂ into the atmosphere exacerbate the problem as the oceans absorb approximately 26 per cent of the CO₂ from the atmosphere (Le Quere et al., 2009). Because the carbonate saturation state in seawater is temperature-dependent, it is much lower in cold waters and therefore cold-water corals lie much closer to the saturation horizon (the depth below which the saturation state is below 1 and carbonate minerals will dissolve) than shallow-water corals. As ocean acidification proceeds, the saturation horizon will become shallower, thus exposing more cold-water corals to undersaturated conditions (Guinotte et al., 2006). Solitary corals of the South Pacific are already facing saturation states below 1 (Thresher et al., 2011), and small reef frameworks constructed by *Solenosmilia variabilis* grow in periodically undersaturated waters on Northeast Atlantic (Henry and Roberts 2014; Henry et al., 2014) and New Zealand seamounts (Bostock et al., 2015). The *Lophelia* reefs of the Gulf of Mexico lie very close to the saturation horizon, at a minimum saturation state of approximately 1.2 (Lunden et al., 2013). Since these recent studies represent the baseline for the deep-water carbonate system, the extent to which anthropogenic CO₂ contributes to these low values remains unclear.

Other possible effects of global climate change include deoxygenation and changes in sea-surface productivity. Declines in oxygen availability are primarily linked to increasing water temperature, but also to synergistic effects of pollution and agricultural runoff, which are most significant in shallow water. However, because some cold-water corals live at oxygen-minimum zone depths (Davies et al., 2010; Georgian et al., 2014), even small changes in oxygen concentration could be significant. Because cold-water corals

live below the photic zone and rely for their nutrition on primary productivity transferred from the surface waters to depth, changes in surface productivity could have significant negative impacts. In particular, the increased stratification of surface waters above the thermocline will lead to decreased productivity in high latitude spring-bloom and upwelling ecosystems (Falkowski et al., 1998). This includes the North Atlantic, where the most extensive examples of the known cold-water coral reefs exist.

Through *in situ* habitat characterization as well as by experimental approaches, it has become clear that acidification and the expansion of oxygen minimum zones, together with rising temperatures, will affect the average metabolism and physiology of most scleractinians (Gori et al., 2013; Lartaud et al., 2014; McCulloch et al., 2012; Naumann et al., 2013). However, whether such changes will result in range shifts, massive extinctions (as suggested by Tittensor et al., 2010), or if species possess the resources to cope with variations through phenotypic plasticity or adaptive genetic changes, is still largely unknown. The solitary coral *Desmophyllum dianthus* and colonial scleractinian *Dendrophyllia cornigera* have shown resistance to high temperature in aquaria (Naumann et al., 2013). The *L. pertusa* colonies from the North Atlantic and Mediterranean have shown the ability to acclimatize to ocean acidification in long-term experiments (Form and Riebesell, 2012; Maier et al., 2012). In other experiments, certain genotypes of *L. pertusa* from the Gulf of Mexico were able to calcify at saturation states as low as 1.0, suggesting a possible genetic basis to their sensitivity to ocean acidification (Lunden et al., 2014). However, to date no long-term studies combining acidification with temperature stress have been produced and long-term effects on bare skeletal structure are unknown. In addition, some cold-water coral species seem to be resilient to some of these processes, and may hold some of the answers for coral survival in future global climate-change scenarios. Regardless, the projected shoaling of the aragonite saturation horizon (Orr et al., 2005) threatens the future integrity of deep-water scleractinian reef structures world-wide (Guinotte et al., 2006).

The ability of these organisms to keep up with the pace of ocean change and disperse into a new environment or to recolonize depleted areas depends on the capacity for mid- or long-distance dispersal. This capacity has been demonstrated for *L. pertusa* by isotope reconstruction and genetic analysis (Henry et al., 2014), supporting the hypothesis of a post-glacial recolonization of the Atlantic by refugees in the Mediterranean (De Mol et al., 2002; De Mol et al., 2005; Frank et al., 2009).

Overall, *L. pertusa* shows a pattern of relative homogeneity within regions (e.g. the North Atlantic), and modest but significant differentiation among regions, both for the Western Atlantic (e.g. Gulf of Mexico vs. Southeast United States vs. North Atlantic; Morrison et al., 2011), as well as along Eastern Atlantic margins from the Bay of Biscay to Iceland for both *L. pertusa* and *M. oculata* (Becheler, 2013). Previous studies on the Eastern Atlantic margin had shown less extensive connectivity, possibly reflecting the peculiar position of fjord populations in Sweden and Norway (Le Goff-Vitry et al., 2004). Preliminary studies on *D. dianthus* suggest a lack of barrier to large-scale dispersal (Addamo et al., 2012), although bathymetric barriers to gene flow are evident (Miller et

al., 2011). Bathymetric barriers to dispersal are also apparent in the phylogenetic community structure of deep-water octocoral assemblages in the Gulf of Mexico (Quattrini et al., 2014).

Finally, the distribution of genetic polymorphism among populations of octocorallians and antipatharians across seamounts of the Pacific spanning 1700 km also showed no evidence for strong endemism, supporting the ability for large scale dispersal of the species studied (Thoma et al., 2009). It is only recently that the embryonic and larval biology of *Lophelia pertusa* has been described (Brooke and Järnegren, 2013). The settlement and benthic juvenile stages have not been observed. Knowledge on the possible effects of ocean acidification on coral reproduction so far comes from tropical corals but it is reasonable to believe that there are many similarities (Albright, 2011).

Altogether, the present state of knowledge of genetic connectivity of deep-water corals suggests that the potential exists for some species to disperse and colonize across large distances in response to major environmental changes, and some species have a more limited dispersal capacity. However, more studies need to be conducted at a finer spatial scale using specific genetic markers (e.g. Dahl et al., 2012) to improve the understanding of the impact of environmental changes on connectivity and persistence at the local scale. These different degrees of differentiation among and within ocean basins indicate the need for regional-scale conservation strategies.

4. Implications for Services to Ecosystems and Humanity

Impacts on cold-water corals and the structures they form would have significant implications for the functioning of the surrounding deep sea and wider oceanic ecosystems. The linkages from shallow to deep water, and back again, implicate cold-water corals as key components of the broader oceanic ecosystem. The physical structures created by cold-water corals support fisheries through the direct provision of habitat, refuge, or nursery grounds, which is likely to lead to increases in commercially significant fish populations. These effects are most pronounced where cold-water corals are known to be highly abundant, such as on the North Atlantic, North Pacific, and Australian and New Zealand seamounts.

The ecosystem services provided go beyond the direct provision of substrate and shelter (see review by Foley et al., 2010). The complex habitat formed by cold-water corals increases the heterogeneity of the continental margin, promoting higher diversity (Cordes et al., 2010). As in other ecosystems (e.g. Tilman et al., 1997), increased diversity mostly promotes higher levels of ecosystem function, including carbon cycling. This specific ecosystem service may be important in relatively oligotrophic regions such as the Gulf of Mexico and the Mediterranean where cold-water corals-enhanced nutrient cycling and remineralization would generate nutrients that may be transported back to the surface. Recent findings from reefs off Norway demonstrated their

significant role in carbon cycling, raising additional concerns as to the impact of their disappearance on global biochemical cycles (White et al., 2012b).

Cold-water corals also hold genetic resources that may provide services to humanity, either directly or through their function as biodiversity hotspots in the deep sea (Arrieta et al., 2010). Taxa such as cnidarians, sponges, and molluscs have been shown to harbour the highest abundance of natural marine products of interest for biotechnology development (Molinski et al., 2009; Rocha et al., 2011). As an example, the anti-AIDS drug AZT was developed from an extract of a sponge from a shallow Caribbean reef (de la Calle, 2009). At least half, and likely far more, of the diversity of corals and sponges lies in deep, cold waters (Cairns, 2007; Hogg et al., 2010), and therefore, these understudied and often unknown species have the highest potential for new discoveries. With this potential comes a management concern, especially as some of the potential genetic resources (see also chapter 29) harboured within the genomes of cold-water corals and sponges lie in areas beyond national jurisdiction (Bruckner, 2002; de la Calle, 2009).

5. Conservation Responses

Raised awareness of the susceptibility of cold-water coral communities to impacts of human activities in recent decades has resulted in national and international actions to protect cold-water corals and facilitate recovery of coral areas adversely affected in the past. In some areas where significant damage was documented, e.g. along the continental shelf off Norway (Fossa et al., 2002) and on seamounts in Australia and New Zealand (Koslow et al., 2001), national legislation was introduced and specific management measures were implemented. A growing number of protected areas and fisheries closures in areas within national jurisdiction in the Atlantic and North Pacific have followed, and in some countries, e.g. Norway, it is illegal to deliberately fish in coral areas even if the area is not formally closed as a protected area.

Since the mid-2000s a series of United Nations General Assembly (UNGA) resolutions (e.g. 61/105, 64/72, 66/68) on sustainable fisheries have called for a number of measures, including the implementation of the International Guidelines for the Management of Deep-Sea Fisheries in the High Seas (FAO, 2009), and action to avoid significant adverse impacts of fisheries on vulnerable marine ecosystems,¹ including e.g. cold water corals.² These resolutions focus in particular on areas beyond national

¹ The International Guidelines for the Management of Deep-Sea Fisheries in the High Seas describe vulnerable marine ecosystems and list characteristics to be used as criteria in the identification of such ecosystems.

² The Annex to the Guidelines refers to “certain coldwater corals” as part of examples of species groups, communities and habitat forming species that are documented or considered sensitive and potentially vulnerable to deep-sea fisheries in the high seas, and which may contribute to forming vulnerable marine ecosystems.

jurisdiction. Some of the protective efforts, including fisheries closures, within EEZs predate the UNGA resolutions, but the resolutions stimulated further action. Such actions run in parallel with efforts to create networks of marine protected areas in areas within national jurisdiction, partly motivated by the need to protect corals.

In response to the measures called for by the General Assembly, seamounts and continental slope habitats with a documented or assumed coral presence have now been set aside as marine reserves or fisheries closures by competent authorities. These areas are protected partly through area-based management tools (for example, by Australia, New Zealand and the United States within areas under their respective national jurisdictions) and partly by regional fisheries management organizations and arrangements (RFMO/As) in the high seas of the North and South-eastern Atlantic. In the north-eastern Atlantic, substantial areas have been protected within national jurisdictions of European Union Member States, as well as of Iceland and Norway. Beyond areas of national jurisdiction, RFMOs/As with competence to regulate bottom fisheries (for example, the Northwest Atlantic Fisheries Organization (www.nafo.int) and the North East Atlantic Fisheries Commission (www.neafc.org)) have closed a range of seamounts and seabed areas to bottom fishing. Within their regulatory areas, these RFMOs have also restricted fishing to a limited agreed set of sub-areas outside the “existing fishing areas”, and have created strict rules and impact assessment requirements for these sub-areas. These measures are intended not only to protect known areas with significant concentrations of cold-water coral, but also essentially to reduce the incentive for exploratory bottom fishing outside existing fishing areas. Similar rules apply in the southeast Atlantic high seas implemented by the South East Atlantic Fisheries Organization (SEAFO, www.seafo.org) which closed selected ridge sections and seamounts to fishing, and restricted fisheries to certain subareas. In the Mediterranean, the General Fisheries Commission for the Mediterranean (GFCM, www.gfcm.org) implemented fisheries restriction zones in specific coral sites.

The Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR, <http://www.ccamlr.org/>) banned bottom trawl fishing within the CCAMLR Convention area. Bottom fishing regulations and area closures aim to facilitate responsible fisheries and to prevent adverse impacts on bottom-associated vulnerable marine communities as defined by FAO (2009). Marine protected areas in this area are being considered but only one MPA has been established thus far.

Currently little information exists to assess the impacts on target or by-catch species by deep-sea fishing on seamounts in the Indian Ocean. The Southern Indian Ocean Deepsea Fishers Association declared a number of seamounts in the Southern Indian Ocean as voluntary areas closed to fishing. The entry into force in 2012 of the Southern Indian Ocean Fisheries Agreement³ (SIOFA), a new regional fisheries management arrangement for the region, may lead to better documentation and regulation of seamount fisheries.

³ United Nations, *Treaty Series*, vol. 2835, No. 49647.

In the North Pacific, the United States designated Habitat Areas of Particular Concern (HAPCs) that contain Essential Fish Habitat (EFH) and closed subareas of the shelf and upper slope from California to the Aleutian Islands to bottom trawling. Additional areas of *L. pertusa* habitat have recently been designated as HAPCs off the southeast coast of the United States. Canada also has a strategy to develop and implement further measures. In areas beyond national jurisdiction in the North and South Pacific, respectively, States which participated in the negotiations to establish the North Pacific Fisheries Commission (NPFC) and the South Pacific Fisheries Management Organization (SPRFMO) introduced measures similar to those adopted by the Atlantic RFMOs.

Within areas under national jurisdiction of the United States in the Gulf of Mexico, mitigation areas are established around mapped seafloor seismic anomalies that often coincide with hardgrounds that may support cold-water coral communities. Although these measures may prevent most direct impacts from infrastructure, the persistent threat of deep-water fishing, accidental loss of gear, and catastrophic oil spills remains a concern.

A continued challenge is to assess the effectiveness of current and new protective measures and to develop management in areas that need greater attention, such as those for which no RFMOs exist. The fisheries sector is often perceived as representing the major threat to cold-water corals, but a growing challenge is to avoid adverse impacts from other industries moving into areas containing known coral habitats, e.g. mining, oil and gas industries, and renewable energy industries operating under different management regimes.

Chapter 43. Tropical and Sub-Tropical Coral Reefs

Writing team: Clive Wilkinson (convenor), Bernard Salvat, C. Mark Eakin, Angelique Brathwaite, Ronaldo Francini-Filho, Nicole Webster, Beatrice Padovani Ferreira (Co-Lead member), Peter Harris (Co-Lead member)

1. Introduction

Many activities and businesses are judged on three criteria, the triple bottom line: economic evaluation; social responsibility; and environmental conservation. Coral reefs make major contributions towards “people, planet, profit”; they are economically beneficial to many countries, especially small island developing States (SIDS), in the provision of food, materials and income from tourism and fisheries; coastal and island societies are often largely or nearly completely dependent on adjacent coral reefs, with cultures developed around those reefs; and reefs contain the largest reservoirs of biodiversity in the world. Moreover, these reefs constitute a very special ecosystem, forming a link between humans on the land and the ocean around them.

Of the 193 Member States of the United Nations, 79 States (41 per cent) have coral reefs in their maritime zones, including a large number of SIDS. These reefs are estimated to cover 249,713 km² (Burke et al., 2011a) to 284,300 km² (Spalding et al., 2001), with an additional 600,000 km² of sandy lagoons. Reefs and nearby seagrass and mangrove ecosystems are of major importance for 275 million people who depend on associated fisheries as their major source of animal protein (UNSG, 2011) and play a role in social stability, especially within a subsistence economy which is often declining in sustainability. Of these 79 States, more than 30 SIDS have coral reefs that provide the major source of food, coastal protection, and a limited amount of rock and sand; and valuable income from tourism; the continual provision of these ecosystem services is dependent on actions focused on sustaining and conserving healthy, productive coral reef ecosystems.

Coral reefs around the world have been in a state of continual decline over the past 100 years, and especially over the past 50 years. The Global Coral Reef Monitoring Network, which has reported since 1998 in the “Status of Coral Reefs of the World” series assessed that approximately 19 per cent of the world’s coral reefs were severely damaged with no immediate prospects of recovery, and 35 per cent of the remaining coral reefs were under imminent risk of degradation from direct human pressures (assessment by the Global Coral Reef Monitoring Network; Wilkinson, 2008; with 372 contributing authors from 96 States and territories). Similar estimates of large-scale degradation have been reported both before and since (Burke et al., 2002; Burke and Maidens, 2004; Bruno and Selig, 2007; Bellwood et al., 2004; Obura et al., 2008). A more

recent study by the World Resources Institute in the “Reefs at Risk Revisited” report (Burke et al., 2011a) calculated that more than 60 per cent of the world’s coral reefs are under immediate threat. Indeed the latest Intergovernmental Panel on Climate Change (IPCC (2014)) report suggests that “coral reefs are one of the most vulnerable ecosystem on Earth” and will be functionally extinct by 2050, without adaptation (worst case scenario), or by 2100 with biological adaptation of the whole ecosystem. Presently the level of threats varies considerably in different geographical regions; reefs of the Pacific Ocean are least threatened, but those throughout Asia and the wider Caribbean and Atlantic regions are under greater threats.

Coral reefs developed throughout millions of years under a wide range of “natural” stresses, such as storms, variations in sea level, volcanic and tectonic plate activity. However recent anthropogenic stresses are overwhelming the natural reef resistance/resilience and recovery mechanisms, resulting in major losses and declines in the reefs and their biological resources in many regions. The major threats are: overfishing and destructive fishing practices; pollution and increased sedimentation; habitat destruction; increases in diseases and predation; and especially impacts of climate change and ocean acidification (OA). This chapter highlights the threats to the world’s coral reefs, lists their current status and reports conservation actions that so far have been successful to ensure that reefs continue to provide ecosystem services to several billion people around the world.

Coastal protection and reef fisheries are of utmost socioeconomic importance for coastal communities; and reefs constitute the basis of many cultures. In addition, they are a source of rock and sand aggregate for construction but frequently such exploitation is unsustainable. The economic value of reefs,, only as a source of raw materials, has been estimated at 28 United States dollars per hectare (Costanza et al., 2014; see also Chapter 7). Reefs underpin the reef-based tourism industry and harbour biodiversity as natural capital.

1.1 Cultural

Since humans began to inhabit coral reef areas, they developed strong cultural links with this ecosystem, both with the habitats and also with many species. Such cultural themes associated with reef ecosystems developed through popular beliefs and the ecosystem services essential to their livelihoods. More importantly for many people, the coral reefs constituted and sustained the land on which they lived. Some of the human communities in South East Asia, which had settled near coral reef waters, migrated outwards during the Holocene and progressively colonized islands throughout the Pacific Ocean. Many Pacific communities developed strong cultural affinities towards the reefs and many of these remain active and recognized by local and national governments.

1.2 Coastal protection

Reefs and mangrove forests provide coastal protection for land resources and human infrastructure, especially where large areas of shallow reef flats are adjacent to the shore and reefs have a distinct crest. This is a continual service, which is especially important during storms and cyclones. This service also includes some attenuation of tsunami waves, as was the case during the 2004 Indian Ocean tsunami (Wilkinson et al., 2006). Coastal protection provided by coral reefs is valued at 10.7 billion dollars (Table 1), which can be considered as a natural alternative to the cost of building seawalls along coasts that are otherwise protected from ocean swell and storm waves by offshore barrier reef systems.

Table 1. Annual net global benefits from coral reef-related ecosystem services in dollars assessed in 2010, with two important States included for emphasis. Values are expressed in millions of United States dollars as net benefits, including costs (from Burke et al., 2011b).

Region & Total	Tourism	Reef Fisheries	Shoreline Protection
Global 29 000	11 500	6 800	10 700
Indonesia 2 014	127	1 500	387
Philippines 1 283	133	750	400

1.3 Fisheries and food

About 275 million people worldwide depend directly on ecosystem services provided by coral reefs and associated ecosystems (Newton et al., 2007; Cinner et al., 2008). This is particularly crucial for SIDS and coastal developing countries (Burke et al., 2011a; see also Chapter 15). Estimates of the value of all goods, services, and livelihoods associated with coral reefs (including tourism, fisheries and protection) exceed 30 billion dollars (Cesar et al., 2003). Fisheries in the tropics feed millions of people (Whittingham et al., 2003); but the importance of reefs extends far beyond economically measurable values, as the identity of many coastal peoples is linked to reefs through their socio-cultural practices (Johannes, 1981; Cinner et al., 2008; Kittinger et al., 2012).

1.4 Rock and sand

Coral reefs produce large amounts of exploitable sand and rock (Reid et al., 2005), which are valuable for many coastal communities, especially those living on coral islands with no other sources of these materials. The use of coral blocks taken off the reef for building construction was sustainable when human populations were lower. However, with increasing demand from growing populations, the practice became unsustainable in some areas, and excessive harvesting of coral rock and sand exposed shorelines to increased erosion, resulting in damage to adjacent communities. The reef flat around

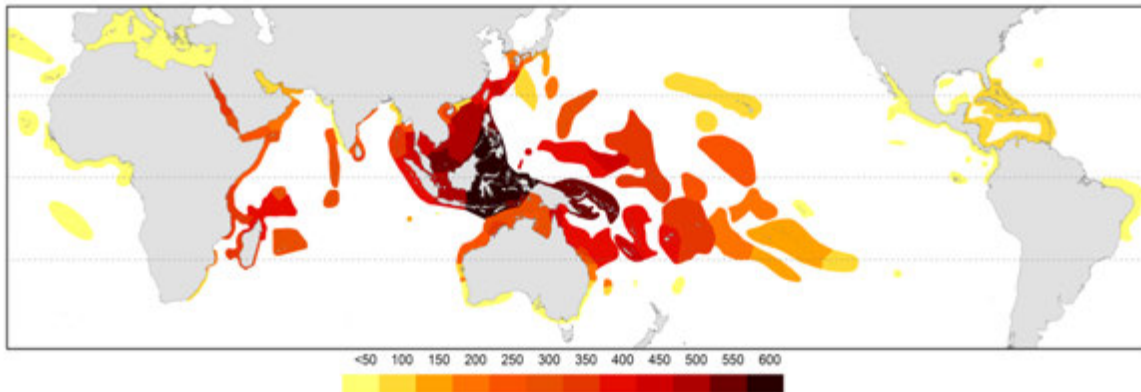

the main island of the Maldives, Malé, was so seriously mined over centuries that the shoreline protection was virtually lost, such that in 1987 storm waves penetrated throughout the city causing massive saltwater damage, including contamination of the groundwater system. Replacement concrete tetrapod seawalls cost more than 10 million dollars per km in the 1990s; the cost would be much higher now (Talbot and Wilkinson, 2001). Such problems create economic dilemmas for governments, as it may be cheaper to mine fringing reefs and sand flats, rather than take the material from land or remote coral structures. This will be exacerbated with climate change-related sea-level rise. Mining also occurs at deeper areas. Large-scale mining projects are predicted for eastern Brazil to explore one of the largest rhodolith beds (i.e., nodules of calcareous coralline algae) in the world (Amado-Filho et al., 2012), aimed at extracting micronutrients and correcting soil acidity for sugar cane plantations.

1.5 Recreation and tourism

Reef-related tourism generates 11.5 billion dollars per year in revenue for the global economy (Table 1). Tourism and recreation in Australia's Great Barrier Reef alone sustain 69,000 jobs and are valued at either 4.4 billion dollars per year (Deloitte Access Economics, 2013) or 11.5 to 15.5 billion dollars (Stoeckl et al. 2014) depending on the methods employed. Reefs contribute about 1 billion dollars per year to the economy of Hawaii, United States of America (Bishop et al., 2011). In 2000-2001, the artificial and natural reefs off southeast Florida supported almost 28 million person-days of recreational diving, fishing and viewing activities. These activities generated about 4.4 billion dollars in local sales, almost 2 billion dollars in local income, and sustained 70,400 full and part-time jobs (Johns, et al., 2001). In Belize, coral reef- and mangrove-associated tourism contributed an estimated 150 - 196 million dollars to the national economy in 2007. Belize is an example of many small developing countries where tourists provide a large proportion of foreign currency earnings. Reef-based tourism is especially sensitive to reef condition, and thus the sector is particularly vulnerable to degradation (Cooper et al., 2008).

1.6 Biodiversity

Coral reefs are the largest reservoirs of biodiversity on earth: they host 32 of 34 recognised phyla and approximately one-third of all marine biodiversity (Spalding et al., 2001; Groombridge and Jenkins, 2002; Roberts et al., 2002; Bouchet, 2006). The centre of global coral reef biodiversity is the "Coral Triangle" (CT), including eastern Indonesia and Malaysia, the Philippines, Timor-Leste, Papua New Guinea and the Solomon Islands (Figure 1). There are more than 550 species of hard corals in the CT area; the diversity decreases away from this focus to the West and to the East, such that less than half this number of species are found in French Polynesia (France), the Hawaiian Islands (United States), and the East African coast. Reef biodiversity in the Caribbean and Atlantic region is also lower; only 65 different coral species are recorded on all these reefs.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. The diversity of hard coral species is greatest within Southeast Asia and the West Pacific; declining diversity radiates out from this area, which is called the Coral Triangle. Much lower diversity of corals is found in the Atlantic and wider Caribbean (from Veron et al., (2015).

2. Major threats

Modern coral reefs have developed since the end of the last ice age (the Pleistocene) when global sea level rose approximately 120 m to just above current levels about 6,500 years ago (Woodroffe and Webster, 2014). Coral reef growth has continued throughout this period, especially during relatively stable sea level (the Holocene); until recently the major stressors were local natural damage, e.g., storms, earthquakes, extreme low tides.

The current serious and further deteriorating status of coral reefs around the world is directly due to damaging stresses that arose during the Anthropocene (Bradbury and Seymour, 2009; Hoegh-Guldberg, 2014); effectively since the mid-18th century, and particularly since 1950, when human pressures ramped up to destructive levels. Assessments of coral reefs cited above and anecdotal reports (Sale and Szmant, 2012) indicate that most reefs were largely “pristine” until direct and indirect human pressures and the advent of “new technology” started affecting many reefs, commencing in the 1970s. This “new technology” permitted far more extensive resource exploitation over far greater areas and to greater depths. This technology (discussed below) includes monofilament lines and nets, and boats with motors. Problems with catchment management, in the face of deforestation for agricultural purposes, have also affected coral reefs, especially coastal reefs off Africa, Australia and South America (Wilkinson and Brodie, 2011).

The degradation of many coral reefs around the world is both directly and incidentally due to increasing anthropogenic pressures arising from increasing population pressures on reefs and their resources, especially through increased economic capacity to use

these resources. The major threats include extractive activities, pollution, sedimentation, physical destruction, and the effects of anthropogenic climate change. Such stressors often interact synergistically with natural stressors, such as storms (Table 2). Carpenter and 38 other authors (Carpenter et al., 2008) have estimated that 33 per cent of all reef-building corals could become extinct due to damage from local threats combined with climate change impacts.

Table 2. Natural and anthropogenic stresses divided into three direct damage categories and one group of organizational factors [summarised from Wilkinson and Salvat, 2012].

1. Natural factors	<i>not readily amenable to conservation measures</i>
i. Catastrophic geological: earthquake, tsunami, volcano, meteors	Potential for rare, but major local damage to coral reefs, especially in Indonesia and South-West Pacific (Papua New Guinea, Solomon Islands, Vanuatu)
ii. Meteorological and climatic: tropical storms, floods, droughts, extremes of heat and cold	Severe storms smash coral reefs or bury them under sediments following floods. Temperature extremes cause coral bleaching and death.
iii. Extreme low tides	Exposes coral reefs leading to widespread mortality e.g., Red Sea
2. Direct human pressures	<i>major target for conservation measures</i>
i. Exploitation: overfishing, bomb fishing and trawler damage (exacerbated by global market pressures)	Harvesting of fishes and invertebrates beyond sustainable yields, includes damaging practices (bomb, cyanide fishing); boat scour and anchor damage to reefs
ii. Sedimentation increases: logging, farming, development	Excess sediment and mud on coral reefs from poor land use, deforestation, dredging; reduces photosynthesis; and associated with disease;
iii. Nutrient and chemical pollution	Organic and inorganic chemicals in sediments, untreated sewage, agriculture, animal husbandry and industry wastes; includes complex organics and heavy metals. Turbidity reduces light, promotes growth of competing algae on corals. Herbicides kill algae associated with coral reefs.
iv. Development of coastal areas	Removal or burial of coral reefs for urban, industrial, transport and tourism developments (e.g., airports); mining reef rock and sand beyond sustainable limits
3. Global change threats	<i>need major global focus; local conservation can assist by increasing reef resilience and raising awareness;</i>
i. Elevated sea-surface temperatures	Bleaching in corals, i.e., loss of photosynthetic zooxanthellae either temporary or lethal; stimulates algal blooms on reefs; increases disease susceptibility; reduces larval survival.
ii. Increased storms, wider climatic fluctuations	Stronger storms will smash or bury coral reefs; increased rain increases sediment flows; can reduce thermal stress locally.
iii. Rising CO ₂ dissolved in seawater with increasing ocean acidification	Increased CO ₂ in seawater increases acidity, which decreases calcification in corals and other organisms and reef cementation and increases erosion (including bioerosion); higher CO ₂ may increase algal productivity;
iv. Diseases, plagues and invasive species	Intensity and frequency of coral diseases and plagues of predators correlated with global climate change, especially higher temperatures.
4. Governance, awareness, political will	<i>major target for conservation measures</i>
i. Rising poverty, increasing populations, alienation from land and sea	More poor, dispossessed people use coral resources for subsistence and habitation.
ii. Poor management capacity and lack of resources	Few trained personnel for coastal management, raising awareness, enforcement and monitoring; lack of funds and logistics for conservation, e.g., smaller countries.

iii. Poor political will and poor oceans governance	Political ignorance, indifference, inertia; corruption and low transparency in governance at global and regional levels all impede decision-making and waste resources.
iv. Uncoordinated global and regional conservation arrangements	Inadequate coordination among multilateral environmental agreements and international donors results in overlapping meeting and reporting requirements which exhaust conservation capacity in smaller countries.

Table 3. A numerical compilation of anthropogenic threats to coral reefs summarized in the graphics in the first map of Burke et al. (2011a), shows that threats are greatest in Southeast and East Asia, with almost 50 percent of reefs at High to Very High threat levels, whereas threats in the wider Pacific and around Australia are much less. Predicted climate change damage, however, will affect all reefs in the world in the next two to three decades. Methodological details are in Burke et al., 2011a.

Region	Low %	Medium %	High %	Very High %
Southeast and East Asia	6	47	28	20
Indian Ocean	34	32	21	13
Caribbean and Atlantic	25	44	18	13
Middle East	35	44	13	8
Pacific	52	28	15	5
Australia	86	13	1	0
World – all areas	39	34	17	10

2.1 *Overfishing*

The major traditional use for coral reefs is extractive exploitation of tropical fisheries resources. For many centuries, these resources, particularly fishes and also turtles, algae, molluscs, crustaceans and echinoids, served as the major animal protein source for many coastal and island communities throughout all oceans. These resources are socially and economically important in sustaining livelihoods of traditional coastal communities, especially through ensuring their food security. However the rate and ease of exploitation has increased, such that in many areas it has reached unsustainable levels and is seriously damaging the ecological integrity of coral reefs. The rate and ease of exploitation has increased in recent decades with the introduction of aluminium boats and motors, monofilament lines and nets, metal hooks, dive masks and spear-guns (now frequently used with underwater lights to catch sleeping fish at night) and use of compressed air (SCUBA and hookah gear). Habitat-damaging practices, such as use of explosives, cyanide or other poisons, also pose a serious threat (Johannes and Riepen, 1995). External markets have driven the increase in the exploitation rate and extension, especially in Asia, to support the tourist demand (see live reef-fish trade below) and also in the wider Caribbean and South America for fresh reef seafood and for export of conch and lobster to the United States. Rapid economic growth throughout Asia has stimulated the lucrative live reef food-fish trade, which is expanding rapidly,

with reef fish taken largely through the use of cyanide and other destructive practices. This trade particularly targets large attractive edible fish, such that one species, the humphead wrasse (*Cheilinus undulatus*) is now listed on the International Union for Conservation of Nature (IUCN) Red List as “Endangered” and several groupers, particularly larger species, are listed as “Near Threatened” (Sadovy et al., 2013). This trade is so valuable that industrial-scale fishing across the Indo-West Pacific targets mass fish-spawning aggregations (Sadovy and Domeier, 2005). Reef fish spawning aggregations have also been drastically reduced across the Caribbean by artisanal fishers. A notable example is the Nassau grouper (*Epinephelus striatus*), once of great commercial importance and now listed as “Endangered” and commercially extinct across much of its range in the Caribbean (Sadovy, 1999). More than a quarter of global records of fish aggregations show a declining trend in numbers of fish aggregating, and 4 per cent are documented as having disappeared entirely (Status Report - Worlds Fish Aggregations 2014; Russell et al., 2014).

Another particularly destructive form of industrial scale fishing is via muro ami (drive net) fishing, observed to operate predominantly from the southern Philippines (Jennings and Polunin, 1996). This practice has been banned from many areas; however, illegal fishing with this method still occurs.

A detailed assessment by the Secretariat for the Pacific Community of current and predicted coral reef fisheries resources in 49 island States reported that catch rates in 55 per cent of them are unsustainable and unlikely to be able to provide food security into the future (Figure 2; Bell et al., 2011b in Bell et al., 2011a). The human population of Oceania has increased fourfold since the middle of the last century. A large proportion of this population is still based on a subsistence economy. The extra fish stocks required will have to come from pelagic species, such as tuna, or through aquaculture, as reef fisheries are declining alarmingly due to over-exploitation, especially through the use of “modern” technology (Figure from Bell et al., 2011).

Data from more than 300 coral reefs in the wider Caribbean show a three to six per cent decline in total fish populations per year over a 50-year period (Paddack et al., 2009). This is in parallel to the decline in mean coral cover from 50 per cent to 10 per cent over a 25-year period (Gardner et al., 2003), and a major loss of reef structural complexity over a 30-year period (Jackson et al., 2014). Large-bodied herbivorous fish from the family Scaridae (parrotfish) play key ecological roles and favour coral health and abundance by controlling overgrowth by algae (Bellwood et al., 2004). A recent large-scale synthesis of peer-reviewed and unpublished data indicates that overfishing of coral reef herbivorous fish is a worldwide problem that deserves urgent attention (Edwards et al., 2013).

Similar declines in reef fish stocks in the Indian Ocean due to over-exploitation are documented (McClanahan et al., 2008; McClanahan et al., 2011), matching reports from the Pacific (Dalzell and Adams, 1996; Zeller et al., 2006).

Figure 2. Current and predicted rates of population (upper diagrams), and the fish stocks needed for food security (lower diagrams) in urban (dark colour) and more remote (pale colour) areas of Melanesia, Micronesia and Polynesia between 2010 and 2030. Note that the scale bar for Melanesia is 10 times larger than the other regions (source: SPC and Bell et al., 2011b in Bell et al., 2011a).

Many coral reef fishes periodically and predictably aggregate to spawn, making them vulnerable to fishing. The problem for management of fishing on these aggregations is particularly challenging because little is known about aggregating fish behaviour and the impacts of fishing, although clear evidence exists of serious declines in several species. Although information on the level of management and monitoring is limited, it appears that 35 per cent have some form of management in place such as marine protected areas, seasonal protection from fishing and/or sale, or fisheries harvest controls, and about 25 per cent have some form of monitoring, such as fish counts (Russell et al., 2014). Multiple management measures are needed for those species, however it is clear that whenever uncontrolled exploitation continues it may lead to major depletions for both fish populations and fisheries and livelihoods they support. (De Michelson et al., 2008; Russell et al., 2014)

2.2 Pollution and sedimentation

Water quality (including elevated nutrient, sediment and contaminant concentrations) is a significant environmental driver for the health of coral reefs. Coral reefs are threatened by a wide range of chemical pollution pressures that are likely to increase with further industrial development and land use (see chapter 20 for more detail). Trace metal contaminants are accumulating in fish, with a clear link to coastal contamination

from mining in New Caledonia (France), while contamination by persistent organic pollutants (POPs) occurs across the whole lagoon region (Briand et al., 2014). Millions of tons of dust are transported in the atmosphere each year from Africa and Asia to the Caribbean. This is a significant input source of trace metals, organic contaminants and potential microbial pathogens in the reef ecosystem which is likely to adversely affect the health of corals (Garrison et al., 2003).

Excess nutrients result in poor water quality and eutrophication. Reefs exposed to poor water quality show significant increases in macroalgal cover and reduced coral richness and recruitment (De'ath and Fabricius, 2010; Fabricius et al., 2012; Vega Thurber et al., 2014). In the mid-1990s, global models of coral reef pollution estimated that 22 per cent of all reefs were classified as being at high (12 per cent) or medium (10 per cent) risk from pollution and soil erosion (Bryant et al., 1998). On the Great Barrier Reef (GBR), central and southern rivers are reported to deliver five- to nine-fold higher nutrient and sediment loads compared with pre-European settlement, largely due to changes in land-use practices, including land clearing, fertilization and urbanization (Kroon et al., 2012). Flood events that deliver high nutrient and sediment loads via river runoff are now directly affecting up to 15 per cent of GBR reefs (De'ath and Fabricius, 2010; Kroon et al., 2012).

Pressures related to elevated sediments include sedimentation, total suspended solids and light attenuation. All of these can damage coral reef species via smothering, shading and blocking of the filter-feeding systems. Specific assessments of sediment stress have been experimentally examined in only 10 per cent of all known reef-building corals; these studies indicate sediment thresholds and also identify response and adaptation mechanisms that corals employ to cope with excess sediments (Erftemeijer et al., 2012). Reduced coral recruitment success and reef overgrowth by microalgae are significant effects of increased sedimentation on coral reefs. In addition, chronic effects from increased sediment loads include reduced reef calcification, shallower photosynthetic compensation points, changes in the community structure of corals, and reduced species richness. This decreased diversity and increased simplification of reef ecosystems with increasing sediment exposure may compromise their ability to maintain critical ecosystem functions (Fabricius, 2005). The impacts of dredging on coral reefs are primarily linked to the intensity, duration and frequency of exposure to increased total suspended solids and sedimentation (Erftemeijer et al., 2012) and whether the sediments include particulate organic matter or dissolved inorganic nutrients (Fabricius, 2005). Total suspended sediment thresholds reported for coral reef systems range from $<10 \text{ mg L}^{-1}$ to $>100 \text{ mg L}^{-1}$ while the maximum sedimentation rates tolerated by corals range from $<10 \text{ mg cm}^{-2} \text{ d}^{-1}$ to $>400 \text{ mg cm}^{-2} \text{ d}^{-1}$ (Erftemeijer et al., 2012).

Pesticides including herbicides have been widely studied in tropical systems. Most pesticides have no natural sources; concentrations detected in the nearshore lagoon of the GBR are positively correlated with low salinity associated with river runoff. The composition and concentration of pesticides entering the marine environment typically

mirror agricultural use in the catchments adjacent to the GBR (Kennedy et al., 2012; Lewis et al., 2009) and on reefs of French Polynesia (France) (Salvat et al., 2012).

Herbicides that inhibit photosystem II in plants are highly persistent in marine environments and are regularly detected in coral reef systems (Schaffelke et al., 2013); with concentrations of herbicides periodically exceeding regulatory guidelines for the GBR during flood plume events (Lewis et al., 2012). These concentrations are known to deleteriously affect corals (Jones and Kerswell, 2003; Negri et al., 2005), microalgae (Bengtson Nash et al., 2005; Magnusson et al., 2008), crustose coralline algae (Negri et al., 2011), foraminifera (van Dam et al., 2012), and seagrass (Haynes et al., 2000; Gao et al., 2011).

The sensitivity of a coral reef to poor water quality largely depends on the pre-existing health of the ecosystem, overall reef resilience and the baseline conditions that the reef normally experiences. For example, the proportion of reefs at risk is highest in countries and entities with widespread land clearing (Burke et al., 2002). It is important that recent research shows that reducing runoff of nutrients, sediments and pesticides from the land will at least partially offset increasing stress and deleterious effects from climate factors for coral reefs (Schaffelke et al., 2013).

2.3 *Diseases and predators*

Coral disease is reported as one of the most prominent drivers of recent coral reef declines (Aronson and Precht, 2006; Bruckner and Hill, 2009; Rogers, 2009; Sokolow, 2009; Weil and Cróquer, 2009). In particular, the Caribbean has been designated as a “coral disease hotspot” due to the rapid spread, high prevalence, and virulence of diseases associated with corals and other reef organisms (Harvell et al., 2002; Weil et al., 2002). Although the Caribbean is home to only eight per cent of the world’s coral reefs, approximately 66 per cent of all coral diseases are found across 38 Caribbean States and territories (Green and Bruckner, 2000). Disease is also reported as the major factor behind a 25-year decline in Caribbean coral reefs, with mean coral cover declining from 50 per cent to only 10 per cent across the entire Caribbean region (Gardner et al., 2003). Disease has also reshaped the community structure of many Caribbean reefs over the last few decades, including: (i) the virtual elimination of Acroporid corals by White Band Disease in the 1980s (Gladfelter, 1982; Ritchie and Smith, 1998; Aronson and Precht, 2001; Bythell et al. 2001; Kline and Vollmer, 2011); (ii) the loss of many *Acropora palmata* by White Pox in the late 1990s (Sutherland et al., 2011); and (iii) the mass mortality of the keystone grazer species, *Diadema antillarum*, by an unidentified disease in the early 1980s (Hughes et al., 1985). The loss of this sea urchin, coupled with declines in herbivorous fish strongly contributed to overgrowth of reefs by macroalgae (Lessios, 1984; Hunte and Younglao, 1988; Hughes, 1994; Jackson et al., 2001), believed to be a contributing factor to coral disease (Nugues et al., 2004).

Coral diseases have now been documented within all major reef systems and ocean basins (Ruiz-Moreno et al., 2012). Indo-Pacific coral reefs are home to 75 per cent of the

world's coral reefs and at least 10 identified coral diseases (~30 per cent of known coral diseases; Willis et al., 2004). It is unclear whether coral disease will have the same impact on Indo-Pacific reefs as it has in the Caribbean due to fundamental differences in their coral reef communities (Wilson et al., 2014). A higher level of diversity and functional redundancy in herbivorous fishes and coral communities, slower macroalgal growth, and less dependence on fragmentation as a reproductive mode, may protect Indo-Pacific reefs from dramatic phase-shifts (Roff and Mumby, 2012).

The recent and rapid increase in disease occurrence worldwide is correlated with increasing environmental stressors that have local and global impacts e.g., elevated seawater temperatures, nutrient enrichment, sedimentation, and fish farming (Sutherland et al., 2004; Sato et al., 2009; Pollock et al., 2014; Vega Thurber et al., 2014; Randall and vanWoesik, 2015). Research is only now starting to determine how diseases are contracted and/or spread from one colony to another. Changes in the coral-associated microbial community and subsequent disease severity are often correlated with bleaching stress in warm summer or winter months (Willis et al., 2004; Bourne et al., 2008; McClanahan et al., 2009, Heron et al., 2010). A significant relationship was shown between the frequency of warm temperature anomalies and white syndrome outbreaks during six years across 48 reefs in the GBR (Bruno et al., 2007). White syndrome was described as either an additional emergent disease, or a group of diseases, among Pacific reef-building corals. Proliferation of disease during the hotter months or during mild winters may be correlated with a greater virulence of coral pathogens at higher temperatures (Miller et al., 2006; Harvell et al., 2007; Heron et al., 2010). Additional anthropogenic factors that are considered to influence disease events include nutrient enrichment from fertilizers (Bruno et al., 2003), sewage pollution (Sutherland et al., 2011), fish farming (Garren et al., 2009), and increased macroalgal abundance as a result of overfishing and disease outbreaks (Nugues et al., 2004).

Crown-of-thorns starfish (COTS; *Acanthaster planci*) were not considered a major problem until the last 40 years or so. Population outbreaks in the 1970s devastated large parts of the GBR and similar outbreaks were reported on other reefs of the Indo-Pacific (COTS do not occur in the wider Caribbean). These outbreaks subsided and most reefs recovered their previous coral cover. However, repeated damaging outbreaks have occurred since, such that COTS are reported as the major destructive factors on reefs in French Polynesia (France) (Adjeroud et al., 2009; Kayal et al., 2012), Fiji, Japan, and parts of the Red Sea (Wilkinson, 2008); and COTS contributed 42 per cent of the recent damage to the GBR, alongside storms (48 per cent) and climate change-related damage (10 per cent) (Great Barrier Reef Marine Park Authority 2014; De'ath et al., 2012).

Previous population outbreaks of COTS are reported from the Red Sea around Egypt, in Kenya and the United Republic of Tanzania, and in Southeast and East Asia, especially in China, Japan and the Philippines, and in the Pacific in Fiji, French Polynesia (France), Guam (United States) and Majuro Atoll (Marshall Islands). In the past, these plagues caused massive losses (often in the vicinity of 90 per cent) of the living coral cover (Wilkinson, 2002). Similar outbreaks are reported of the coral-eating mollusc (*Drupella cornus*) on reefs in western Australia and southern China. After apparently abating,

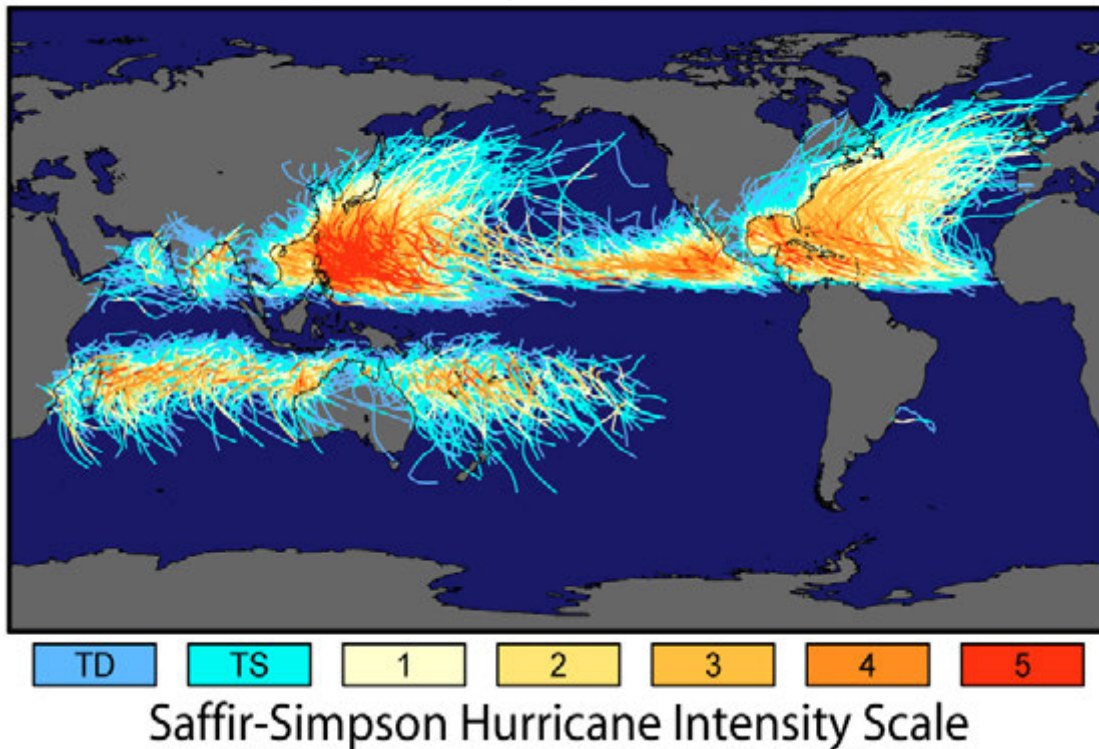

major outbreaks have occurred simultaneously with mass coral bleaching in 2005 and 2006.

Four widely supported but not mutually exclusive theories to explain COTS outbreaks are: (a) fluctuations in COTS populations are a natural phenomenon; (b) removal of natural predators (such as large molluscs and some fishes) of the COTS has allowed populations to expand; (c) human-induced increases in the nutrients flowing to the sea have resulted in an increase in planktonic food for larvae of the COTS which leads to an increase in the number of adult starfish causing outbreaks (Fabricius et al., 2010); and (d) increased COTS larval survival as ocean temperatures increase (Uthicke et al., 2014).

2.4 *Natural stresses (cyclones, tsunami)*

Although many reefs lie outside the zone of frequent tropical cyclones and hurricanes (approximately between 7°N and 7°S latitude), storms regularly damage coral reefs outside this latitudinal zone (Figure 3). Storm damage is exacerbated by storm surge and both reduce the ability of coral reefs to return to their mean pre-disturbance state or condition by slowing coral recruitment, growth, and reducing fitness (Nyström et al., 2000). The combination of tropical storms with other stressors has caused successive and substantial losses of corals worldwide (Harmelin-Vivien, 1994; Done, 1992; Miller et al., 2002; Fabricius et al., 2008; Williams et al., 2008a). However, tropical storms also benefit reefs when the storms are sufficiently distant to not inflict damage, but close enough to cool waters through enhanced wave-induced vertical mixing and to reduce bleaching risk (Szmant and Miller, 2005; Manzello et al., 2007; Carrigan and Puotinen, 2014). A recent modelling study predicted that Caribbean coral reefs with intact herbivore fish and urchin populations would likely maintain their community structure and function under any expected level of tropical cyclone activity, as long as other stressors, such as local pollution and thermal bleaching, are minimal (Edwards et al., 2010).

Tracks and Intensity of All Tropical Storms

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 3: These plots of tropical cyclones (and typhoons) over the past 100 years illustrate that damaging storms are rare within a band between 7° North and South of the Equator, such that a large proportion of the high biodiversity reefs in Indo-Pacific are rarely damaged by damaging storms (courtesy of NASA, USA, 2008). There are predictions that under increasing climate change, the damaging strength of cyclones will increase with more category 4 and 5 storms, but the number of storms may not change (Wilkinson and Souter, 2008).

2.5 Climate change effects and predictions

The most recent report of the IPCC (2014) stated that “Coral reefs are one of the most vulnerable marine ecosystems (*high confidence*) and more than half of the world’s reefs are under medium or high risk of degradation”. The effects of anthropogenic climate change on coral reefs include: (a) thermal stress causing coral bleaching; (b) storm damage to reefs; (c) sea-level rise; and (d) acidification causing reduced coral accretion and increased erosion.

2.5.1 Thermal stress and coral bleaching

Coral bleaching was a relatively unknown phenomenon until the early 1980s, when a series of local bleaching events occurred principally in the eastern tropical Pacific and wider Caribbean regions, but was also noticed in the Indo-Pacific. Coral bleaching refers to the expulsion of symbiotic algae, the zooxanthellae, in response to stress. Corals can

withstand mild to moderate bleaching but severe, prolonged or repeated bleaching can lead to colony mortality. Corals' physiological processes are optimized to the warmest temperatures they normally experience, so an increase of only 1 -2°C above the normal local seasonal maximum can induce bleaching (Fitt and Warner, 1995). Although most coral species are susceptible to bleaching, thermal tolerance varies amongst taxa and along geographic gradients (Marshall and Baird, 2000; McClanahan et al., 2007). Bleaching is best predicted by using an index of accumulated thermal stress above a locally established threshold (Atwood et al., 1992; Eakin et al., 2009). Many heat-stressed and/or bleached corals subsequently die from coral diseases (reviewed in Burge et al., 2014).

The strong El Niño - La Niña events of 1998 brought a global focus on coral bleaching when approximately 16 per cent of the world's coral reefs in almost all tropical ocean basins were massively damaged and lost most of their corals (Wilkinson, 2000). Rising temperatures have accelerated bleaching and mass mortality during the past 25 years (Brown, 1997a; Eakin et al., 2009), when coral bleaching was documented throughout various parts of the world (Eakin et al., 2009; Eakin et al., 2010; Wilkinson and Souter, 2008; Williams and Bunkley-Williams, 1990). A global analysis of threats to coral reefs shows that this widespread threat has significantly damaged most coral reefs around the world (Burke et al., 2011a).

Although some recovery occurred in the Caribbean from the 1987 (Fitt et al., 1993) and the 1995 bleaching events, bleaching in 1998 and 2005 caused high coral mortality at many reefs with little evidence of recovery (Eakin et al., 2010; Goreau et al., 2000; Wilkinson and Souter, 2008). The subsequent strongest recovery was on reefs that were highly protected from anthropogenic pressure. This led to recognition of the importance of maintaining resilience in coral reef ecosystems (Nyström et al., 2000; Hughes et al., 2007; Anthony et al., 2014). An example of reef resilience was observed on the remote Scott Reef off western Australia, when the reef was severely damaged during the 1997-98 El Niño. However, the herbivore fish population grew rapidly to control algal overgrowth, allowing many new coral recruits to restore most of the lost coral cover after 12 years (Gilmour et al., 2013). Additionally, certain factors such as reef depth and structural complexity were shown to increase reef resilience after the 1998 bleaching in the Seychelles (Graham et al., 2015).

A comparison of the recent and accelerating thermal stress events with the slow recovery rate of most reefs (Baker et al., 2008), suggests the temperature increase has exceeded the balance between event recurrence and recovery rate. It appears that some coral species are less sensitive to short-term temperature anomalies than others, although there are significant geographic variations (McClanahan et al., 2007) and some corals may have already adapted or acclimatised to warming (Guest et al., 2012), albeit not quickly enough to prevent major losses (Logan et al., 2013). Some heritable epigenetic adaptation to frequent heat stress may occur in some species of lagoonal corals (Palumbi et al., 2014; Eakin, 2014). However, adaptation potential may be limited in species where larval survival has been shown to decline at high temperatures (Randall and Szmant, 2009a; 2009b).

Climate models are able to predict the potential consequences of future warming on corals, including the future frequency of thermal events exceeding the bleaching threshold for a given area (map 3.3 in Burke et al., 2011a). In the absence of adaptation, there are predictions that many of the world's coral reefs will experience annual bleaching by mid-century (Donner et al., 2005; Donner, 2009; Logan et al., 2013; van Hooidonk et al., 2013a).

2.5.2 *Storm damage to reefs*

One consequence of global climate change will be an increase in the frequency of more damaging Category 4 and 5 tropical cyclones; however the number of tropical storms is not predicted to increase. Such intense Category 4 and 5 tropical cyclones (hurricanes) will significantly damage coral reefs and the communities that depend upon them in the wider Caribbean, where evidence is already available (Salvat and Wilkinson, 2011); whereas in other regions, the evidence is less clear (IPCC, 2013).

Corals have withstood and recovered from tropical cyclones for millennia; a seriously damaged reef will normally recover in 15 to 20 years, provided there are no other disturbances during that period (Salvat and Wilkinson, 2011). However, in the last 100 years the combination of natural and anthropogenic stresses (bleaching, sedimentation, eutrophication, ocean acidification) has reduced the ability of many coral reefs to recover from storm damage by slowing coral recruitment and growth, and reducing fitness (Nyström et al., 2000).

2.5.3 *Sea-level rise*

If CO₂ emissions continue to increase at current rates (exceeding Representative Concentration Pathways RCP 8.5), sea level is predicted to rise 0.5-1.0 m by 2100 (IPCC, 2013), and the impacts on coral reefs will vary depending on local conditions. Corals may be able to colonise reef flats as sea levels rise, and oceanic reefs will not be adversely affected but may benefit from new space to grow upwards. Rates of reef growth at many sites kept up with rising sea levels after the last ice age (about 20 mm yr⁻¹ Dullo, 2005, Montaggioni et al., 2005; and up to 40 mm yr⁻¹ Camoin et al., 2012) but reefs are now accreting more slowly (Perry et al., 2013). However, reefs adjacent to coasts may be affected by increased wave action in lagoons, and flooding of polluted coastal plains will increase erosion of coastal sediments (Adey et al., 1977; Lighty et al., 1978), increase sediment transport (Hopley and Kinsey, 1988), and increase turbidity (Storlazzi et al., 2011). This will reduce the ability of corals and reefs to keep up with rising sea level. Simultaneously, increasing ocean acidification will decrease coral reef accretion. Finally, as sea level rises, some coastal systems may undergo landward retreat, and others will experience coastal squeeze as eroding shorelines approach hard, immobile, structures. These may be either natural or man-made; the latter are increasing by coastal hardening to protect human infrastructure. Coastal squeeze may shrink habitats, affecting the survivability of a variety of organisms (Jackson and McIlvenny, 2011).

2.5.4 Ocean acidification

The first detailed prediction of the potential for increasing ocean acidification to damage coral reefs was made in 1992 at the 7th International Coral Reef Symposium (Buddemeier 1993). Experimental studies confirmed these predictions of damage to coral calcification in the 1990s (Gattuso et al., 1998; Gattuso et al., 1999). The IPCC (2014) report determined that under medium- to high-emission scenarios (RCP4.5, 6.0 and 8.5), ocean acidification poses substantial risks to coral reefs through its effects on the physiology, behaviour, and population dynamics of individual species from phytoplankton to animals (*medium to high confidence*, IPCC, 2014). Also the lowering of pH will favour the dissolution of the calcareous matrix of coral reefs. These effects will be additive or synergistic with damage from rising sea-surface temperatures. Further experiments with increased concentrations of CO₂ in seawater have shown decreased calcification rates by corals and other calcium carbonate-secreting organisms (Barker and Elderfield, 2002; Doney et al., 2009; Riebesell et al., 2000; see also Chapter 7). A doubling of current atmospheric CO₂ concentrations reduced calcification by 11 per cent to 37 per cent in many corals (Langdon et al., 2003; Marubini et al., 2003; Langdon and Atkinson, 2005). However, some corals show either limited or no response when provided with elevated nutrients (Holcomb et al., 2010; Chauvin et al., 2011). This suggests that nutrient-enriched corals may use more dissolved inorganic carbon to maintain calcification rates.

Ocean acidification also reduces calcification and skeletal growth in post-settlement and juvenile corals (Albright et al., 2008; Albright et al., 2010; Cohen et al., 2009; Kurihara, 2008; Suwa et al., 2010). Fertilization success during spawning and subsequent settlement of *Acropora palmata* were significantly reduced at increased CO₂ levels (Albright et al., 2010); and larvae of *Acropora digitifera* showed reduced metabolism and suppressed metamorphosis (Nakamura et al., 2011). No effect was observed in *Porites astreoides* larvae (Albright et al., 2008).

Reefs found in naturally acidic waters are poorly cemented, unstable, and fragile (Manzello et al., 2008) and show rapid rates of bioerosion (Eakin, 1996; 2001; Glynn, 1988; Reaka-Kudla et al., 1996). Similarly, in “natural experiments” where coral is reduced or absent around volcanic seeps of CO₂ near Papua New Guinea (Fabricius et al., 2011) and Italy (Rudof-Metalpa et al., 2011), coral calcification is reduced and species composition changes along the pH gradient. Bioerosion by filamentous eroding algae (Tribollet et al., 2009) and boring sponges (Fang et al. 2013; Wisshak et al., 2012) are enhanced under acidified conditions. Other experiments show there may be declines in the growth of crustose coralline algae (Jokiel et al., 2008; Kuffner et al., 2007).

3. Social and economic considerations.

Economic valuation of coral reefs is a relatively recent process (Cesar, 1996; Cesar et al., 2003) to demonstrate the importance of reef ecosystem services and encourage greater conservation efforts. However, there is a potential critical error in that high-value, short-term economic gains that result from development activities can occur at the expense of longer-term benefits. Economic valuation provides more complete information on the economic consequences of decisions that lead to degradation and loss of natural resources, as well as the short- and long-term costs and benefits of environmental protection. Many studies have assessed the value of ecosystem services provided by coral reefs, at local to global scales. The focus is predominantly on tourism and reef-related fisheries; because these are widely studied and direct-use data are more readily available. It is more difficult to estimate indirect-use values, such as shoreline protection, and most difficult with controversial methods to estimate non-use values, such as cultural, biodiversity and heritage values. The annual net global benefits from coral reefs have been estimated at 29 billion dollars

(11.5 billion dollars tourism; 6.8 billion dollars fisheries; 10.7 billion dollars shoreline protection) (Burke et al., 2011a). This emphasizes that tourism and fisheries are especially important as direct money earners for coral-reef communities and their countries. But such an evaluation is for current values and does not take into account all future consequences of changes, such as cultural aspects, community livelihoods, and social and political stability in coral reef communities and their countries, which, if disrupted, will result in other cascading damage. A specific example is the reported value of the GBR to the Australian economy. The total estimated value varies between 4.4 and 15.5 billion dollars, comprising 84 per cent for tourism, 4.6 per cent for other recreational activities, 2.6 per cent for fisheries, and 1.5 per cent for scientific research and management with employment estimated at 69,000 people (Deloitte, 2013; Stoeckl et al. 2014)).

4. Management and conservation.

Calls for increased protection of the marine environment from many organizations and in conventions have specifically addressed the need to protect coral reefs. This includes developing and facilitating the use of diverse approaches and tools, including the ecosystem approach, the elimination of destructive fishing practices, the establishment of marine protected areas (MPAs) consistent with international law and based on scientific information, and the establishment of representative networks and time/area closures. Among the Aichi Biodiversity Targets adopted at the 10th Meeting of the Conference of the Parties to the Convention on Biological Diversity in 2010 was Target 10: "By 2015, the multiple anthropogenic pressures on coral reefs, and other vulnerable ecosystems impacted by climate change or ocean acidification are minimized, so as to

maintain their integrity and functioning”. The United Nations General Assembly has supported these calls (amongst others) in “The Future We Want” (resolution 66/288) with specific mentions in paragraph 177 and subsequent paragraphs on SIDS.

According to the World Resources Institute, an estimated 2,679 MPAs that coincide with coral reef areas exist worldwide, encompassing approximately 27 per cent of the world’s coral reefs (Burke et al., 2011a). Nevertheless global protection of coral reefs is considered by Burke et al. (2011a) to provide effective protection for only 6 per cent of coral reefs, due to shortcomings in planning, management and enforcement of regulations. The benefits of MPAs for achieving targets of conservation of coral reef areas, however, have been reported widely in the scientific literature, in particular when extractive activities are not allowed, as in the no-take areas or marine reserves (Lubchenco et al., 2003; Halpern 2003).

The designs of MPAs range from small units to networks of no-take areas (NTMRs) and large scale marine protected areas (LSMPAs). The first major MPA was the Great Barrier Reef Marine Park in 1975 with 20,679 km² of coral reefs. It now has established no-take areas that protect 33.5 per cent of coral reefs (6,928 km²), to form a network of no-take areas.

Since 2004, ten LSMPAs were established in the Pacific and Indian Oceans in areas within national jurisdiction, and two-thirds of them were declared as marine reserves representing more than 80 per cent of the worldwide MPA coverage (Leenhardt et al., 2013; Table 3).

Table 3. Large Marine Protected Areas that have been established to include significant areas of coral reefs.

Name of Marine Protected Area	Country	Date	Area km ²
Pacific Remote Islands Marine National Monument	United States	2014	2,025,380
Le Parc Naturel de la Mer de Corail (<i>Natural Park of the Coral Sea</i>) (New Caledonia)	France	2014	1,291,000
Cook Islands Marine Park	Cook Islands	2012	1,065,000
Coral Sea Commonwealth Marine Reserve	Australia	2011	989,842
Kermadec Benthic Protection Area	New Zealand	2007	620,500
Chagos Marine Protected Area	United Kingdom ¹	2010	545,000

¹ In its award of 18 March 2015 in the matter of the *Chagos Marine Protected Area Arbitration (Mauritius v. United Kingdom)*, the Arbitral Tribunal established under Annex VII to the United Nations Convention on the Law of the Sea, found, *inter alia*, that, as a result of undertakings given by the United Kingdom in 1965 and repeated thereafter, Mauritius holds legally binding rights (i) to fish in the waters surrounding the Chagos Archipelago, (ii) to the eventual return of the Chagos Archipelago to Mauritius when no longer needed for defence purposes, and (iii) to the preservation of the benefit of any minerals or oil discovered in or near the Chagos Archipelago pending its eventual return. The Tribunal held that in declaring the

Phoenix Islands Protected Area	Kiribati	2008	408,250
Papahānaumokuākea (<i>Northwestern Hawaiian Islands</i>)	United States	2006	362,100
Great Barrier Reef Marine Park	Australia	1975	344,400

Those areas face major logistical and economic challenges of implementing, managing and monitoring (Leehardt et al., 2103).

Emslie et al. (2015) showed that expanding NTMR networks had clear benefits for fishery target, but not non-target, species. During the study, a cyclone caused widespread degradation, but target species biomass was retained within NTMRs, with greater recovery potential for adjacent areas.

MPAs, even with no-take management, cannot be assured of full protection to reefs. Reefs inside MPAs may still be affected by pollution and sedimentation. In these cases, catchment management has been shown to be effective in promoting reef recovery (many examples in Wilkinson and Brodie, 2011).

Another mechanism targeted at conserving vulnerable species, including those on coral reefs, has been through the Convention on International Trade of Endangered Species and Wild Fauna and Flora (CITES), listing them in Appendices II and III (<http://www.cites.org/>).

5. Integrated assessment of the status of the habitat.

Reefs in Southeast Asia, the Caribbean and along the East coast of Africa are the most threatened, and this is correlated with high levels of human exploitation of, and dependence on, coral reef resources. In the wider Caribbean, live coral cover has declined by 80 per cent between 1976 and 2001 (Gardner et al., 2003). Further declines following mass coral bleaching linked to climate change occurred in 2005 (Wilkinson and Souter, 2008; Eakin et al., 2010). According to Burke et al. (2011a), coral reefs around Australia were less degraded, although a year later De'ath et al. (2012) reported a loss of 50 per cent of initial coral cover occurred over the 1985-2012 period on the GBR, especially for the central and southern sections where more anthropogenic disturbances occur. In the Central Pacific, far from continents and with low human pressure, reefs are much less threatened and are in better condition and more resilient to natural destructive effects (Salvat et al., 2008; Burke et al., 2011a; Chin et al., 2011). On a regional basis, and based mainly on material from Wilkinson (2008), the condition of reefs is summarized as follows:

Marine Protected Area, the United Kingdom failed to give due regard to these rights and had breached its obligations under the United Nations Convention on the Law of the Sea.

5.1 *Indian Ocean*

During the first half of 1998, the most severe El Niño event ever recorded resulted in the loss of more than 90 per cent of live coral cover throughout large parts of the Indian Ocean. Damage was particularly severe in the Maldives, Chagos Archipelago, Seychelles and Kenya. Prior to 1998, reefs adjacent to large human populations along the coast of East Africa, India and Sri Lanka had already suffered serious damage from excessive and destructive fishing, nutrient pollution, increased sediment input from land and direct development over the reefs, including coral mining.

Reefs on remote islands and in the Red Sea were generally in good health prior to 1998. Since 1998, coral recovery has been minimal in the Persian Gulf and Gulf of Oman, with recovery often reversed by more bleaching. Throughout the Arabian Peninsula region, massive coastal development and dredging to create oil industrial sites and residential and tourist complexes has occurred. Many reefs in the Red Sea continue to be healthy, although COTS (crown-of-thorns starfish) have caused damage, and expanding tourism in the Northern Red Sea is accelerating some coral losses.

Along the coastline of Eastern Africa, a mix of reef recovery and reef degradation is observed as management efforts are directed at controlling the effects of rapidly growing populations and at involving local communities in coastal management. All States are increasing their networks of marine protected areas and States are improving management capacity and legislation.

Reefs of the southwestern islands in the Indian Ocean continue to recover after devastation in 1998. Some reefs of the Seychelles and Comoros have regained about half or more of their lost coral cover but recovery has been poor on reefs damaged by human activities. Recovery rates in the Seychelles varied, in part, due to factors that have now been shown to increase reef resilience – depth and structural complexity (Graham et al., 2015).

The reef decline in South Asia continues, as large human populations further impact coral reefs, adding to the damage that occurred in 1998. Recovery has been observed in the reefs of the western Maldives, Chagos Archipelago, the Lakshadweep Islands (India) and off northwest Sri Lanka, with seemingly locally extinct corals making major recoveries, e.g., some reefs have gone from less than five per cent coral cover to 70 per cent in 10 years. The 2004 Indian Ocean earthquake and tsunami caused significant reef damage at some sites, but many are recovering. In Sri Lanka, bleaching was reported in 2010, fisheries continue to be the biggest chronic impact, and pollution has increased tremendously in the coastal waters of Colombo. Although fisheries management areas have been declared, lack of enforcement is still hindering effectiveness.

5.2 *Southeast and Northeast Asia*

The reef areas of Southeast Asia contain the highest concentration of biodiversity and also the largest concentrations of human populations. Overfishing, increasing

sedimentation and urban and industrial pollution from rapid economic development are accelerating reef degradation and more than 50 per cent of the region's mangroves have been lost.

Coral reefs in Northeast Asia have shown an overall decline since 2004; most reefs are coming under significant levels of human pressures, as well as bleaching and COTS stress. In China, coastal development and overfishing has destroyed 80 per cent of coral cover over the past 30 years (Hughes et al., 2013). A few reefs with high coral cover remain, such as Dongsha Atoll between Taiwan Province of China and the mainland of China. Increased coral reef monitoring and research, including the establishment of a regional database, is occurring in Japan; Hong Kong, China; Taiwan Province of China; and Hainan Island (China), and the region is stimulating more awareness and cooperation by having held the Asia Pacific Coral Reef Symposium in 2006, 2010 and 2014. Awareness of the need for coral reef conservation is rising rapidly in most countries.

5.3 Australia and Papua New Guinea

Australian reefs continue to be relatively stable due to several management measures. Since 2004, no major bleaching events have occurred, although two significant cyclones have resulted in major damage to some reefs. Particular features are the effective partnerships between coral reef science and management. The future outlook for the GBR is regarded as poor, especially in the southern half of the area, where anthropogenic stresses are strongest. Climate-change impacts are considered to be the greatest long-term threat to the whole GBR system (GBRMPA 2014).

In Papua New Guinea, capacity-building for reef management is being conducted via large NGOs working with local communities. Papua New Guinea still has vast areas of healthy and biologically diverse coral reefs, but human pressures are increasing.

5.4 Wider Pacific

The coral reefs of the Pacific remain the most healthy and intact, compared to reefs elsewhere. Many of these reefs grow on seamounts in deep oceans far removed from land-sourced pollution. Moreover, the human populations are not concentrated as they are in Asia and the Caribbean. In the broader Micronesian region, reefs are recovering well after major coral bleaching in 1998, when, coral mortality was as high as 90 per cent on many reefs around Palau. The Federated States of Micronesia, Marshall Islands, Palau, Guam (United States) and Northern Mariana Islands (United States) seek to conserve 30 per cent of their marine resources by 2020 through the designation of more protected areas (www.themicronesiachallenge.org/).

Climate-related coral bleaching continues to be the greatest threat to the reefs of the southwestern Pacific; human impacts, although growing, are not (yet) resulting in major reef loss on large scales. The University of the South Pacific and the CRISP (Coral Reef

Initiatives for the South Pacific) programme (www.crisponline.net) focused on building more capacity for monitoring and conservation, with the Locally Managed Marine Area network developed in Fiji leading the way in the establishment of community-managed MPAs. It is noted that periodically harvested reserves (modelled on the traditional Qoliqoli or rahui system of management) have significantly higher target fish biomass than other fished areas. Outbreaks of COTS have re-appeared in Fiji, starting in the Mamanucas (2006-10), then moving to the Coral Coast and Beqa (2009-12). Currently active outbreaks exist in Taveuni and the lower Lomai Viti Islands. Large reef areas of New Caledonia (France) have gained World Heritage listing in recognition of the large extent and high biodiversity content of the reefs and adjacent ecosystems.

Climate change impacts, tropical cyclones and COTS have also caused major reef damage in the Southeast Pacific (Polynesia). The reefs have remained relatively stable since the 1998 bleaching event, although COTS are still present in some sites, especially in French Polynesia (France). Reef awareness and conservation activities have gradually increased. Many coral reefs surround uninhabited islands; climate-change bleaching and ocean acidification are at present the only major future threats. Thus, many Pacific reefs are considered to be ideal targets for the creation of “reservoir” protected areas to conserve species threatened with over-exploitation or other human stresses. Kiribati has recognized this with the declaration of the Phoenix Islands Protected Area (PIPA), which is also a World Heritage site.

The United States Pacific islands are regarded as globally important reservoirs of virtually pristine coral reefs. Thus the Northwestern Hawaiian Islands were declared to be the Papahānaumokuākea Marine National Monument and in 2014 more islands were included in the enormous Pacific Remote Islands Marine National Monument. Management is increasing around the main Hawaiian Islands, but overfishing and sediment pollution continue as major threats. The depletion of aquarium species is being addressed through the establishment of industry-recognised MPAs.

Warm water corals are limited to the northern region of New Zealand with the situation in Kermadec Ridge being unique with warm- and cold-water corals present. The warm-water (hermatypic) zooxanthellate stony corals are at or near their southernmost limit at shallow depths around the various Kermadec Islands, with *Pocillopora* and *Tubinaria* genera prevalent. Of the 17 hermatypic species, 16 are found on the Australian Great Barrier Reef; but these corals do not form coral reefs (Brook 1999). Ahermatypic corals without zooxanthellae occur in deeper waters along the ridge, including black, gorgonian, scleractinian, and stylasterid corals.

5.5 *The Wider Caribbean*

These reefs suffered massive losses from coral diseases since the mid-1980s and more recently during the major climate-related events of 2005, when all regions of the Wider Caribbean were affected by record coral bleaching and tropical cyclone (hurricane) damage.

Reefs of the United States Caribbean are the focus of increased scientific and conservation efforts and results are variable: some improvements but also major coral reef losses are observed. The reefs immediately adjacent to the Florida protected areas (Florida Keys National Marine Sanctuary) are showing minimal recovery, if any, as pollution and excessive tourism threats impede many years of management efforts. More remote reefs, like the Tortugas and Flower Garden Banks, are healthier, but Puerto Rico and the United States Virgin Islands are threatened by overfishing, pollution from the land, and these threats are all compounded by coral bleaching and disease.

Reefs in the Northern Caribbean and Western Atlantic were also severely damaged in 2005 including those under strong conservation efforts. A wide disparity exists in the economic status of the States and territories in the region. Some wealthier territories, such as Bermuda (United Kingdom) and the Cayman Islands (United Kingdom), are applying considerable reef management programmes. Some encouraging signs of coral recovery after major losses in the 1980s and 1990s are found, especially around Jamaica, but unusually frequent and intense tropical cyclones are affecting reef recovery. A ban on using fish traps has been followed by significant increases in fish populations, accompanied by coral cover increases, especially in Bermuda (United Kingdom).

The 2005 coral bleaching event caused major damage in the Lesser Antilles, where coral cover was reduced by about 50 per cent on many reefs. Recovery has been slow or non-existent in reefs under high human pressures. Algal cover has increased and coral diseases have been particularly prevalent since 2005. Most of these small islands depend heavily on their coral reefs for tourism income and fisheries, and this awareness is increasing calls for reef conservation, such as the Caribbean Challenge (<http://www.caribbeanchallengeinitiative.org/>), as well as local initiatives. Reefs of the Netherlands Antilles harbour some of the highest coral cover seen throughout the wider Caribbean.

Reef status along the Mesoamerican Barrier Reef and Central America has similarly declined, after a long series of losses that started in the 1980s. Bleaching and especially tropical cyclones in 2005 caused considerable destruction around Cozumel (Mexico). The trend is for decreasing coral cover, averaging around 11 per cent since 2004, and some reefs have lost more than 50 per cent coral cover. Major programmes have considerably raised capacity and improved management of MPAs, but sedimentation and overfishing continue to impede reef recovery. While fisheries regulations like the 2009 ban on the take of parrotfish have helped, MPAs in Belize have not been adequately managed, such that the Belize Barrier Reef Reserve System was listed as World Heritage in Danger in 2014.

The main drivers of coral decline in the Southern Tropical Americas are pollution, sedimentation and overfishing. Coastal reefs have been historically affected by sedimentation due to deforestation of the Atlantic forests (Macedo and Maida, 2011). Coral bleaching associated with the El Niño phenomenon is affecting both coastal and

oceanic systems, in varying degrees of intensity (Ferreira et al., 2013; Kelmo and Attrill, 2013). Coastal reefs in the region are particularly affected by pollution and sedimentation (Bruce et al., 2012; Silva et al., 2013). Overfishing of key large-bodied herbivorous fish is a worrying trend (Francini-Filho and Moura, 2008; Ferreira et al., 2012). An important threat to coral reefs in Brazil is the invasion and rapid spread of the sun coral *Tubastraea coccinea* and *Tubastraea tagusensis* (Silva et al., 2014). Diseases were first recorded in 2005, and now represent an increasing threat (Francini-Filho et al., 2008). Comparison with reports from earlier surveys indicate dramatic declines in coastal reefs during the last 50 years (Ferreira and Maida, 2006), with signs of stability in coral cover (Francini-Filho et al., 2013) or disturbance followed by recovery (Kelmo and Attrill, 2013) in the last two decades. Recent trends include the Brazilian Coral Reef National Action Plan and regulation of fisheries over reef fish species considered as threatened (MMA, 2014).

6. Gaps in scientific knowledge

One long-lasting difficulty with monitoring the state of marine ecosystems is the lack of long-standing databases. Although coral reefs have been monitored for decades within countries in many parts of the world, in other regions monitoring is more recent, or interrupted, or collected with a wide range of methods that preclude standardization. Coral reefs are iconic ecosystems and around the world national governments and voluntary organizations have been engaged in coral reef monitoring. The International Coral Reef Initiative (ICRI)² has specifically assisted many countries with assessment and monitoring of their coral reefs by supporting the Global Coral Reef Monitoring Network. Other networks for monitoring, awareness and protection are also organized by NGOs; the largest is Reef Check, operating in 90 countries since 1998 (www.reefcheck.org).

A study published by Wilson et al. (2010) canvassed the opinions of 33 experts to identify crucial knowledge gaps in current understanding of climate-change impacts on coral reef fishes. Out of 153 gaps reported by the experts, 42 per cent related to habitat associations and community dynamics of fish, reflecting the established effects and immediate concerns pertinent to climate change-induced coral loss and habitat degradation (i.e., how does coral mortality influence the capacity of a wide range of fish populations to persist?).

Existing maps of the spatial distribution of coral reefs largely are based on satellite images and aerial photographs. Submerged coral reefs (also known as mesophotic coral reefs) that occur below a water depth of around 30 m cannot easily be detected using satellites or aerial photography, even in clear waters. Consequently, their spatial

² The Global Coral Reef Monitoring Network (<http://www.icriforum.org/gcrmn>) is assisted by the International Coral Reef Initiative (ICRI), an informal partnership between 34 States and a range of organizations, governmental and non-governmental, that also establishes committees to deal with several coral reef conservation- and management-related issues.

distribution and even their existence are unknown in most reef provinces. For this reason, deeper reefs have been underestimated in analyses of the available area of coral habitat and are not included in assessments for conservation measures, despite recent evidence that these areas may be significant (Locker et al., 2010; Bridge et al., 2013). A recent study suggests that the area of submerged reefs in the GBR may be equal to that of near-surface reefs (Harris et al., 2013). Understanding the extent of submerged reefs is therefore important, because they can support large and diverse coral communities (Bridge et al., 2012) and hence may provide vital refugia for corals and associated species from a range of environmental disturbances (Riegl and Piller, 2003; Bongaerts et al., 2010).

The scientific consensus is that threats associated with climate change (bleaching, ocean acidification, stronger storms etc.) pose the greatest threat to the medium- to long-term existence of coral reefs around the world. What is unknown is whether reefs can and will respond to these threats with greater resilience. Reefs contain very high biodiversity and have progressed through major climate change events in the geological past; how will they be able to respond in the next decades to rapid climate changes? There are early indications that some corals can adapt to warmer temperatures and grow in more acidic water, but it is predicted that many corals and other reef organisms do not have that capacity. The adaptation potentials of coral reef organisms are areas for more targeted research which will significantly increase our ability to reliably predict how reefs will fare into the future.

7. Final remarks

There are strong economic, cultural, biodiversity and natural-heritage reasons to conserve tropical and sub-tropical coral reefs and to ensure that their goods and ecosystem services continue to be provided to user communities and the world at large. There are three levels at which these pressures come together and emphasise the knowledge and capacity-building gaps in this field:

7.1 At the level of the local community

Coral reefs will not be able to continue to provide the goods and ecosystem services on which local communities have relied for generations, unless:

- (i) The fishing techniques that are adopted are focused on maintaining a sustainable fishery, and destructive fishing practices (such as dynamiting) cease;
- (ii) Populations of breeding fish and invertebrates, including spawning aggregations, are conserved;

(iii) The pollution of coastal waters by harmful substances (heavy metals and persistent organic pollutants) is prevented, and amounts of inputs of sediment and nutrients are kept at levels that do not damage the reefs (see chapter 20);

(iv) Any development in coastal areas is kept to levels and forms that are consistent with the continued health of the reefs.

Without the active involvement of the coastal communities that have the necessary knowledge and skills, there are likely to be serious difficulties in achieving these goals.

7.2 At the national level

In many of the countries that are the guardians of tropical and sub-tropical coral reefs, there are significant gaps in the knowledge and skills needed for the relevant authorities to play their part in sustaining the reefs. In particular, where marine protected areas are an appropriate method of delivering some of the goals, there are gaps at both national and local levels in capacities for the scientific identification of such areas, for the development of management plans for them, and in enforcing the regulations that may be required.

7.3 At regional and supra-regional levels

The conservation of specific local areas can frequently only be achieved as part of a network of such areas, since the ocean is a dynamic ecosystem and biota are commonly mobile in their early life-stages. Given the interactions among many forms of human activity in the ocean and between them and local ecosystems, management methods that do not take account of those interactions will be ineffective in delivering a sustainable future for tropical and sub-tropical reefs. Integrated management methods on a large scale can only be achieved where there is a widespread social understanding and knowledge of the pressures (such as climate change, acidification, fisheries, seabed mining (see Van Dover et al., 2012; Boschen et al., 2013), pollution and coastal development), the scales on which they operate and their interactions. All this implies that, without efforts to promote understanding of the ocean and without cooperation at the appropriate national, regional and (in some cases) global level between the relevant regulatory authorities, the pressures described in this chapter will persistently undermine the continued delivery by tropical and sub-tropical coral reefs of the goods and ecosystem services on which local communities, countries and the world have been relying.

Chapter 44. Estuaries and Deltas

Contributors: Peter Harris (Convenor), José Muelbert, Pablo Muniz, Kedong Yin, Kawser Ahmed, Regina Folorunsho, Margarita Caso, Claudia Câmara Vale, John Machiwa, Beatrice Ferreira (Lead member), Patricio Bernal and Jake Rice (co-lead members and editors for Part VI Biodiversity)

1. Introduction.

Estuaries and deltas are amongst the most heavily populated areas of the world (about 60 per cent of the world's population live along estuaries and the coast) making them the most perturbed parts of the world ocean (Kennish, 2002; Small and Cohen, 2004). Of the 32 largest cities in the world, 22 are located beside estuaries. They are adversely affected by invasive species, sedimentation (from soil erosion caused by deforestation, overgrazing, and other poor farming practices), overfishing, drainage and filling of wetlands, eutrophication due to excessive nutrients from fertilizer, sewage and animal (including aquaculture) wastes, pollutants including heavy metals (see Chapter 20), polychlorinated biphenyls, radionuclides and hydrocarbons from sewage inputs and diking or damming for flood control or water diversion. Estuaries and deltas provide protected harbours used as ports that are associated with introduced marine pests. They are foci of human attention, attracting potentially incompatible uses by society such as heavy industry, urbanization and recreation; they are affected by global sea-level rise and climate change (Crossland et al., 2005). Estuaries and deltas “form a major transition zone with steep gradients in energy and physicochemical properties at the interface between land and sea” (Jennerjahn and Mitchell, 2013).

More than 50 per cent of large river systems are affected by dams, based on a global synthesis on river fragmentation and flow regulation (Nilsson et al., 2005), with obvious consequences for the estuaries and deltas at their coastal termini. The mean age of river water at river mouths has increased from about two weeks to over one month on a global scale and to more than one year in extreme cases (Vörösmarty et al., 2003). Over the last few centuries, the global annual sediment flux into the coastal zone has increased by 2.3×10^9 tons due to human-induced soil erosion and decreased by 3.7×10^9 tons due to retention in reservoirs, the net effect being a reduction of sediment input by 1.4×10^9 tons (Syvitski et al., 2005). A major environmental consequence of river sediment starvation is erosion of the coast and attendant loss of habitat.

2. Major threatening processes.

Processes affecting the health and condition of estuaries and deltas may be classified into three broad categories that can interact:

(a) “Short-term” pressures associated with the near-term effects of human expansion (e.g., coastal development, land-based inputs of nutrients, over-fishing, aquaculture, and maritime operations);

(b) “Medium- to long-term” pressures associated with anthropogenic climate change (e.g., sea-level rise, increases in atmospheric heat and CO₂ fluxes into the oceans, a strengthening global hydrological cycle, and the increasing magnitude of tropical cyclones); and

(c) Extreme natural events.

A list of processes and impacts is given in Table 1 (see Chapter 44 Appendix, online only).

3. Social and economic considerations.

Estuaries are tourist attractions and provide a centrepiece for development (a harbour view). Estuaries and deltas provide natural harbours that are used for transport and industry as the ideal location of major port facilities. They have ecological importance to a diverse biota, including economic importance to commercial and subsistence fisheries. People value estuaries for recreation, scientific knowledge, education, aesthetics, and traditional practices. Boating, fishing, swimming, surfing, and bird watching are just a few of the numerous recreational activities people enjoy in estuaries and deltas. Their unique habitats make them valuable laboratories for scientists and students. Considering the sum of human activities that depend upon the existence of estuaries and deltas and their ecosystem services (e.g., Barbier et al., 2011), their total economic value to society is vast (Costanza et al., 1997; Costanza et al., 2014). Costanza et al. (1997) estimated their value at approximately 4.1 trillion United States dollars (equal to 6.1 trillion dollars in 2014 dollars).

Some indications of the social and economic value of functioning estuarine and deltaic ecosystems can be found from examples where human activities have impaired such functions. Economic losses due to anthropogenic changes in river discharge are one example. The down-stream consequences of dam-building are often not fully considered when the decision is taken to build a dam on a river system. The economic losses from reduced fisheries landings, due to the reduction in nutrients entering the Indian Ocean at the Sofala Bank fishery (Arthurton, 2002), following alteration to the Zambezi River freshwater flows, has been estimated at between 10 and 20 million dollars (Turpie, 2006). In an extreme case, the Colorado River, prior to the completion

of the Hoover Dam in 1935, delivered a combination of nutrient-rich water and silt to the historic Delta, comprised over 2.5 million acres of wetlands, habitat for an estimated 400 species of plants and wildlife and home to some 20,000 Cocopah Indians (Glenn et al., 2001). All of the freshwater discharge was impounded behind dams by 1963; the wetlands dried up, affecting many dependent species. In 2014, an experimental release of 130 million m³ of water allowed the restoration of the Colorado Delta to begin, although it will take many years to restore even part of the original wetland area (Witze, 2014).

Some of the first and most severe impacts of climate change will come through greater storm surges caused by a combination of higher sea levels and stronger storms in some areas. In the absence of storm surge, a 20-80 cm rise in mean sea level will place 7 – 300 million additional people at risk of being flooded each year (Geneva Reports, 2009, No. 2, 138 pp. www.genevaassociation.org). Increases in storm surge will increase these numbers substantially. The Organization for Economic Cooperation and Development (OECD) estimates that, in the absence of adaptation, the population in 136 major port cities exposed to storm surges could increase from 40 million in 2005 to ~150 million in the 2070s, with exposed assets rising from 3,000 billion dollars to 35,000 billion dollars (Nicholls et al., 2008). By 2050, sea-level rise in the Ganges-Brahmaputra Delta could directly affect more than three million people and Bangladesh could lose nearly one-quarter of the land area it had in 1989 by the end of this century, in a worst-case scenario (Ericson et al., 2005). As a proportion of GDP, economic losses from flooding are much higher for developing countries than for developed countries (Ramcharan, 2007). Financial losses from weather events are currently doubling every 12 years at an annual rate of 6 per cent (UNEP, 2006). In the Sacramento Delta in San Francisco Bay, California, United States, global sea-level rise places about 500,000 acres of agricultural lands in the inner Delta at significant risk of flooding in the first half of the 21st century. Total losses for the wider area—including multiplier effects—could reach 1,800 jobs per year, 130 million dollars in value added, and nearly 14 million dollars in state and local tax receipts (Medellín-Azuara et al., 2012). These examples provide some context for the potential impacts of water abstraction and global warming and sea-level rise on ecosystem services upon which estuarine- and deltaic-based societies and economies depend.

4. Management and conservation.

Healthy estuaries and deltas maintain water quality that benefits both people and marine life. They provide a natural buffer between the land and ocean, absorbing floodwaters and storm surges. Estuaries and deltas help maintain biodiversity by providing a diverse range of unique habitats, including mangrove forests, salt marshes, mud flats and seagrass beds, which are critical for the survival of many species. Many species of commercially important fish and shellfish use estuarine and deltaic habitats

as nurseries to spawn and allow juveniles to grow. Maintaining such ecosystem services is commonly declared as a management goal and is the focus of conservation efforts.

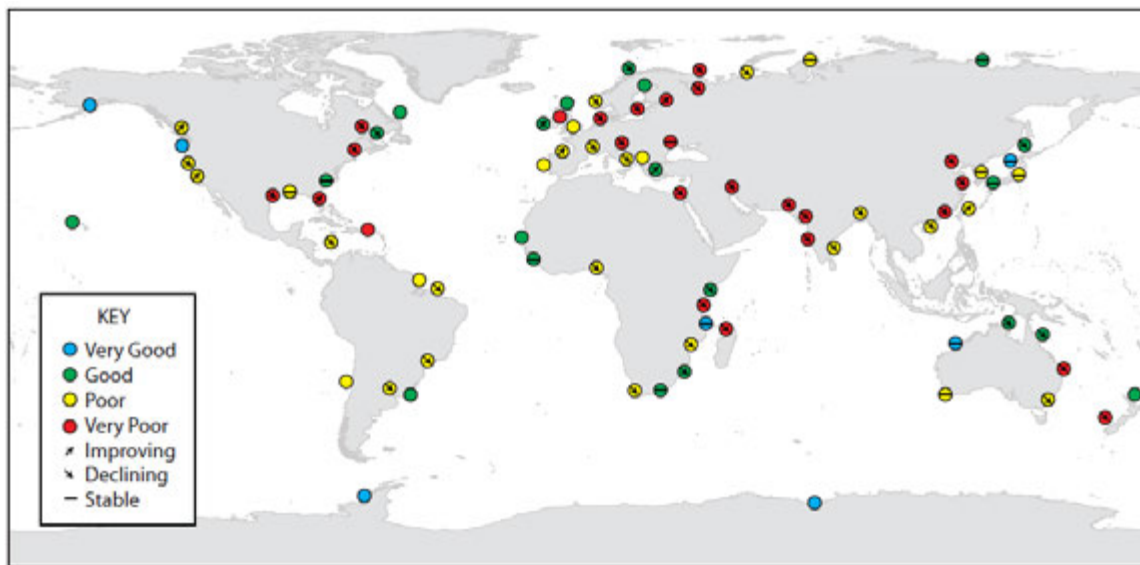

In considering the management of estuaries and deltas, the question of the number of estuaries and deltas on earth arises, given that an inventory of any asset is a prerequisite to its management. The number of estuaries and deltas, in turn, is dependent upon scale and definition of what constitutes an estuary or delta. In their estimate of river sediment discharge based on a 30 minute (55.56 km) grid, Syvitski et al. (2005) identified 4,464 river basins > 100 km² in area that are not covered by ice sheets of the Antarctica, Greenland and portions of the Canadian Archipelago and have a positive discharge to the ocean/sea. Given that every estuary or delta is associated with a river that discharges into the ocean/sea, and noting this size limit on catchment area, therefore about 4,464 estuaries and deltas are found on earth.

A search on the IUCN Protected Areas database (<http://protectedplanet.net>) for “estuaries” yielded 275 results, of which 156 are in Europe (including 107 in the UK alone), 79 are in the Americas (including 53 in the USA), 19 are in Oceania, 11 in Asia and 10 in Africa. A similar search conducted for “deltas” found 210 results, of which 127 are in Europe (including 35 in Greece), 51 are in the Americas, 17 in Asia, 12 in Africa and three in Oceania. In terms of level of protection, only five out of 275 estuaries and 12 out of 210 deltas are in IUCN category Ia (Strict Nature Reserve) or Ib (Wilderness Area), with over 50 per cent in categories IV (Habitat/Species Management Area) and V (Protected Landscape/ Seascape). However, these figures may not capture all estuaries or deltas under protection since in the exact word “estuary” or “delta” must be contained in the place name for the search to recognize the location as containing as estuary or delta; so a place that is named as a “bay” or other term would not be counted. Furthermore, the protection of the marine habitat may not be effective if the catchment itself is not well managed. Nevertheless, the figures give some broad indication of the level of protection afforded to estuaries and deltas on earth.

5. Integrated assessment of the status of the habitat.

In order to produce a global, integrated assessment of estuary and delta condition, a literature search was carried out for papers and reports that have provided an assessment on estuarine and coastal habitats. Studies that reported on the condition of individual estuaries or groups of estuaries within a broad area were included. Where possible, the results given in the reports were converted into a report card score on a scale of 1 to 4 (Very Good, Good, Poor, Very Poor) and the date of assessment recorded (the criteria used to identify the condition category are given in Appendix, online only). In addition, a trend for overall condition was extracted (declining, stable or improving) and the timeframe over which the trend was observed was recorded. The raw data are recorded in a table (Appendix, online only).

Based on published assessments for 103 areas, the global condition of estuaries and deltas (Figure 1) is Poor overall (mean score of 2.07 out of 4). The published assessments gave a Very Poor rating in 31 areas, a Poor rating in 32 areas, Good in 31 areas and a Very Good rating in only eight areas (Table 2 in Appendix, online only). These results are biased by the fact that many studies are carried out in affected areas and hence the scores are skewed (i.e., the overall “Poor” rating is influenced by the many studies that are conducted on affected systems). On the other hand, many of the available assessments are based on only a few measured variables (typically related to water quality or fisheries) and they do not give an overall (integrated) picture of the health and condition of estuarine ecosystems. This factor can influence the outcome of a non-integrated assessment for systems in which the impact is not measured by the parameters used.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Estuarine and deltaic condition assessments based on reports for 100 regions (listed in Appendix).

For example, one of the six Very Good ratings (Table 2 in Appendix) was assigned by UKTAG (2008) for Estuaries and Lochs in Scotland based on the winter mean of dissolved inorganic nitrogen over a six-year period (2001-2006). However, the ecology of at least one of these Scottish lochs (the Firth of Clyde) has been described by Thurstan and Roberts (2010) as “a marine ecosystem nearing the endpoint of overfishing, a time when no species remain that are capable of sustaining commercial catches”. Hence, whereas the water quality in this estuary may be rated as very good, the ecosystem has been significantly affected by over-fishing to the extent that an integrated assessment would likely give a rating of Very Poor for this estuary. Such cases serve to elevate the global score of “Poor” such that it is unrealistically positive.

Seventy-five studies reported a trend in terms of improving, stable or declining condition (Table 2 in Appendix). Out of those 75 studies, 46 (62 per cent) reported that conditions are declining, 19 (24 per cent) reported conditions were stable and ten (14 per cent) reported an improvement. On no continent does the number of estuaries showing an improving condition exceed the number of assessments of declining condition. Europe has the greatest number of studies that reported improving conditions (five), but only one area was reported to be in a “very good” condition; Africa, Australia and the South Pacific had no studies where conditions were improving. Asia (Japan) Australia and Africa each had one area where the condition was assessed as very good and stable.

6. Gaps in scientific knowledge

Out of the 101 areas assessed, only some are the subject of integrated assessments that include multiple aspects of estuarine environment, including habitats, catchment management, species, ecological processes, physical and chemical processes and socioeconomic aspects. Very few (about 10) areas had assessments that included all aspects of estuarine environments, to provide “fully integrated” assessments. There are 41 areas where assessments included at least three different aspects, producing partially integrated assessments. Another 25 areas had assessments concerned only with some aspect of estuarine water or sediment quality. Thus a critical gap in scientific knowledge is the availability of fully integrated environmental assessments for estuaries and deltas.

Out of the many possible aspects of the environment that could be assessed, water quality and biological aspects are most common, whereas socioeconomic aspects are assessed the least often, which is thus a knowledge gap. One other aspect of condition assessment is the trend (improving, stable or declining) that was assessed in 74 out of 103 areas. The assessment of trends is a critical piece of information for decision-makers, but which is missing in about 26 per cent of assessments. Furthermore, the time interval over which the trend is measured varies between studies, from one year to other arbitrary periods of human impact (as much as a century or longer). Thus the comparison of trends is confounded by differences in the time spans they relate to; international agreement on standards for reporting condition trends is needed to overcome this problem.

Chapter 44

Appendix. List of condition assessments

List of condition assessments (ranked as very good, good, poor, very poor) for estuaries and deltas in different regions, and the trend in condition (over time interval specified). Year of assessment, the number of estuaries or deltas included and references are indicated for each region. Indicative grading statements used to define the condition are as follows:

Very Good = Estuarine habitats are essentially structurally and functionally intact and able to support all dependent species. Only a few, if any, species populations have declined as a result of human activities or declining environmental conditions. There are no significant changes in physical-chemical-ecological processes or ecosystem services as a result of human activities.

Good = There is some habitat loss or alteration in some small areas, leading to minimal degradation but no persistent substantial effects on populations of dependent species. Populations of a number of significant species but no species groups have declined significantly as a result of human activities or declining environmental conditions. There are some significant changes in physical-chemical-ecological processes as a result of human activities in some areas, but these are not to the extent that they are significantly affecting ecosystem functions or services.

Poor = Habitat loss or alteration has occurred in a number of areas, leading to persistent substantial effects on populations of some dependent species. Populations of many species or some species groups have declined significantly as a result of human activities or declining environmental conditions. There are substantial changes in physical-chemical-ecological processes as a result of human activities, and these are significantly affecting ecosystem functions and services in some areas.

Very Poor = There is widespread habitat loss or alteration, leading to persistent substantial effects on many populations of dependent species. Populations of a large number of species or species groups have declined significantly as a result of human activities or declining environmental conditions. There are substantial changes in physical-chemical-ecological processes across a wide area of the region as a result of human activities, and ecosystem function and services are seriously affected in much of the region.

Key	
	Integrated assessment, including multiple indicators or indices of habitat, biota, water quality and socioeconomics
	Partly integrated assessment based on several (3 or more) indicators and/or multiple studies
	Assessments based on one or only a few (<3) indicators, mainly water quality

Name of Region	Number of estuaries and deltas	Condition	Trend	References	Parameters assessed and other notes
Australia and South Pacific					
Australia, SW Coast	20	Very Poor (2011)	Stable (2006-11)	Department of Environment (2011) Harris and Heap (2003)	Integrated assessment
Australia, NW Coast	162	Very Good (2011)	Stable (2006-11)	Department of Environment (2011) Harris and Heap (2003)	Integrated assessment
Australia, North Coast	164	Good (2011)	Declining (2006-11)	Department of Environment (2011) Harris and Heap (2003)	Integrated assessment
Australia, Moreton Bay	1	Very Poor (2006)	Declining (historic)	Lotze et al. (2006)	Integrated assessment
Australia, NE Coast	199	Good (2011)	Declining (2006-11)	Department of Environment (2011) Harris and Heap (2003)	Integrated assessment
Australia, SE Coast	172	Poor (2011)	Declining (2006-11)	Department of Environment (2011) Harris and Heap (2003)	Integrated assessment

New Zealand, Waikato Region	5	Good (2013)		Waikato Regional Council (2013)	Water quality (dissolved oxygen, pH, turbidity, total ammonia, nitrate, total phosphorus and chlorophyll a)
New Zealand, New River	1	Very Poor (2011)	Declining (2007-2011)	Environment Southland (2011)	Water quality
North America					
Canada, Nova Scotia	?	Good (2009)	Declining (1985-2000)	Nova Scotia (2009)	Water quality
Canada, Gulf of St Lawrence and Bay of Fundy	1	Very Poor (2006)	Declining (historic)	Lotze et al. (2006)	Integrated assessment
Canada, Salish Sea	>4	Poor (2011)		Barrie et al. (2012)	Benthic habitat mapping – impacted by fishing, pollution, catchment disturbance
Canada, Gilbert Bay, Southern Labrador	1	Good (2011)		Copeland et al. (2012)	Benthic habitat mapping – impacted by scallop dredging
United States, Massachusetts Bay, Delaware Bay, Chesapeake Bay, Pamlico Sound	4	Very Poor (2006)	Declining (historic)	Lotze et al. (2006)	Integrated assessment
United States, NE Coast	12	Very Poor (2000-02)	Declining (2000-02)	EPA (2007) Bricker et al (2007)	Based on five indicators of ecological condition: water quality index (including dissolved oxygen, chlorophyll a, nitrogen, phosphorus, and water clarity), sediment quality index (including sediment toxicity, sediment contaminants, and sediment total organic carbon [TOC]), benthic index,

					coastal habitat index, and a fish tissue contaminants index.
United States, Hudson River Estuary	1	Very Poor (2012)	Stable (2005-2010)	New York and New Jersey Harbor and Estuary Program (2012)	Assessment of marine habitats, fish, birds and pollution impacts.
United States, SE Coast	2	Good (2000-02)	Stable (2000-02)	EPA (2007) Bricker et al (2007)	Based on five indicators of ecological condition...
United States, Gulf Coast	7	Poor (2000-02)	Stable (2000-02)	EPA (2007) Bricker et al (2007)	Based on five indicators of ecological condition...
United States, W Coast	6	Poor (1999-03)	Improving (1999-03)	EPA (2007) Bricker et al (2007)	Based on five indicators of ecological condition...
United States, Glacier Bay, Alaska	1	Good (2011)		Cochrane et al. (2012)	Benthic habitat mapping – area impacted by fishing and tourism
United States, Alaska		Very Good (1999-03)		EPA (2007)	Based on five indicators of ecological condition...
United States, Hawaii		Good (1999-03)		EPA (2007)	Based on five indicators of ecological condition...
United States, San Francisco Bay	1	Poor (2011)	Declining (2011)	Lotze et al. (2006); San Francisco Bay Partnership (2011)	Integrated assessment (2003) plus water quality (2008)
United States, Oregon	30	Very Good (1999)		Sigmon et al. (2006)	General habitat condition; Water quality; Pollutant exposure and Benthic condition
United States, Puerto Rico	6	Very Poor (2002)		EPA (2007)	Based on five indicators of ecological condition...
United States, Florida Everglades	1	Very Poor (1900-2010)	Improving (1986-2006)	Entry and Gottlieb (2014)	Water quality
Central and South America					

Caribbean river basins	>4	Poor (2002)	Declining	Kjerfve et al. (2002)	Integrated LOICZ assessment covering Caroni River (Trinidad), Kingston Harbour (Jamaica), Parque Nacional Morrocoy (Venezuela) and Magdalena River (Costa Rica)
Uruguay, Río de la Plata, estuarine environment Montevideo Bay (including Montevideo Harbour)	1	Poor to very poor (1997-2010)	Improving	Muniz et al., (2002, 2004, 2005, 2006, 2011, 2012) García-Rodríguez et al. (2010) Burone et al. (2006, 2011) Danulat et al (2002) Gómez –Erache et al. (2001)	Biotic indices based on benthic communities; coastal eutrophication; heavy metals and PAH in sediments
Uruguay, Río de la Plata estuarine environment (seaward), Montevideo Coastal zone	1	Poor to good (1997-2012)	Declining	Muniz et al., (2002, 2004, 2005, 2006, 2011) Burone et al. (2006) Venturini et al. (2004, 2012, in press) Muniz & Venturini (2011) Gómez-Erache et al (2001) García-Rodríguez et al. (2011, 2014)	Biotic indices based on benthic communities; coastal eutrophication; contaminants in water, sediment and biota
Río de la Plata estuarine environment	1	Poor (1980-2000)	Declining	Nagy et al. (2000, 2002) FREPLATA 2005	Eutrophication
Argentina, North Coast of Río de la Plata	1	Good (2005-2010)		Gómez et al. (2012)	Biotic index indicative of eutrophication and organic pollution
East coast of Uruguay	6	Good (2007-2008)		Defeo et al. (2009) Muniz et al. (2012)	Biotic indices based on benthic communities

(coastal lagoons and sub-estuaries)				Conde & Rodríguez-Gallego (2002)	
Brazil, Ceará River	3	Poor (2006-2007)	Declining (2006-2007)	Nilan et al (2013)	Toxicity bioassays and metal distribution
Brazil, Santos-São Vicente Estuary	1	Poor (2007)	Declining (2007)	Buruaem et al. (2013)	Acute toxicity of whole sediment and chronic toxicity of liquid phases, grain size, organic matter, organic carbon, nitrogen, phosphorus, trace metals, polycyclic aromatic hydrocarbons, linear alkylbenzenes and butyltins; benthic community descriptors.
Brazil, Pará River (Amazon estuary)	1	Poor (2009)		Viana et al. (2012)	Multimetric indices of ecosystem integrity: Abundance Biomass Comparison (ABC); Biological Health Index; Estuarine Fish Community, Transitional Fish Classification and Estuarine Biotic Integrity Indexes
Chile, Lenga Estuary	1	Poor		Moscoso et al (2006); Díaz-Jaramillo et al (2013)	Benthic Macroinfauna; oxidative stress responses, including glutathione-S-transferase (GST) activity, total antioxidant capacity (ACAP) and lipid peroxidation levels (TBARS) in estuarine crabs
Chile, Tabul-Raqui Estuary	2	Good		Díaz-Jaramillo et al (2013)	Oxidative stress responses, including glutathione-S-transferase (GST) activity, total antioxidant capacity (ACAP) and lipid peroxidation levels (TBARS) in estuarine crabs.
Asia					

Russian Federation, North Dvina River Estuary	1	Very Poor (1990-2006)	Declining (2006)	Gordeev et al. (2006)	LOICZ – DPSIR approach based mainly on water quality (heavy metals and hydrocarbons, acidification and radionuclide contamination)
Russian Federation, Small rivers of the Kola Peninsula	>5	Very Poor (1990-2006)	Declining (2006)	Gordeev et al. (2006)	LOICZ – DPSIR approach based mainly on water quality
Russian Federation, Pechora Estuary	1	Poor (1990-2006)	Declining (2006)	Gordeev et al. (2006)	LOICZ – DPSIR approach based mainly on water quality
Russian Federation, Ob River	1	Poor (1990-2006)	Stable (2006)	Gordeev et al. (2006)	LOICZ – DPSIR approach based mainly on water quality
Russian Federation, Yenisey River	1	Very Poor (1990-2006)	Stable (2006)	Gordeev et al. (2006)	LOICZ – DPSIR approach based mainly on water quality
Russian Federation, Lena Delta	1	Good (1990-2006)	Stable (2006)	Gordeev et al. (2006)	LOICZ – DPSIR approach based mainly on water quality
Bangladesh, Ganges – Brahmaputra Delta	1	Poor (2005)	Declining	Ramesh et al. (2009); Ahmed et al., (2010, 2011)	LOICZ – DPSIR approach – integrated assessment. Heavy metals in water, sediment and fish from Buriganga River channel; Heavy metal concentrations in macrobenthic fauna from Sundarbans mangrove forest.
India and Sri Lanka, Peninsular	4	Poor (2005)	Declining	Ramesh et al. (2009)	LOICZ – DPSIR approach – integrated assessment

rivers					
India, small western rivers flowing into the Arabian Sea	?	Very Poor (2005)	Declining	Ramesh et al. (2009)	LOICZ – DPSIR approach – integrated assessment
India and Pakistan, Indus River	1	Very Poor (2005)	Declining	Ramesh et al. (2009)	LOICZ – DPSIR approach – integrated assessment
India, Sabarmati River	1	Very Poor (2014)	Declining (2009-2014)	Haldar et al (2014)	Turbidity, dissolved oxygen, BOD, phenol, and petroleum hydrocarbons, phytoplankton and total and selective bacterial count.
South China Sea estuaries and deltas		Poor (2012)	Declining (2005-2012)	Ward (2012)	Integrated assessment
China, Changjiang (Yangtze) River estuary	1	Very Poor (2003)	Declining (1999-2010)	Xiao et al. (2007); Wang (2007); Liu et al (2013)	Eutrophication - ASSETS and AMBI index methods
China, Jiaozhou Bay	1	Very Poor (2006)	Declining (1980-2005)	Dang et al. (2010); Sun and Sun (2008)	Eutrophication; Index based on macrobenthic community, phytoplankton community, sediments , water quality.
China, Pearl River Estuary	1	Very Poor (2009)	Declining (1980-2009)	Chen et al. (2013)	Ecosystem health index based on biodiversity, water and sediment quality
China, Huanghe (Yellow) River Delta	1	Very Poor (2008)	Declining (2008)	Zhu et al (2003); Fan and Huang (2008)	Water quality; dissolved inorganic nitrogen
Taiwan, Dapeng Bay	1	Poor	Improving (2003-2009)	Hung et al. (2013)	Eutrophication
Iraq, Shat al	1	Very Poor	Declining	Richardson and Hussain	Plant and fish communities and

Arab Waterway		(2012)		(2006); Mohamed et al. (2012)	production, changes in water quality, and specific populations of rare and endangered species
Republic of Korea, Gwangyang Bay	1	Good (2012)	Stable (2010-2012)	Kim et al., (2008); Lee et al., (2010); KIOST (2013)	Organochlorine pesticides; Water quality, the carbon isotope ratio of particulate organic matter and sediment, and the nutrients limiting phytoplankton growth; marine ecosystem health index (MEHI) based on water quality, sediment quality, plankton, and benthos
Republic of Korea, Jinhae Bay	1	Poor (2012)	Stable (2010-2012)	Lim et al., (2012); KIOST (2013)	Sediment core records of C, N, CaCO ₃ , trace metals; MEHI
Japan, Mutsu Bay	1	Good (2012)	Declining (2004-12)	Environment Management Bureau, Ministry of the Environment (2005-13)	Environmental status evaluated by Dr. K. Kohata from Japanese Environmental Quality Standards (for Living Environment)
Japan, Toyama Bay	1	Very Good (2012)	Stable (2003-12)	Toyama Prefecture (2009, 2014)	Environmental status evaluated by Dr. K. Kohata from Japanese Environmental Quality Standards
Japan, Tokyo Bay	1	Poor (2012)	Stable (2003-12)	Environment Management Bureau, Ministry of the Environment (2013)	Environmental status evaluated by Dr. K. Kohata from Japanese Environmental Quality Standards
Japan, Ise Bay	1	Poor (2012)	Improving (2003-12)	Environment Management Bureau, Ministry of the Environment (2013)	Environmental status evaluated by Dr. K. Kohata from Japanese Environmental Quality Standards
Japan, Osaka Bay	1	Poor (2012)	Stable (2003-12)	Environment Management Bureau, Ministry of the Environment (2013)	Environmental status evaluated by Dr. K. Kohata from Japanese Environmental Quality Standards
Japan, Ariake Sea and	1	Good (2012)	Stable (2003-12)	Environment Management Bureau, Ministry of the	Environmental status evaluated by Dr. K. Kohata from Japanese Environmental

Shimabara Bay				Environment (2013)	Quality Standards
Japan, Yatsushiro Sea	1	Good (2012)	Stable (2003- 12)	Environment Management Bureau, Ministry of the Environment (2013)	Environmental status evaluated by Dr. K. Kohata from Japanese Environmental Quality Standards
Africa					
South Africa, Cool Temperate	23	Poor (1993-99)	Declining (2004)	Turpie (2004); Harrison and Whitfield (2006) Van Niekerk et al (2013)	Integrated assessment
South Africa, Warm Temperate	104	Good (1993-99)	Stable (2004)	Turpie (2004); Harrison and Whitfield (2006)	Integrated assessment
South Africa, Subtropical	62	Good (1993-99)	Declining (2004)	Turpie (2004); Harrison and Whitfield (2006)	Integrated assessment
Guinea Current LME		Poor (2013)	Declining (2008-2013)	Guinea Current Report some.grida.no	Integrated assessment
Niger Delta Nigeria	21	Poor (2011)	Declining 2000 -present	Awosika et al (1993); Folorunsho et al. (1994); Awosika and Folorunsho (in press); Folorunsho and Awosika (in press); UNEP (2011)	Petroleum pollution
The Gambia, Gambia Estuary	1	Good (2006)		Simier et al. (2006)	Fish assemblages
Sierra Leone	>1	Good (2014)	Stable (2014)	http://some.grida.no/sierra-leone/1-habitat.aspx	Integrated assessment
Ghana, Iture Estuary	1	Very Poor (2006)		Fianko et al (2007)	Cd, Zn, Se and Pb in water samples
Egypt, Nile Delta	1	Very Poor (2010)	Declining (1984-2010)	El-Asmar and Al-Olayan (2013)	Satellite image analysis of coastal change; heavy metal pollution

				Gu et al. (2013)	
Kenya, Tana and Athi-Sabaki estuaries	2	Good (2009)	Declining	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	Nutrient levels in the Tana and Athi-Sabaki estuaries are high; the threshold chemical contamination levels of both Tana and Athi-Sabaki rivers have not been attained
Tanzania, Pangani Estuary	1	Very Poor (2009)	Declining	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	Poor water quality, stream morphology and aquatic life (low DO and eutrophication)
Tanzania, Rufiji Estuary	1	Good (2009)	Stable	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	DDT and nutrient flows from agricultural activities – local effects only to date.
Mozambique, Ruvuma River Estuary	1	Very Good (2009)	Stable	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	Best preserved mangrove forests along the coastline
Mozambique, Zambezi River Delta	1	Poor (2009)	Declining	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	Changed river flow caused loss of fisheries; pollution from sewage and industrial waste
Mozambique, Pungwe River Estuary	1	Good (2009)	Declining	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	Water abstraction has lead to reduced sediment loads and habitat loss.
Mozambique, Limpopo River Delta	1	Poor (2009)	Declining	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	Increasing salinity; discharge of untreated or partially treated domestic and industrial effluents; declining of river flows due to escalating demands for water; and discharge of untreated loads from upstream mining activities.
Madagascar, Betsiboka Estuary	1	Very Poor (2009)	Declining	UNEP/Nairobi Convention Secretariat and WIOMSA (2009)	Eutrophication, chemical pollution due to mining, port activities, effluent from oil refinery, harmful algal blooms, loss of

					mangrove and coral reef habitat, overfishing
Europe					
United Kingdom, England	43	Poor (1993-99)		UKTAG (2008)	Dissolved inorganic nitrogen
United Kingdom, Scotland	51	Very Good (1993-99)		UKTAG (2008)	Dissolved inorganic nitrogen
United Kingdom, Scotland, Firth of Clyde	1	Very Poor	Declining	Thurstan and Roberts (2010)	Fisheries data (species, population, catch statistics)
United Kingdom, Wales	17	Good (1993-99)		UKTAG (2008)	Dissolved inorganic nitrogen
United Kingdom, Bristol Channel	1	Poor (2011)		James et al. (2012)	Benthic habitat mapping
United Kingdom, Northern Ireland	10	Good (1993-99)		UKTAG (2008)	Dissolved inorganic nitrogen
Ireland	67	Good (2001-2005)	Improving (1995-2005)	Environmental Protection Agency (Ireland), (2006); Borja et al (2012)	Eutrophication
Adriatic Sea	1	Very Poor (2006)	Declining	Lotze et al. (2006)	Integrated assessment
Wadden Sea	1	Very Poor (2006)	Declining	Lotze et al. (2006) Dankers et al. (2012)	Integrated assessment
Baltic Sea	1	Very Poor	Declining	Lotze et al. (2006)	Integrated assessment

		(2006)		Ezhova et al. (2012)	
Finland, Kvarken Archipelago	1	Good (2010)		Kotilainen et al., (2012)	Benthic habitat mapping
Russian Federation, Neva Bay, Gulf of Finland	1	Very Poor (2005)	Improving (2000-2005)	Balushkina (2009)	Water quality, species diversity of zoobenthos
Spain, Basque Country	18	Good (1995-2003)	Improving (1995-2003)	Muxika et al. (2007); Borja et al (2012)	Physico-chemical, chemical, hydromorphological, and biological (phytoplankton, macroalgae, macroinvertebrates, and fishes) elements
Portugal, Mondego estuary	1	Good (2000-2001)		Chainho et al. (2007)	Benthic invertebrate communities
France, Mediterranean lagoons	7	Poor (2011)	Declining 2000-2011	Ifremer (2011); Borja et al (2012)	Eutrophication, including physicochemical elements in water and sediment, phytoplankton, macroalgae, and macroinvertebrates
Italy, Italian estuaries	22	Poor (2004)	Improving (2004)	Giordani et al. (2005)	LOICZ – water quality, DIN levels
Greece, Amvrakikos Gulf	1	Poor (1996-98)		Tsangaris et al. (2010)	Combination of bioenergetics and biochemical biomarkers in mussels
Greece, Saronikos Gulf	1	Good (2000-2012)	Improving (2000-2012)	Simboura et al (2013)	Benthic communities (BENTIX index)
Romania, Danube Delta	1	Very Poor (2001-2007)	Stable (2001-2007)	Török et al (2008)	Eutrophication
Norway, Southern fjords		Poor (2014)	Declining	www.environment.no/Topics/Marine-	Eutrophication problem areas, sugar kelp forests have almost disappeared

on the Skagerrak coast				areas/Coastal-waters/	
Norway, Northern fjords		Good (2014)	Declining	www.environment.no/Topics/Marine-areas/Coastal-waters/	
Antarctica					
Prydz Bay fjords	1	Very Good (2010)		O'Brien et al. (2012)	Benthic habitat mapping
Antarctic Peninsula, Fjords		Very Good (2010)		Grange and Smith (2013)	Benthic megafaunal abundance, community structure, and species diversity

Chapter 44

Chapter 45. Hydrothermal Vents and Cold Seeps

Contributors: Nadine Le Bris (Convenor), Sophie Arnaud-Haond, Stace Beaulieu, Erik Cordes, Ana Hilario, Alex Rogers, Saskia van de Gaever (lead member), Hiromi Watanabe

Commentators: Françoise Gaill, Wonchoel Lee, Ricardo Serrão-Santos

The chapter contains some material (identified by a footnote) originally prepared for Chapter 36F (Open Ocean Deep Sea). The contributors to that chapter were Jeroen Ingels, Malcolm R. Clark, Michael Vecchione, Jose Angel A. Perez, Lisa A. Levin, Imants G. Priede, Tracey Sutton, Ashley A. Rowden, Craig R. Smith, Moriaki Yasuhara, Andrew K. Sweetman, Thomas Soltwedel, Ricardo Santos, Bhavani E. Narayanaswamy, Henry A. Ruhl, Katsunori Fujikura, Linda Amaral Zettler, Daniel O B Jones, Andrew R. Gates, and Paul Snelgrove.

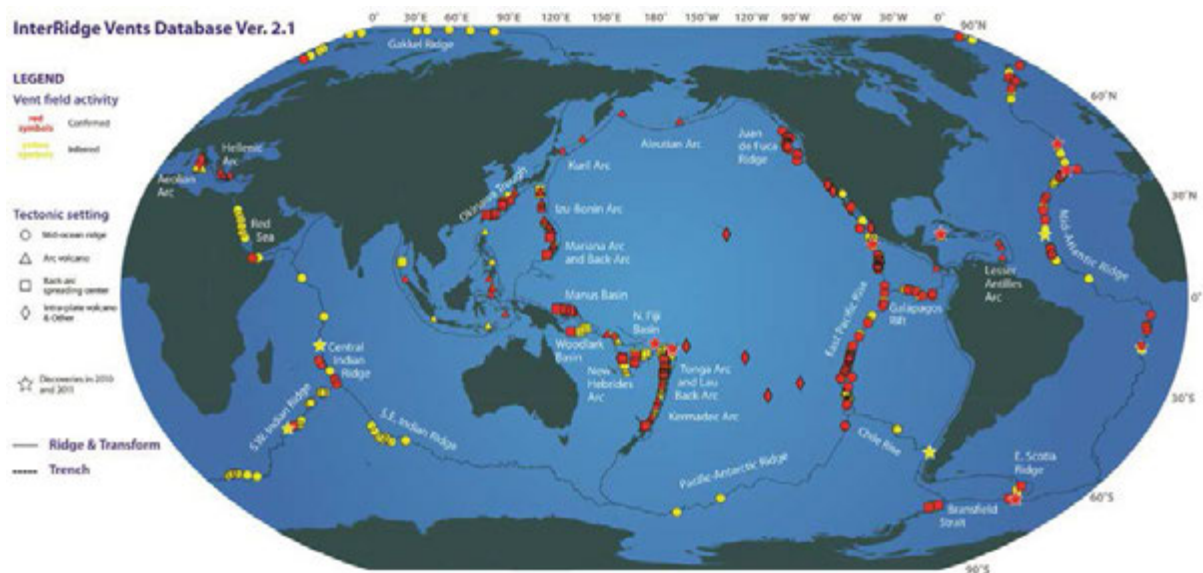

1. Inventory

Hydrothermal vents and cold seeps constitute energy hotspots on the seafloor that sustain some of the most unusual ecosystems on Earth. Occurring in diverse geological settings, these environments share high concentrations of reduced chemicals (e.g., methane, sulphide, hydrogen, iron II) that drive primary production by chemosynthetic microbes (Orcutt et al. 2011). Their biota are characterized by a high level of endemism with common specific lineages at the family, genus and even species level, as well as the prevalence of symbioses between invertebrates and bacteria (Dubilier et al., 2008; Kiel, 2009).

Hydrothermal vents are located at mid-ocean ridges, volcanic arcs and back-arc spreading centres or on volcanic hotspots (e.g., Hawaiian archipelago), where magmatic heat sources drive the hydrothermal circulation. Venting systems can also be located well away from spreading centres, where they are driven by exothermic, mineral-fluid reactions (Kelley, 2005) or remanent lithospheric heat (Wheat et al., 2004). Of the 521 vent fields known (as of 2009), 245 are visually confirmed, the other being inferred active by other cues such as tracer anomalies (e.g. temperature, particles, dissolved manganese or methane) in the water column (Beaulieu et al., 2013) (Figure 1).

Sediment-hosted seeps occur at both passive continental margins and subduction zones, where they are often supported by subsurface hydrocarbon reservoirs. The migration of hydrocarbon-rich seep fluids is driven by a variety of geophysical processes, such as plate subduction, salt diapirism, gravity compression or the dissociation of methane hydrates. The systematic survey of continental margins has revealed an increasing number of cold seeps worldwide (Foucher et al., 2009; Talukder, 2012). However, no recent global inventory of cold seeps is available.

Both vent and seep ecosystems are made up of a mosaic of habitats covering wide ranges of potential physico-chemical constraints for organisms (e.g., in temperature, salinity, pH, and oxygen, CO₂, hydrogen sulphide, ammonia and other inorganic volatiles, hydrocarbon and metal contents) (Fisher et al., 2007; Levin and Sibuet, 2012; Takai and Nakamura, 2010). Some regions (e.g., Mariana Arc or Costa Rica margin) host both types of ecosystems, forming a continuum of habitats that supports species with affinities for vents or seeps (Watanabe et al., 2010; Levin et al., 2012). Habitats indirectly related to hydrothermal venting include inactive sulphide deposits and hydrothermal sediments (German and Von Damm, 2004). Similarly, cold-water corals growing on the carbonate precipitated from the microbial oxidation of methane are among the seep-related habitats, although they typically occur long after seepage activity has ceased (Cordes et al., 2008; Wheeler and Stadnitskaya, 2011).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

2. Features of trends in extent or quality

Chemosynthetic ecosystems in the deep sea were first discovered 40 years ago using towed camera systems and manned submersibles; hydrothermal vents in 1977 for diffuse vents on the Galapagos Spreading Center (Corliss et al. 1979), and in 1979 for black smokers on the East Pacific Rise (Spiess et al., 1980), and cold seeps at the base

of the Florida escarpment in the Gulf of Mexico in 1984 (Paull et al., 1984). Compared to other deep-sea settings, the exploration of vent and seep habitats is thus recent (Ramirez-Llodra et al., 2011). In the last decade, high-resolution seafloor mapping technologies using remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs) have yet enhanced the capacity to explore the deep seabed.

Since the last global compilation (Baker and German, 2004), the known number of active hydrothermal vent fields has almost doubled, with an increasing proportion of new discoveries being in arc and back-arc settings, as a result of increasing exploration efforts (Beaulieu et al., 2013). These exploration efforts have emphasized the highly heterogeneous and patchy distribution of habitats associated with diffuse and focused-flow vents, hosting diverse microbial and faunal communities.

A large spatial and temporal variability of vent fluid temperature and chemical properties over mid-ocean ridges and arc and back-arc settings has been described, in relation to different geological substrate, hydrothermal activity, volcanic or tectonic instability (e.g. eruptions) (German and Von Damm, 2004; Charlou et al., 2010). This variability generates strong environmental constraints on chemosynthetic primary producers (Amend et al., 2011; Le Bris and Duperron, 2010; Takai and Nakamura, 2010) and dominant fauna including vent-endemic species of tubeworms, mussels, gastropods, clams, shrimp or crabs (Desbruyères et al., 2001; Fisher et al., 2007; Watanabe et al., 2010).

Common features are shared among vent and seep ecosystems. At seeps, microbial consortia oxidizing methane and their end-product (e.g., sulphide) sustain abundant microbial populations exhibiting diverse metabolic pathways. These microbes produce large amounts of organic matter, fuelling high invertebrate biomass. Many forms of symbiosis between chemosynthetic bacteria and host-invertebrates have adapted specifically to the energy-rich environmental conditions of vent and seep environments (Dubilier et al., 2008).

Within methane seeps and other types of seeps, different seepage intensities create distinct habitats dominated by chemosynthetic bacterial mats, and endemic and non-endemic species of tubeworms, mussels, gastropods, clams, shrimp or crabs, and supporting numerous associated invertebrate species. Faunal biodiversity is generally low within each seep habitat (Levin, 2005) but the vast array of geomorphic and biogenic habitats, each with highly adapted species, contributes significantly to beta diversity in the deep-sea (Cordes et al., 2010). Extensive trophic niche partitioning of microbes by heterotrophs also contributes to biodiversity at seeps (Levin et al., 2013). Methane seep sediments share many species with surrounding margin sediments (Levin et al., 2010), and numerous families and genera with hydrothermal vents and organic falls (Bernardino et al., 2012)¹.

¹ Text originally prepared for Chapter 36F (Open Ocean Deep Sea)

Despite recent global efforts, biological inventories are still largely incomplete. At the end of the Census of Marine Life programme (CoML, Crist et al., 2010), the ChEssBase dedicated to chemosynthetic ecosystems reported 700 hydrothermal vent species and 600 species from cold seeps (Ramirez-Llodra and Blanco, 2005; German et al., 2011). Around 200 new species were reported between 2002-2010 (i.e., 25 species/year), most of them belonging to mega and macrofauna. Much remains to be described, particularly in the meiofauna. Currently, vent fauna constitute between 7 and 11 biogeographic provinces, including new discoveries in the Arctic and Southern Oceans (Bachraty et al., 2009; Moalic et al., 2012; Rogers et al., 2012). Each newly identified vent or seep contains a diversity of unidentified species and these biogeographic patterns should be considered as preliminary (German et al., 2011). Furthermore, new types of chemosynthetic ecosystems are still being discovered, such as serpentinite-hosted ecosystems found on continental margins, ridges and trenches (Ohara et al., 2012; Kelley, 2005).

Few vent and seep areas have repeated observations over more than ten years from which temporal trends can be described (Glover et al., 2010). Recolonization of habitats impacted by volcanic eruptions was repeatedly documented on the 9°50'N vent field of the fast-spreading East Pacific Rise (Shank et al., 1998) and over different locations of the intermediate-spreading Juan de Fuca Ridge (Tunnicliffe et al., 1997). The resilience capacity of vent communities, however, cannot be generalized from the re-establishment of microbial communities and few dominant fauna species adapted to these highly unstable systems. Even on those areas, persistent effects on larvae patterns have been documented over years after an eruption suggesting long-lasting impacts on community recovery (Mills et al., 2013). Volcanic activity is furthermore much less frequent at slow or ultra-slow spreading ridges (e.g. Mid-Atlantic Ridge), resulting in a much lower frequency of natural perturbations, and in the absence of knowledge about the potential response of their specific communities to major disturbance. Succession at cold seeps, including later stages of deep-water coral colonization, may proceed over centuries to millennia with slow-growing and long-lived species that should be considered particularly vulnerable to disturbance (Cordes et al., 2009).

Life histories of key species and their links with resource and habitat variability have just started to be described (Ramirez-Llodra et al., 2010). Important biodiversity components supporting ecosystem functions also remain under-studied. In particular, a much lower number of studies dealt with meiofaunal organisms (< 1mm) from vent and seep sites than with macrofauna (Vanreusel et al., 2010). Following the massive molecular inventories allowed by New Generation Sequencing, we are just now getting glimpses into the diversity of microbes in both vent and seep environments. That diversity appears higher by orders of magnitude than those hitherto revealed with classical sequencing and cloning tools. Insufficient knowledge of the drivers of ecosystem and community dynamics at vent and seeps makes anticipating any trends in their ecological status problematic or even elusive in a context of multiple pressures.

3. Major pressures linked to the trends

The deep sea is being seen as a new frontier for hydrocarbon and mineral resource extraction, as a response to increasing demand for raw materials for emerging high-technology industries and worldwide urbanization. As a consequence, vent and seep ecosystems, so far preserved from direct impacts of human activities, are confronted with increasing pressures (Ramirez-Llodra et al., 2011; Santos et al., 2012).

Offshore oil extraction increasingly occurs in waters as deep as 3000 m and exploration for oil and gas now predominantly occurs in deep water (> 450m) or ultra-deep water (> 1500m depth), where typical seep ecosystems are found. Seafloor installations can directly affect cold seep communities in their impact area, if visual surveys and Environmental Impact Assessments (EIAs) are not completed prior to drilling. In addition, an increasing threat exists of large-scale impacts from accidental spills, such as the 2010 *Deepwater Horizon* blowout in the Gulf of Mexico, which was the largest accidental release of oil into the ocean in human history (McNutt et al., 2012) with a significant impact on surrounding deep-seabed habitats (Montagna et al., 2013; Fisher et al., 2014).

Further pressures on cold seep communities may arise from the combined effects of increasing demand for energy and technological progress in the exploitation of new types of energy resources. This type of development is shown by the world's first marine methane hydrate production test in the Nankai Trough in 2013. Sequestration of CO₂ in deep-sea sedimentary disposal sites and igneous rocks (Goldberg et al., 2008) should also be considered a potential threat specific to these communities (IPCC, 2005).

The increased demand for metals is promoting deep-sea mineral resource exploration both within Exclusive Economic Zones (EEZs) and in the Area (as defined in the United Nations Convention on the Law of the Sea), raising the issue of potential impacts on vent ecosystems (Van Dover, 2012). In 2011, the granting of a mining lease to exploit sulphide minerals for gold, copper and zinc in the EEZ of Papua New Guinea will shortly turn the deep-sea mining industry into a reality. Additionally, in the last five years, the International Seabed Authority has granted two new exploration permits for polymetallic sulphide deposits and two others are about to be signed for sites on the Atlantic and Indian mid-ocean ridges (<http://www.isa.org.jm/en/scientific/exploration/contractors>).

Significant threats are anticipated on the largely unknown communities associated with active hydrothermal deposits and the typical vent communities that can occur in close proximity to these areas (ISA, 2011). Inactive areas, which no longer had any detectable fluid venting with temperature anomaly as defined in the InterRidge Vents Database, have been mostly described so far in the vicinity of active areas with typical vent communities. These active areas where venting fluid is warmer than ambient, are inclusive of low-temperature diffuse flow and will require systematic exploration surveys and dedicated impact studies. Communities from inactive areas furthermore still need to be described. It is, for example, unclear whether they encompass species assemblages closely related to deep seabed areas out of any hydrothermal influence, or whether they host specific fauna adapted to the local

metal-rich substrate or to the proximity of highly productive chemosynthetic ecosystem at local to regional scale. Furthermore, despite the absence of high temperature associated with black smokers, some of these inferred 'inactive' areas may display diffuse flow vents, that are much more difficult to detect from water column surveys.

Indirect pressures on vent and seep ecosystems resulting from global anthropogenic forcing, including pollution and climate change, are not well constrained. These systems are less sensitive to changes in photosynthetic primary production than other deep-sea ecosystems, but potential threats also exist. Changes in water-mass circulation could affect larval dispersal, potentially reducing the capacity for species' populations to maintain themselves across fragmented habitats (Adams et al., 2011). The extension of hypoxia or anoxia on continental margins and in semi-enclosed seas could also profoundly alter the functioning of these ecosystems because of the high oxygen demand of chemosynthetic activity (Childress and Girguis, 2011). Warming is already affecting the deep ocean waters, especially at high latitudes (e.g., Arctic) and in enclosed seas (e.g., Mediterranean) hosting vent and seep ecosystems (Glover et al., 2010). Cold seep ecosystems could be affected, through direct impacts on the activity of fauna and the microbial consortia or major disturbances, such as landslides and gas extrusion caused by hydrate destabilization.

These ecosystems occupy fairly small areas of the seabed (typically km-scale) and may be more vulnerable to common deep-sea pressures such as deep-sea fishing or waste dumping. Deep-sea fishing on seamounts flanks and margins down to at least 1500m depth are part of the existing pressure on cold seep, even though rarely documented so far (Ramirez-Llodra et al., 2011). This pressure is potentially exerted on vent communities occurring at those depths on mid-ocean ridge flanks or volcanic arc and back-arc seamount chains. Even activities such as scientific research or bioprospecting can pose a threat to the integrity of these unique communities and their endemic species (Baker et al., 2010). Impacts of ecotourism on vent environments should also be accounted, since this is a growing activity.

4. Implications for services to ecosystems and humanity

Chemosynthetic communities are functionally distinct from other marine communities, with capacity to form very high biomasses relative to other deep-sea ecosystems, though many questions remain open about their distribution, diversity, functioning and environmental features that limit the ability to estimate associated ecosystem services (Armstrong et al., 2012).

Nevertheless, deep-sea vents and seeps represent one of the most physically and chemically diverse biomes on Earth and have a strong potential for discovery of new species of eukaryotes and prokaryotes (Takai and Nakamura, 2011). Their specialized phyla are adapted to a range of environmental constraints. Archaea that live at extremes in pressure, temperature and pH are particularly attractive to industrial sectors (UNU-IAS, 2005). The hydrothermal vent and cold seep animals have evolved traits that allow them to not only tolerate extreme environmental conditions, but in

some cases to accumulate and transport chemicals toxic to most other marine species (Childress and Fisher, 1992; Le Bris and Gaill, 2007).

This makes these ecosystems a vast genomic repository of unique value to screen for highly specific metabolic pathways and processes. The vent and seep biota thus constitute a unique pool of potential for the provision of new biomaterials, medicines and genetic resources that has already led to a number of patents (Gjerde, 2006; Arrieta et al., 2010; Thornburg et al., 2010). This great potential value to humankind is accounted for in the public awareness of potential threats and acceptability of deep-sea conservation programmes (Jobstvogt et al., 2014).

Chemosynthetic ecosystems are linked with adjacent deep-sea ecosystems through dispersing larvae and juveniles, and through the export of local productivity to mobile fauna and surrounding deep-sea corals and other filter-feeding communities, but the quantitative importance of their chemosynthetic production at the regional scale still remains to be appraised. At the global scale, a significant role of seep ecosystems is recognized in the regulation of methane fluxes, oxygen consumption and carbon storage from anaerobic methane oxidation by microbial consortia in sediments (Boetius and Wenzhöfer, 2013). Recent evidence shows that hydrothermal vent plumes sustain microbial communities with potential connections to zooplankton communities and biogeochemical fluxes in the deep ocean (Dick et al., 2013). The biological stabilization of metal (e.g., iron, copper) from hydrothermal vents under dissolved or colloidal organic complexes for long-range export in the water column has been documented recently (Wu et al., 2011; Hawkes et al., 2013). Recent assessments of these iron sources indicate their significance for deep-water budgets at oceanic scales and underscore the possibility for fertilizing surface waters through vertical mixing in particular regional settings (Tagliabue et al., 2010) and supporting long-range organic carbon transport to abyssal oceanic areas (German et al., 2015).

Because of their unique biodiversity and ecological functions in the Earth's biosphere, their geophysically-driven primary production sustained by chemosynthesis, their significance in global element cycles (i.e., iron), and their potential for natural products, vent and seep areas hold important (yet largely unknown) implications for services to ecosystems and humanity. As such, they will benefit from protection from adverse impacts caused by human activities. Furthermore, beyond the requirement to maintain biodiversity for future generations, cultural ecosystem services such as generation of scientific knowledge and inspiration for citizens to learn about the natural world and for new generations to enter scientific careers, and tourism, should also be recognized in an assessment of their economic value (Jobstvogt et al., 2014).

5. Conservation responses

Action to protect vents and seeps has taken place at national and international levels through the development of informal or voluntary protection plans or codes of conduct and formal protection measures under State or international law. An

example of informal measures is the adoption by the scientific community of the InterRidge Statement of Commitment to Responsible Research Practices (Devey et al., 2007). The marine mining industry has also produced the International Marine Minerals Society Code for Environmental Management of Marine Mining (IMMS, 2011), which outlines principles and best practice for use by industry, regulatory agencies, scientists and other interested parties (Boschen et al., 2013). The OSPAR Commission recommended strengthening the protection of hydrothermal vents/fields occurring on oceanic ridges as a threatened and/or declining habitat in order to recover the habitat, to improve its status and ensure its effective conservation in Region V of the OSPAR maritime area (OSPAR, 2014).

Formal protection measures for hydrothermal vent ecosystems have been undertaken mainly within the EEZs of States (Table 1). The Rainbow hydrothermal vent field was proposed to be included in the Azores Marine Park by the Portuguese Government at an OSPAR meeting considering these questions, even though it lies outside the EEZ (Ribeiro, 2010; Calado et al., 2011). Portugal proceeded with this area as a Marine Protected Area on the understanding that the area is located on its extended continental shelf. It is also notable that some areas protected from bottom fishing also contain chemosynthetic ecosystems (e.g., on several southern hemisphere ridges), although this protection does not apply to other activities, such as mining.

The Strategic Plan for conservation of Biodiversity 2011-2020 adopted by the Conference of the Parties at the Convention on Biological Diversity (CBD) established a target stating that 10 per cent of marine areas are conserved through systems of protected areas and other effective area-based conservation measures (Aichi Biodiversity Target 11²). In decision IX/20, the Conference of the Parties adopted the scientific criteria for identifying Ecologically or Biologically Significant Marine Areas (EBSAs) in need of protection in areas beyond national jurisdiction, and the scientific guidance for designing representative networks of marine protected areas. Because of their unique biodiversity, ecological properties and potential services, vent and seep areas meet the scientific and technical criteria defined for EBSA (Clark et al., 2014; Dunn et al., 2014; CBD scientific criteria for ecologically or biologically significant areas annex I, decision IX/20). As emphasized by decision X/29 of the Conference of the Parties, the identification of EBSAs and the selection of conservation and management measures is a matter for States and competent intergovernmental organizations, in accordance with international law, including the United Nations Convention on the Law of the Sea (CBD COP decision X/29, para. 26, 2010).

Scientists have called for the development of a cohesive network of such protected areas in which management of marine mining activities would be extremely risk averse, and often mining would be prohibited (Boschen et al., 2013; Van Dover et al.,

² Aichi Biodiversity Target 11 states “By 2020, at least 17 per cent of terrestrial and inland water, and 10 per cent of coastal and marine areas, especially areas of particular importance for biodiversity and ecosystem services, are conserved through effectively and equitably managed, ecologically representative and well connected systems of protected areas and other effective area-based conservation measures, and integrated into the wider landscapes and seascapes”.

2012). It is important to note that, in the context of vents and seeps, natural variability is acknowledged to underlie many of the changes that are happening. Knowledge gaps concerning the ecological dynamics and responses to combined pressures, therefore, currently make it difficult to devise effective conservation measures. In any case, implementation of such measures would require actions at the national, regional and (in some cases) global level to be coordinated with each other.

At present, in the absence of any formal framework for general coordination, voluntary cooperation among the International Seabed Authority (ISA) and RFMOs is taking place. Without further efforts to promote cooperation between the relevant sectoral regulatory authorities and to close gaps in knowledge, both the effectiveness of on-going conservation measures and the development of more wide-ranging protection for vents and seeps are likely to be put at risk.

Table 1. Summary of vent and seep ecosystems protected to date under national or international law (Santos et al., 2012; Calado et al., 2011; ISA, 2011; USFWS, 2012; NTL 2009-G40 ; New Zealand ENMS circular 2007; Gouvernement de Nouvelle Calédonie)

Ocean region	Name of site	Type of chemosynthetic ecosystem	Depth & location	Legal framework
North East Pacific	Endeavour hydrothermal vents MPA	Five vent fields including black smokers	2250m depth, 250km SW of Vancouver Island in Canadian EEZ.	Protected under the Canadian Government's Ocean Act.
North East Pacific	Guaymas Basin Hydrothermal Vents Sanctuary	Hydrothermal vents located in a sedimented seabed.	Gulf of California, depth of ~2500m, Within Mexican EEZ.	Protected under Mexican State Law.
North East Pacific	Eastern Pacific Rise Hydrothermal Vents Sanctuary	Hydrothermal vents located on the East Pacific Rise	East Pacific Rise, depth of ~2800m, in Mexican EEZ.	Protected under Mexican State Law.
North West Pacific	Mariana Trench National Monument	Hydrothermal vents, CO ₂ vents, sulphur lake.	Located around three northernmost Mariana Islands & Mariana Trench 10m - 1650m depth.	Protected under US Law following Presidential Proclamation.
South West Pacific	Several deep-sea benthic protection areas	Hydrothermal vents	Northern to mid-Kermadec arc	New Zealand
West Pacific	Parc naturel de la mer de Corail (nature park of the Coral Sea)	Hydrothermal vent and cool seeps (suspected)	Up to 7919 m, encompassing the whole French EEZ around New Caledonia	Protected under New Caledonia Government
Gulf of Mexico	Numerous individual sites hosting 'high-densities benthic communities'	Hydrocarbon seeps and associated deep-sea corals	400 - 3300 m, in US EEZ	US Legal Framework: Bureau of Ocean Energy Management Notice to Lessees
North Atlantic	The Azores Hydrothermal Vent MPA	Seven hydrothermal vent fields including Lucky Strike, Menez Gwen, Rainbow and Banco Dom João de Castro. Except for Rainbow they are all Natura 2000 SAC (special areas of	Amongst or to the south west of Azores Islands, N. Atlantic. 40m - 2300m depth.	Protected under Portuguese national & EU Habitats Directive, Rainbow is the first protected vent site located outside of an EEZ. It is included in the Azores Marine Park.

		conservation under the EU habitats directive)

Chapter 46. High-Latitude Ice and the Biodiversity Dependent on it

Contributors: Jake Rice and Enrique Marschoff (Co-Lead members)

1. Description of the ice systems and their biodiversity

1.1 *Annual ice and multi-year ice*

The high-latitude ocean areas are ice-covered for much or all of the year. Multi-year ice and annual ice have different physical and chemical properties that make them also differ in terms of their ecological communities. The multi-year ice, in particular, is globally unique, and supports unique communities of ice algae and species of larger invertebrates, fish, birds and mammals wholly or largely dependent on the multi-year ice and on multi-year and annual ice margins. Sea ice is a technical term that refers to floating ice formed by the freezing of seawater. This chapter uses “high-latitude ice” as a more generic term for a variety of critically important high-latitude marine habitats, which include ice shelves, pack ice, sea ice, and the highly mobile ice edge. These forms of high-latitude ice complement and modify other types of habitats, including extensive shallow ocean shelves and towering coastal cliffs (CAFF, 2013. Meltofte, 2013).

The Arctic Ocean is unique in that it contains a deep ocean basin, which until recently was almost completely covered in multi-year ice (chapter 36H). No other area in the world has such an ice-dominated deep ocean. The Southern Ocean is unique in that it contains both icebergs (floating freshwater ice) calved from glaciers and ice shelves and sea ice. Also there is no limit to the northwards extension of the winter pack ice. Thus seasonal variations are much larger in the Antarctic (Ropelewski 1983). Three biogeographic regions have been recognised in the Antarctic, defined by differences in ice cover (Treguer and Jaques, 1992): ice-free, seasonally or permanently covered by high-latitude ice.

1.2 *Biodiversity associated with the ice*

The high-latitude ice-covered ecosystems host globally significant arrays of biodiversity, and the size and nature of these ecosystems make them of critical importance to the biological, chemical and physical balance of the globe (ACIA 2005). Biodiversity in these systems presents remarkable adaptations to survive both extreme cold and highly variable climatic conditions. Iconic ice-adapted species such as polar bear, narwhal, walrus, seals, penguins and seabirds have adapted to different ice conditions, including extreme examples such as the emperor penguin living among thousands of lesser known species that are adapted to greater or lesser degrees to exploit the habitats created by high-latitude ice (Meltofte, 2013; De Broyer et al. (eds.) 2014).

1.2.1 Primary production and lower trophic level communities

These high-latitude seas are relatively low in biological productivity, and ice algal communities, unique to these latitudes, play a particularly important role in system dynamics. Ice algae are estimated to contribute to more than 50 per cent of the primary production in the permanently ice covered central Arctic (Gosselin et al. 1997, Sakshaug 2004). Ice algae can be divided into communities on the surface, interior and bottom of the ice (Horner et al. 1992). In addition to microalgae, bacteria are an important component of the ice-algal community, but many other groups of organisms (e.g. archaea, fungi, ciliates, kinetoplastids, choanoflagellates, amoebae, heliozoans, foraminiferans and some protists that belong to no known group) also occur in ice communities (Lizotte 2003). Poulin et al. (2010) reported a total of 1027 sympagic taxa in the Arctic Ocean. Many of the dominant ice algae are diatoms that sink and are eaten by different benthic organisms or broken down by bacteria (Boetius et al., 2013), thus creating a link between ice and bottom ecosystems. In the Southern Ocean, the distribution of primary productivity is associated with frontal zones, areas of broken sea ice, and with the divergences linked to the bottom topography, with high horizontal variability at the local scale while the vertical distribution is more regular. Chlorophyll concentration is practically nil below 250 m with maxima around 50 m. This general pattern is highly modified in coastal areas (El-Sayed, 1970).

The primary productivity in the Antarctic is much lower than might be expected given the nutrient concentrations observed. Early in Antarctic research the factors regulating the distribution of primary producers have been discussed (Hart, 1934). In coastal waters nutrients might reach very high values (El-Sayed 1985, Holm-Hansen 1985) and phytoplankton blooms have been observed to deplete these high concentrations (Nelson and Smith 1986, Bienatti et al. 1977).

The marginal ice zone (MIZ), at and near the ice edge, is a highly productive area for phytoplankton (Sakshaug & Holm-Hansen, 1984, Sakshaug & Skjoldal 1989). Stable water masses due to ice melt coupled with high nutrient availability and light result in an intense phytoplankton bloom. As water masses become stratified due to surface heating, nutrient flow from below is inhibited. Consequently, the bloom in marginal ice areas starts earlier than in adjacent areas never experiencing high-latitude ice. The bloom follows the ice edge as it retreats in the spring. This “spring bloom” can occur in autumn in the areas of maximum ice retreat (Falk-Petersen et al. 2008). The ice-edge bloom is likely to weaken with time over the season (Wassmann et al. 2006).

Arctic planktonic herbivores, such as *Calanus hyperboreus*, are able to utilize the vast area of the Arctic Ocean and to feed and store lipids for over-wintering until the sun disappears in October (Falk-Petersen et al. 2008). In the Antarctic the same pattern of seasonal feeding expended in reproductive processes and lipid storage is followed by a suite of herbivores (De Broyer et al. (eds.) 2014) such as euphausiids (i.e. *Euphausia superba*, *Thysanoessa macrura*), copepods and salps (i.e. *Calanus simillimus*, *C. propinquus*, *C. acutus*, *Salpa thompsoni*).

Around the annual ice, in general there are steep gradients in temperature, salinity, light and nutrient concentrations creating different habitats throughout the ice, the 0.2 m on the lower ice surface having the most favourable conditions for growth among the interior communities (Arrigo 2003). However, with respect to biomass and contribution to primary production, the sub-ice community is the most important in annual ice. In addition there are seasonal trends and inter-annual variations in species composition, biomass and production as a result of several factors, including light, age and origin of the ice (e.g., distance to land and water depth). Thus, there is a high spatial heterogeneity when larger areas are considered.

Sea-ice algae start their growth ahead of phytoplankton. An extended growth season in the Arctic areas forms ice algal communities that are grazed actively by both ice fauna and zooplankton and may be an important component of the diet of some species during the winter. Ice algae contribute 4–26 percent of total primary production in seasonally ice-covered waters (Gosselin et al. 1997, Sakshaug 2004). *Apherusa glacialis* is probably the most numerous amphipod species in the central Arctic Ocean. *Onisimus glacialis* may be common in some areas. In the Antarctic sea ice the calanoid copepods are dominant while larvae of *E. superba* benefit from ice for overwintering; to date no species fully dependent on high-latitude ice has been identified (Arndt & Swadling, 2006).

1.2.2 Macrofauna

The ice structure and surfaces include a number of larger invertebrates that also are believed to live their entire life connected to the multi-year ice (e.g. nematode worms, rotifers and other small soft-bodied animals within the ice and amphipodes on the underside). Some of these dominate the biomass of macroinvertebrates (Arndt & Swadling 2006) and are the important food items for high-latitude fish. Antarctic euphausiid larvae spend the winter in close association with icebergs or sea ice. The permanent pack-ice zone of the Southern Ocean represents the habitat for a highly confined community of seabirds, the most unvarying of any seabird assemblage in the Southern Hemisphere (Ribic and Ainley, 1988). It is composed of Adélie and Emperor penguins, Snow and Antarctic petrels, with the addition during the summer of South Polar skua and Wilson's storm-petrel.

In the Arctic, Polar bears *Ursus maritimus* are highly dependent on high-latitude ice and are therefore particularly vulnerable to changes in ice extent, duration and thickness. Three ice-associated cetacean species also reside year-round in the Arctic, mostly connected to the marginal ice zone, including the Bowhead whale (*Balaena mysticetus*) that is assessed as highly endangered in part of its range. The reproduction of some Antarctic seal species is also linked to extent of ice (e.g. *Lobodon carcinophagus*, *Leptonychotes weddellii*) while others are temporarily associated to ice for rest and refuge. Penguin species also use icebergs or sea ice during foraging trips and follow the ice border in winter. Permanent ice shelves strongly modify the habitats and the sea bottom fauna below the shelves (Gutt et al. 2013, Lipps et al., 1977; Lipps et al., 1979; Post et al., 2014).

2. Changes to these systems and their biodiversity

2.1 *Changes in the ice structures*

These high-latitude ecosystems are undergoing change at a more rapid rate than other places on the globe, threatening the existence of ecosystems such as multi-year high-latitude ice. In the past 100 years, average Arctic temperatures have increased at twice the average global rate (IPCC 2007). Recent changes in Arctic and Antarctic sea-ice cover, driven by climate change including rising temperatures and winds (Stammerjohn et al., 2012), have affected the timing of ice break-up in spring and freeze-up in autumn, as well as the extent and type of ice present in different areas at specific dates. Overall, multi-year ice is rapidly being replaced by first-year ice. The extent of Arctic ice is shrinking in all seasons, but especially in the summer. In some regions of the Antarctic ice shelves are rapidly disappearing, while the maximum extension of winter ice appears to increase (Turner et al., 2009, pg. 130).

In the Arctic Ocean multi-year ice changed from covering more than two-thirds of the Arctic Ocean to less than one-third in less than a decade. For instance, multi-year ice now occupies only part of the deep areas of the Arctic Ocean beyond areas within the national jurisdiction of Canada and is projected to be virtually ice-free in summer within 30 years, with multi-year ice persisting mainly between islands of Canada and in the narrow straits between Canada and Greenland, Denmark (Meltofte, 2013). Similar projections of a largely ice-free Arctic Ocean in summer have been made from the Arctic-Pacific interface as well (Overland and Wand 2013). The multi-year ice that remains is also much younger than previously as the oldest multi-year ice classes have declined more than other classes (AMAP 2011), and even if conditions changed to allow the return of the lost/declined ice cover, it would take many years to return to the state of just a few decades ago.

2.2 *Changes in biodiversity*

A change in timing and duration of the ice edge bloom increases the probability of a “mismatch” in productivity, which may have severe consequences for zooplankton that are dependent on this bloom today, with potential cascading effects throughout the ecosystem. However, the timing of ice formation and melt also influences the distribution and intensity of the primary production in the water column. Such primary production is likely to increase in areas with less ice but may then become limited by nutrient availability, including trace nutrients such as iron.

Boreal species of algae, invertebrates, fish, mammals (Kaschner et al., 2011) and birds are expanding into these higher latitudes, while some ice-adapted species are losing habitat along the edges of their ranges. Changes are too rapid for evolutionary adaptation, so species with inborn capacity to adjust their physiology or behaviour will

fare better. Species with limited distribution, specialized feeding or breeding requirements, and/or high reliance on high-latitude ice for part of their life cycle are particularly vulnerable (Meltøfte, 2013). In the Antarctic, seal and penguin species dependent on ice distribution seem to be likely to respond to changes in extreme events, as had happened in some years of anomalous El Niño – Southern oscillation events. Significant declines in ice – even at the regional or local scales – may lead to the replacement of antarctic by subantarctic species (Turner et al., 2009, pg. xxv).

Krill plays a central role in the trophic structure of Antarctic ecosystems. Its abundance and distribution depend on the coupling of reproductive events and oceanic circulation. It is not clear to what extent its population declined and which are the factors involved (Ainley et al., 2005; 2007). The decrease in krill abundance and the increase in salps abundance are thought to be related with changes in ice cover (Loeb et al., 1997).

There are indications that populations of *Pleuragramma antarcticum*, a key fish species of the trophic web, and whose reproduction is closely associated to high-latitude ice, declined at some localities, to be replaced by myctophids, a new food item for predators (Turner et al. 2009, pg. 360).

3. Implications and risks

Reduced high-latitude ice, especially a shift towards less multi-year ice, will affect the species composition in these waters. With decreasing ice cover, the effects on the ice fauna will be strongest at the edges of the multi-year high latitude ice. Seasonal/annual ice has to be colonized every year, as opposed to multiyear ice. In addition, multi-year ice has ice specialists that do not occur in younger ice (von Quillfeldt et al. 2009). The previously very low biological production of the deep basins may also change in this region as light, temperature and storminess increase and currents shift. In addition, wind-driven mixing of the ocean is more efficient over open water and over the thinner, more-mobile, seasonal ice than over multi-year ice, with the potential to also increase productivity.

Due to low reproductive rates and long lifetime, it has been predicted that the polar bears will not be able to adapt to the current fast warming of the Arctic and become extirpated from most of their range within the next 100 years (Gorbunov and Belikov, 2008; Schliebe et al., 2008). Other Arctic ice dependent species such as ringed seal (Kovacs et al. 2008), possibly narwhal, Ross gull (Blomquist & Elander, 1981, Hjort et al., 1997) and ivory gull (Gilg et al., 2010) are also expected to decrease as high-latitude ice, especially multi-year ice, decreases.

The reduction in ice cover in the Arctic is creating the potential for increased utilization of natural resources, including fish stocks, including in the central portion of the Arctic Ocean beyond national jurisdiction (Lin et al. 2012, Arctic Nations 2013). Among non-renewable natural resources, the Arctic is estimated to contain a quarter of the world's remaining oil and gas reserves, the development of which is expected to increase.

Already, 10 per cent of the world’s oil and 25 percent of the world’s natural gas is produced in the Arctic, with the majority coming from the Russian Federation (AMAP 2007, see also chapter 21 of this Assessment).

In the Antarctic, the sea-ice cover is predicted to decrease by 33 per cent in this century (Turner et al., 2009, pg. 384) as well as coastal ice shelves. This would imply a significant stress for marine organisms but no species might be singled out as candidate for extinction in this period. Signy Island and some sites at the West Antarctic Peninsula have witnessed an explosion of the fur-seal numbers that may be related to decreased ice cover resulting in increasing areas available for resting and moulting, but which may also be related to population increases; the growing seal population in Signy Island has had deleterious impacts on the local terrestrial vegetation (Turner et al., 2009, pg. 360).

Chapter 47. Kelp Forests and Seagrass Meadows

Contributors: John A. West, Hilconida P. Calumpong, Georg Martin (Lead member), Hilconida P. Calumpong, Saskia van Gaever (Co-lead members)

1. Introduction

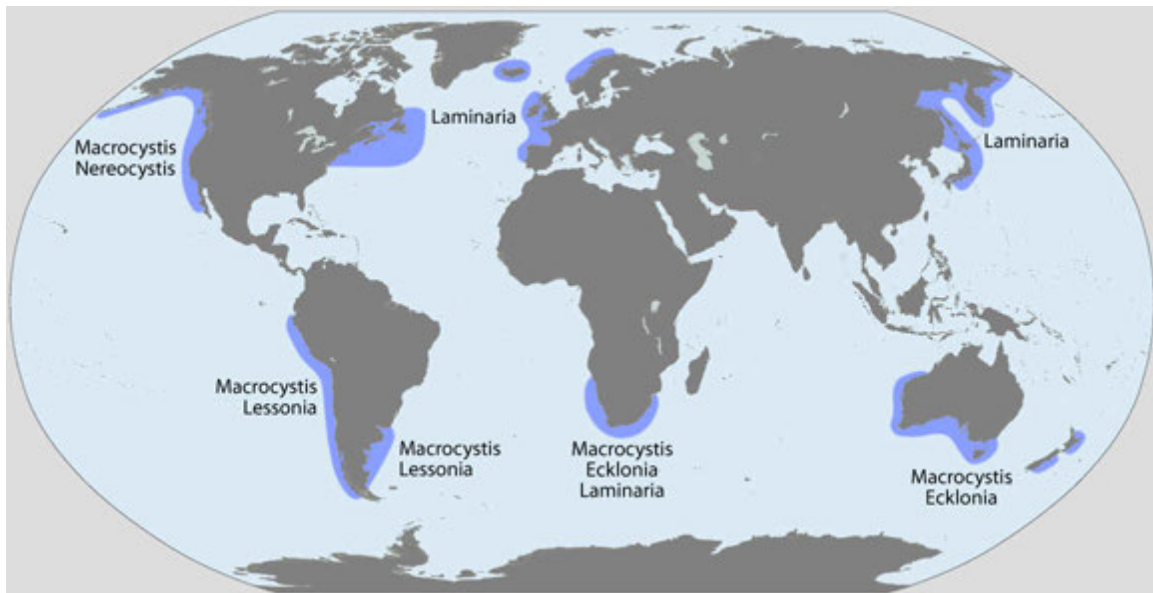

Kelp forests and seagrass meadows form shallow benthic marine habitats. Whereas kelp forests are limited to temperate areas (see Figure 47.1), seagrasses are found throughout all climatic zones (den Hartog 1970; Phillips and Meñez 1988), except in the Polar Regions (see Figure 47.2a). Both provide food and habitat to many economically exploited species, have high productivity (see Chapter 6 for values) and thus, play a significant role in ecological balance. Apart from goods (e.g. associated fisheries, food, phycocolloids) produced by these two ecosystems, kelps and seagrasses also provide many ecosystem services such as carbon sequestration and climate regulation (Raven 1997, Thom 1996; Beer and Koch 1996; Fourqurean et al., 2012), nutrient cycling (Fenchel, 1970; Robertson and Mann 1980; Suchanek et al., 1985; Wahbeh and Mahasneh, 1985; Wood et al., 1969), sediment stabilization and shoreline protection (Barbier et al., 2013), habitat and nursery functions (Duggins et al., 1990; Heck et al., 2003), especially for high value organisms such as crabs, shrimps, clams, flounder, spiny lobster (Kikuchi and Peres, 1977; Tegner and Dayton, 2000). The values of these services vary across geographic regions and cultural groups (see Barbier et al., 2011; Costanza et al., 1997; Cullen-Unsworth, 2014).

The kelp forest is characterized by about 30 species of large brown seaweeds belonging to the order Laminariales (Steneck et al., 2002). Together with its associated animals and other seaweeds, it is considered to be among one of the economically important ecosystems, especially for peoples who have traditionally used them for food, chemicals such as alkali and iodine (Robinson, 2011), and fertilizer and animal feed supplements (Stephenson, 1968). Currently, kelps are still harvested mainly for food and as source of the phycocolloid alginate, which has many uses in industry (see Chapter 14). The brown seaweeds, which are composed primarily of kelps, contribute about half of the total world seaweed production from aquaculture of about 6.8 million tons a year (averaged over a 10-year period between 2003-2012; data from FAO).

The kelp forest is structured like any forest, with different species forming layers or tiers, and large canopy species reaching heights to 45 metres (Steneck et al., 2002). Dominant species differ across regions (see Figure 47.1). Although kelps are not considered to be taxonomically diverse, because most genera are composed of only one species, they support economically important fisheries, such as abalone, lobster, and cod (Steneck et al. 2002). Some host marine mammals, such as sea otters, harbour seals and other pinnipeds (Tegner and Dayton, 2000). Species like the rockfish (*Sebastes* spp.)

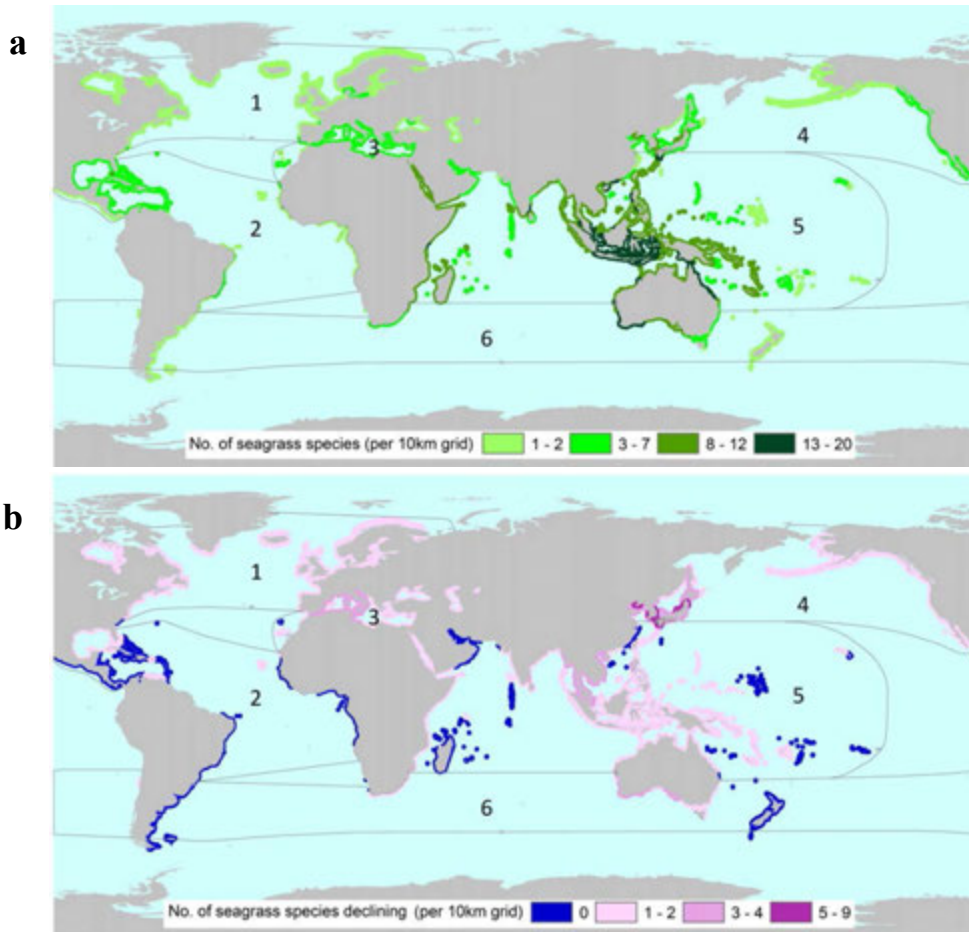

use kelp habitats during some or most of their life histories (Duggins et al., 1990; Eckman et al., 2003).

Seagrasses are a group of about 72 species of flowering plants in six families (Short et al., 2011) adapted to living and reproducing in the marine environment. They are not true grasses but are named for their close morphological resemblance to terrestrial grasses. They form underwater meadows at depths reached primarily by sunlight in the red wavelength part of the spectrum. In addition, they have unusually high light requirements, approaching 25 per cent of incident radiation for some species (Dennison et al., 1993). Tropical seagrasses tend to have deep lower limits as a result of clear water (and hence, greater light penetration) while most temperate seagrasses are limited to considerably shallower depths. Hence, only a few species grow below 20 m of depth, such as some *Halophila* species which have been reported to occur at 40 m (Philipps and Meñez, 1988) and *Posidonia* at 45 m (Pergent et al., 2010). Seagrasses are not presently harvested commercially but they are critical food sources for large herbivores that are specialized for eating seagrass such as manatees, dugongs, green turtles (Philipps and Meñez, 1988) birds, particularly Brant geese (*Branta bernicia*) as they require temperate eelgrass beds as a primary food source (Baldwin and Lovvorn, 1994), and certain commercial fish species such as rabbitfish, and for many other species that feed on the epiphytes and epifauna (Moncreiff and Sullivan, 2001).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Map showing the approximate location of kelp forests and their dominant species. Modified from: Steneck et al., 2002 extracted from http://commons.wikimedia.org/wiki/File:Kelp_forest_distribution_map.png.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Map showing (a) worldwide distribution and species richness of seagrass meadows; and (b) number of species having declining population trends (sensu IUCN) from Short et al. (2011). Numbers on the map refer to Bioregions. 1-Temperate North Atlantic; 2-Tropical Atlantic; 3- Mediterranean; 4-Temperate North Pacific; 5-Tropical Indo-Pacific; 6-Temperate Southern Oceans.

2. Population trends and pressures

The harvest of kelps for food and industry is the major pressure on the kelp population worldwide (Vasquez and Santelices, 1990; Millar, 2007; see also Chapter 14). This has resulted in changes in the kelp community structure and habitat well described by McLaughlin et al. (2006) in Chapter 14, and in more recent studies conducted by Estes

2011, Ling et al., 2015; Rocha et al., 2015; Russell and Connell, 2014; Steneck et al., 2013.

Apart from overexploitation, kelp population and distribution worldwide are reported to be affected by a variety of factors. Connell et al. (2008) reported on a wholesale loss of canopy-forming kelp forests (up to 70 per cent) on the Adelaide metropolitan coast of South Australia where urbanization occurred. Overfishing of high value predators often causes explosions in herbivore populations, such as sea urchins, that feed on kelps, resulting in massive reduction of kelp cover and consequently affecting other trophic levels (see Connell et al., 2011; Moy and Christie, 2012; and also Chapter 14). Steneck et al. (2002) reported this threat to kelp beds to be highest roughly in the 40–60° latitude range in both the northern and southern hemispheres. Other mechanisms of kelp forest decline are mechanical damage from destructive fishing gears and boat propellers, pollution, nutrient availability, diseases and parasites, and climatic changes.

Kelp die-off along the coasts of Europe has been reported (Raybaud et al., 2013; Brodie et al., 2014), e.g. in Norway (Moy and Christie, 2012), as well as off the coast of Australia (Smale and Wernberg, 2013; Wernberg et al., 2013). In addition, changes in the distribution of species have been reported in the polar North Atlantic (Müller et al., 2009), and off the coasts of southern England of the United Kingdom (Brodie et al., 2014; Pereira et al., 2011), South Africa (Bolton et al., 2012) and Australia (Connell et al., 2008; Millar 2007; Russell 2011; Smale and Wernberg, 2013; Wernberg et al., 2011; Wernberg et al., 2013) due to increased seawater temperatures. In 2011, the high biodiversity Indian Ocean region of Western Australia experienced a heat wave, which raised seawater temperatures by 2–4°C, causing a significant decline in the canopy-forming brown macroalgae *Scytothalia* and *Ecklonia radiata*, which are important in stabilizing habitats. *Scytothalia* had a 100-km southward retraction from its northernmost limit (Smale and Wernberg, 2013; Wernberg et al., 2013). A similar pattern of southern retraction by other temperate macroalgae caused by seawater warming is evident along the Pacific Ocean coast of eastern Australia (Wernberg et al., 2011). Kelps are most affected by rising water temperature, because sexual reproduction (gamete formation) in most kelps will not occur above 20°C (Dayton, 1985; Dayton et al., 1999). This has been found to be amplified negatively by synergistic interactions between nutrient enrichment and heavy metals, the presence of competitors, low light and increasing temperature and competition with mat-forming seaweeds (Strain et al., 2014).

Seagrass beds are reported to be among the most threatened ecosystems on earth with an estimated disappearance rate of 110 km² per year since 1980; the rates of decline accelerating from a median of 0.9 per cent per year before 1940 to 7 per cent year⁻¹ since 1990 (Waycott et al. 2009). According to their assessment, 29 per cent of the known areal extent has disappeared since seagrass areas were initially recorded in 1879. For example, in the Baltic Sea, where only one main seagrass species (*Zostera marina*) exists, seagrass meadows have significantly declined (Boström et al. 2014). In terms of species, Short et al. (2011) reported that 22 of 72 species (31 per cent) of the world's total number of species have declining populations, 29 species (40 per cent) have stable

populations, five species (seven per cent) have an increasing population (see Figure 47.2b), and the status of 16 species (22 per cent) is unknown. Two of the species with increasing population (*Halophila stipulacea* and *Zostera japonica*) have been reported to have recently expanded across the Pacific and Atlantic Oceans (Short et al. 2007, Willette and Ambrose 2009). Reported areas of highest decline (80-100 per cent of all species) are in: (a) in China-Korea-Japan region, where the decline is associated with heavy coastal development and extensive coastal reclamation, (b) southeast Asia (one species) due to aquaculture, fisheries and heavy watershed siltation, (c) Australia (three species), and (d) the Mediterranean (four/five species). Declines in Australia and the Mediterranean are primarily attributed to mechanical damage from propellers and ship grounding, degraded water quality, and competition with introduced species such as *Caulerpa* (Williams and Smith 2007). Short et al. (2011, Table 4, p. 1969) rated coastal development as representing the highest threat (93 per cent of the species affected), degraded water quality (53 per cent), mechanical damage (44 per cent), aquaculture (39 per cent), fisheries (38 per cent), excess siltation/sedimentation (36 per cent), competition (7 per cent), and disease (2 per cent).

As for kelps, overfishing of top predators often results in an increase in herbivores, such as sea urchins, that leave barren 'halos' in seagrass beds. Another reported cause of population decline is the "wasting disease" that wiped out the seagrass meadows in the Pacific Northwest and on both sides of the North Atlantic in the 1930s, due to a marine slime mould (*Labyrinthula*) infestation (Rasmussen, 1977); this organism reappeared in New Hampshire and Maine in 1986 (Short et al., 1986). The effects of climate change on seagrasses are just beginning to be studied (Chust et al., 2013; Valle et al., 2014). Of the 72 species, 15 or 24 per cent (Short et al., 2011), are currently classified under the International Union for Conservation of Nature (IUCN) criteria as Threatened (Endangered or Vulnerable) or Near Threatened.

3. Ecological, economic, and social implications

Ecologically, the loss of these two ecosystems will reduce the amount of "blue" carbon stored in submerged marine habitats and thus, increase impacts and changes worldwide on weather patterns, directly putting coastal residents, their livelihoods and food production at risk (see Nelleman et al., 2009; Byrnes, et al., 2011; see also Chapter 6).

Losses of kelp and seagrass beds will affect populations of large marine herbivores, such as manatees, dugongs and green turtles, thus further undermining their already poor conservation status. Short et al. (2011) reported that 115 marine species that live in seagrass beds, including some invertebrates, fishes, sea turtles, and marine mammals, are listed by IUCN as threatened. In addition, reef and mangrove ecosystems biodiversity will be affected by the loss of seagrass habitats since many fish and invertebrate species found in coral reefs and mangroves have been reported to spend their juvenile stages in seagrass beds (Dolar, 1991; Orth, 2006).

Furthermore, the loss of seagrass beds and kelp forests will deprive commercially important fish (such as rabbit fish and cod) and invertebrate species (such as abalone and lobster) of food, habitat and nursery areas, thus undermining their growth and reproductive success and reducing the chances of the stocks either being maintained or being brought back to pre-depletion levels (Orth et al., 2006). This will affect catches of fishers and threaten food security.

Kelp forest losses will reduce the supply of commercially important alginates and fucoidan, thus raising their prices or making them less readily available for new applications (see further Chapter 14). Also, loss of kelp may have an adverse effect on the number of coastal residents whose livelihoods depend on kelp harvesting.

4. Management and conservation responses

Many strategies have been employed in the management of kelps and seagrass meadows. These include: protection through declaration of sanctuaries and protected areas,¹ regulation of harvesting through permitting system for kelps (Leschin-Hoar, 2014), regulation of fishing methods destructive to kelps and seagrasses, such as trawls and seines; transplantation and restoration of seagrass beds (Calumpong and Fonseca, 2001; Fonseca et al., 1998), and systematic monitoring (www.seagrassnet.org).

5. Information and knowledge gaps

The biology and population dynamics of some kelp and seagrass species are still unstudied. Nine of 72 seagrass species are designated by IUCN as Data Deficient due to lack of information about them, while population trends of 16 species remain unknown (Short et al., 2011). Data on relative impacts of anthropogenic factors as well as interactions with climatic changes are lacking (Larkum et al., 2006; Chust et al., 2013; Doney et al., 2009; Duarte, 2002; Grech et al., 2012; Roleda et al., 2012; Valle et al., 2014). Active research is being conducted in the areas of economic valuation of ecosystem services provided by these two ecosystems.

Chapter 48. Mangroves

Contributors: Mona Webber (Convenor), Hilconida Calumpong (Co-Lead Member), Beatrice Ferreira (Co-Lead Member), Elise Granek, Sean Green (Lead Member), Renison Ruwa (Co-Lead Member) Mário Soares

Commentator: James Kairo

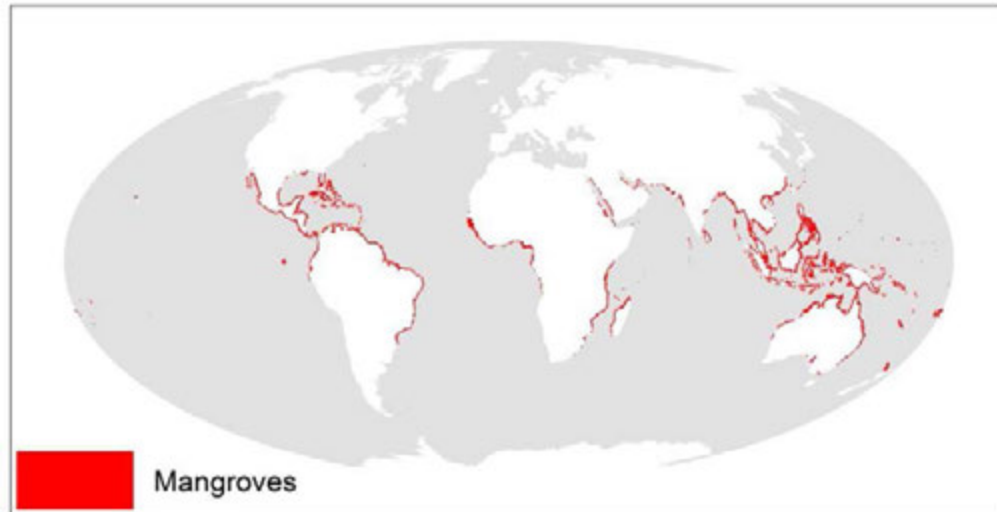

1. Definition and significance

Mangroves dominate the intertidal zone of sheltered (muddy) coastlines of tropical, sub-tropical and warm temperate oceans. The word 'mangrove' is used to refer to both a specific vegetation type and the unique habitat (also called tidal forest, swamp, wetland, or mangal) in which it exists (Tomlinson 1986; Saenger, 2003; Duke et al., 2007; Spalding et al., 2010). Mangrove areas often include salt flats, which are mostly observed in arid regions or areas with well-defined dry seasons, and where the frequency of tidal flooding decreases progressively toward the more landward zones of the forest leading to an accumulation of salts. In such mangrove areas, a continuum of features may be observed, which, as described by Woodroffe et al. (1992), may include: (a) mudflats in the zone below mean sea level; (b) mangrove forests in the zone between mean sea level and the level of higher neap tides; and (c) salt flats in the zone above the level of higher neap tides. These transition zones and their tidal positions vary globally as they are dependent on many factors (e.g. climate, topography and hydrology). Mangrove trees, along with other floral inhabitants of the mangrove area, such as shrubs, ferns and palms, are highly adapted with aerial roots, viviparous seeds and salt exclusion/excretion mechanisms (Tomlinson, 1986; Hogarth, 2007), thus coping with periodic immersion and exposure by the tide, fluctuating salinity, low oxygen concentrations in the water and sediments, and sometimes high temperatures (Hogarth, 2007). Mangroves have been used by coastal inhabitants for centuries with the earliest reports from 10,000 - 20,000 years ago (Allen, 1987; Luther and Greenburg, 2009). Mangroves continue to be of tremendous value to humanity through a range of ecosystem services. Several reviews are dedicated to mangrove forests, addressing their global distribution (area covered and biomass), ecology, biology and value/uses (Dittmar et al., 2006; FAO, 2007; Walters et al., 2008; Ellison, 2008; Costanza et al., 2008; Spalding et al., 2010; Giri et al., 2011; Horwitz et al., 2012; McIvor et al., 2012; Hutchinson et al., 2014).

2. Spatial patterns and inventory

Mangrove distribution correlates with air and sea surface temperatures, such that they extend to $\sim 30^{\circ}\text{N}$, but to 28°S on the Atlantic coast (Soares et al., 2012), and in the Indo-West Pacific (IWP), to $38^{\circ}45'\text{S}$ to Australia and New Zealand (Hogarth, 2007). The latitudinal distribution of mangroves is limited by key climate variables such as aridity and frequency of extreme cold weather events (Osland et al., 2013, Saintilan et al., 2014). The distribution and structural development within areas with suitable temperatures is further limited by rainfall or freshwater availability (Osland et al., 2014; Alongi 2015). The area covered by mangroves (between 137,760 and 152,000 km^2) and the number of countries in which they exist (118 to 124) have been the focus of many studies (FAO, 2007; Alongi, 2008; Spalding et al., 2010; Giri et al., 2011). The accuracy of these ranges is affected by the different methods (with varying spatial resolutions) used for area surveys and the exclusion of some countries with small mangrove stands (FAO, 2007; Giri et al., 2011). However, what is more generally accepted is that mangrove coverage is extremely low, accounting for less than 1 per cent of tropical forests and 0.4 per cent of global forest areas (FAO, 2007; Spalding et al., 2010, Van Lavieren et al., 2012). Mangrove area has declined globally over the last 30 years (1980 – 2010), (Polidoro et al., 2010; Donato et al. 2011) and this decline continues in many regions.

Uncertainty also surrounds the number of mangrove species found globally. Spalding et al. (2010) reported 73 mangrove species (inclusive of hybrids), of which 38 were called 'core species', , also called 'foundation species', indicating those which typify mangroves and dominate in most areas (Ellison et al., 2005, Osland et al., 2014. Polidoro et al. (2010) listed a similar number of species (70), which did not include hybrids, but used the criteria of "anatomical and physiological adaptations to saline, hypoxic soils". Thus their list included both 'true' mangroves and mangrove 'associates', classifications by Tomlinson (1986) and Hogarth (2007). Tomlinson (1986) lists the criteria of 'true or strict' mangroves as: (i) occurring in the mangrove environment and not extending into terrestrial communities; (ii) having a major role in the structure of the community; (iii) possessing morphological specialization that adapts them to their environment; (iv) possessing physiological mechanisms for salt exclusion; and (v) having taxonomic isolation from terrestrial relatives, at least at the generic level.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. The global range of mangroves is demarcated in red (Giri et al., 2011). Used with permission from UNEP-WCMC.

It has been argued that ignoring the distinction between ‘true’ mangroves and mangrove ‘associates’ may lead to cryptic ecological degradation, as the latter may include species, such as *Acrostichum aureum*, which can totally replace mangrove trees in some regions, with an accompanying change in mangrove functionality (Dahdouh-Guebas et al., 2005), but without change in areal extent. This idea is controversial and is made more problematic by the inclusion by some of beach grass and scrub vegetation in the category of ‘mangrove associates’. It is also difficult to resolve the issue of the exact number of mangrove species recognized worldwide due to taxonomic inconsistencies caused by the use (or not) of the most recent phylogenetic listings. Angiosperm phylogeny listings are constantly updated, most recently with the APGIII (2009). Addressing issues with mangrove taxonomy would enhance our ability to track global species extinctions (Polidoro et al., 2010). Furthermore, it would be useful to base species identification on molecular attributes (not just morphological descriptions), which could address many controversies surrounding use of terms like ‘mangrove associates’ or ‘mangrove hybrids’.

Globally, the IWP and the Atlantic, East Pacific (AEP) have different mangrove species groups (Hogarth, 2007; Spalding et al., 2010). The IWP region has over 90 per cent of species and 57 per cent of global area coverage; the AEP has less than 10 per cent of species and 43 per cent of global area coverage. Fifteen countries account for 75 per cent of global mangrove area (Giri et al., 2011) and these countries are distributed across both regions. Indonesia in the IWP accounts for 22.6 per cent of global mangrove area, and Brazil in the AEP has 8.5 per cent (Spalding et al., 2010). Brazil has the largest continuous mangrove forest (6,516 km²), which lies between Maranhão and Pará in northern Brazil. In the IWP, the Sundarbans, located in India and Bangladesh, extend 85 km inland and cover an area of 6,502 km² (Spalding et al., 2010). These regions have no

true mangrove species in common, except for *Rhizophora mangle*/*R. samoensis* (Duke and Allen, 2006). *Acrostichum aureum*, which is classified by some as a mangrove 'associate', is also found in both regions. The genera *Rhizophora* and *Avicennia* are unique in having worldwide distribution (Duke et al., 2002).

3. Rate of loss/changes and major pressures

Despite widespread knowledge of their value, mangroves are being lost globally at a mean rate of 1-2 per cent per year (Duke et al., 2007; FAO, 2007), and rates of loss may be as high as 8 per cent per year in some developing countries (Polidoro et al., 2010). Between 20 and 35 per cent of mangroves have been lost since 1980 (FAO, 2007; Polidoro et al., 2010), which is greater than losses of tropical rain forests or coral reefs (Valiela et al., 2001). Spalding et al. (2010) report losses of over 20 per cent in all regions except Australia over a 25-year period (1980-2005). However, their assessments of loss indicate that the global rate of loss has been declining over the last three decades (1.04 per cent in the 1980s; 0.72 per cent in the 1990s and 0.66 per cent in the five year period up to 2005 (Spalding et al., 2010). This could be an indication of increasing resilience of the remaining mangroves or the result of effective conservation and restoration/rehabilitation efforts.

Unfortunately, in some regions, responses to mangrove loss and mitigation remain inadequate, along with the realization that it is more economical to conserve than to restore mangroves (Ramsar Secretariat, 2001; Gilman et al., 2008; Webber et al., 2014). Particular species of mangroves or specific geographic areas have been identified as being more threatened by extinction than others (Polidoro et al., 2011). Although the primary threats to all mangroves are destruction through conversion of mangrove habitat and over-exploitation of resources, pressures that result in loss of area and ecosystem function vary somewhat across regions (Valiela et al., 2001). Two areas have shown the greatest per cent loss between 1980 and 2005: the Indo-Malay-Philippine Archipelago (IMPA) with 30 per cent reduction, and the Caribbean, with 24-28 per cent reduction in mangrove area (McKee et al., 2007b; Gilman et al., 2008; Polidoro et al., 2010). The major pressure resulting in losses in the IMPA is conversion of mangrove habitat for shrimp aquaculture; while in the Caribbean numerous pressures cause habitat loss, including coastal and urban development, solid waste disposal, extraction of fuel-wood, as well as conversion to aquaculture and agriculture (Polidoro et al., 2010).

Climate change, particularly sea level rise, is considered a threat to mangrove habitat and functionality in all regions (McLeod and Salm, 2006; Gilman et al., 2008; Van Lavieren et al., 2012; Ellison and Zouh, 2012). Mangrove areas most vulnerable to sea level rise are believed to be those of low-relief carbonate islands with a low rate of sediment supply and little available upland space (Schleupner, 2008) as well as those in arid, semi-arid, and dry sub-humid regions (Osland et al., 2014). Mangroves on wet,

macrotidal coastlines (>4 m tidal amplitude) with significant riverine inputs, are believed to be least vulnerable (Ellison and Zouh, 2012). While there are varying opinions on the nature and level effects on mangroves from climate change drivers, it is widely agreed that the vulnerability of mangrove forests is increased by occupation and urbanization of the coastal zone, including the conversion of mangrove area to other land uses (Soares, 2009).

Some of the other effects of climate change (e.g., increased precipitation, temperature and atmospheric CO₂ concentration) may actually increase mangrove productivity (Gilman et al., 2007) and the ability of mangroves to keep pace with sea level rise (Henzel et al. 2006; McKee et al., 2007a; Langley et al., 2009; McKee, 2011; Krauss et al., 2014) because elevated CO₂ increases productivity and biotic controls of soil elevation. Increased temperatures are correlated with mangrove range expansion (Osland et al. 2013), due to the reduction in intensity, duration and frequency of extreme cold-weather events that are expected to support mangrove poleward migration. The genus *Avicenna* has already proliferated at or near their polar limit at the expense of salt marshes (Saintilan et al., 2014). Mangroves may therefore be more resilient to climate change than was previously thought (Alongi, 2007) and certainly the effects will vary greatly depending on local conditions (e.g., geomorphology and shoreline stability). Indeed, the role of mangroves in carbon sequestration and mitigation of climate change effects (Siikamäki et al., 2012) is such that there may be net global economic gains from their protection, especially when all other economic and ecological uses are factored in to the calculation. Mangroves have high rates of atmospheric carbon capture and storage, (Mcleod et al., 2011; Van Lavieren et al., 2012). Their productivity and substantial below- and above-ground biomass, although varying with geomorphology and coastal conditions, can yield sequestration rates of over 174 gCm⁻² yr⁻² (Alongi, 2012), making them prime targets for not just conservation but active reforestation and restoration. Although mangroves account for a small percentage of the earth's forest cover (Donato et al., 2011; Giri et al., 2011) and hence only 1% of global forest sequestration (Alongi, 2012), they account for 14% of carbon sequestration by the global ocean.

4. Implications for services to the marine ecosystem and humanity

Mangroves provide a suite of regulating, supporting, provisioning and cultural ecosystem services from which humanity benefits (MEA, 2005; Haines-Young and Postchin, 2010; Van Lavieren et al., 2012). Supporting and regulating ecosystem services provided by mangroves include: (i) habitat for a wide range of organisms (Nagelkerken et al., 2000; Granek et al. 2009) including juvenile reef fishes that are essential components of coral reef ecosystems and, in many cases, are important food fish in their own right (Robertson and Duke, 1987; Laegdsgaard and Johnson, 1995; Mumby et al., 2004; Manson et al., 2005); (ii) carbon sequestration (Fujimoto, 2004; Lal, 2005; Donato et al. 2011; Alongi, 2012; 2014); (iii) climate regulation (Mcleod et al., 2011); (iv)

shoreline stabilization and coastal protection (Kathiresan and Rajendran, 2005; Wells et al., 2006, 2005; Alongi, 2008; Barbier et al., 2008; Koch et al., 2009), water filtration (Alongi et al., 2003) and pollution regulation (Harbison, 1986; Primavera, 2005; Primavera et al., 2007). Mangroves also provide a suite of provisioning ecosystem services, including: (i) fisheries production (Nagelkerken et al., 2000; Dorenbosch et al., 2004; 2005); (ii) aquaculture production (Minh et al., 2001); (iii) pharmaceutical generation (Goodbody, 2003; Abeysinghe, 2010); (iv) production of timber and fuelwood (the latter being important in the Caribbean and Pacific) (Lugo, 2002; Walters, 2005; Walters et al., 2008). Finally, mangroves provide cultural services that include: (i) recreation and tourism (Bennett and Reynolds, 1992; Thomas et al., 1994; Brohman, 1996); (ii) educational opportunities (Bacon and Alleng, 1992; Field, 1999); (iii) aesthetic and cultural values (e.g., Field, 1999; Ronnback, 1999). The provision of these services is reduced or lost when mangrove habitat is degraded or transformed; this loss of services frequently declines in a non-linear fashion such that beyond a certain threshold (which varies spatially, temporally, and by species), mangroves are no longer able to provide significant coastal protection or fisheries benefits (Barbier et al., 2008; Koch et al., 2009).

Mangrove management is not currently practiced on a global scale. However, there are examples of intensive management of large forests in Asia (Spading et al., 2010). Many such forests are managed for commercial purposes but it would be useful to consider management in light of the tradeoffs among ecosystem services. Because provisioning services are easiest to quantify and assign an economic value, mangroves are frequently managed for one or a few provisioning services at the cost of managing for the full suite of services mangrove ecosystems provide. For example, mangrove ecosystems may be converted to produce aquaculture services; such management can contribute to the decline of other supporting and regulating services, such as pollution regulation and shoreline stabilization. When mangrove management focuses on maximization of one ecosystem service to the detriment of others, some individuals (e.g., aquaculture operators) gain, while others (e.g., coastal residents requiring shoreline protection) often lose. Policies and management of the coastal region that focus on preserving the functional diversity of mangrove ecosystems (multiple services), including the associated salt flats, enhance the possibility of having the highest number of beneficiaries. Whether state management or community-based management will be most effective may be context-dependent and worth consideration (Sudtongkong and Webb, 2008).

5. Conservation responses

The dramatic decline in global mangrove cover (Giri et al., 2011) and the on-going removal of mangrove habitat have led both governmental and non-governmental organizations to take actions to protect mangroves. Worldwide, commercial organizations have exerted, and continue to exert, strong pressures to modify policies

that conserve mangroves (Brazil offers one example among many other countries (Glazer, 2004)), yet progress is being made through legislation, new partnerships between governments and local communities, and the REDD+ programme (Reduced Emissions from Deforestation and forest Degradation) in developing countries. Mangrove conservation measures range from traditional approaches including creation of designated areas protected from clearing and legislation restricting or prohibiting clearing, to conservation, education and restoration projects on local, national, regional, or international scales. These often involve local communities and organizations as stewards of mangrove ecosystems and may allow sustainable harvest within the project areas (Lugo et al. 2014).

5.1 *Conservation through conventions and protected areas*

Multiple international conventions and programs protect mangrove habitats. The Convention on Wetlands of international importance especially as waterfowl habitat¹ (Ramsar convention), an international treaty whereby member countries commit to maintaining the ecological characteristics of their “Wetlands of International Importance”, protects mangrove forests at 278 Ramsar mangrove sites in 68 countries (numbers as of 2014). World Heritage sites, UNESCO-designated sites of cultural and natural heritage of outstanding value to humanity, include 26 Sites that protect mangrove habitat within their boundaries and UNESCO Man and the Biosphere Programme sites, many of which include mangrove habitat.

Establishing terrestrial and marine protected areas, including national parks and marine reserves is often used as a management tool to protect mangrove habitat. Examples of national parks that protect mangroves include Mangroves National Park in the Democratic Republic of Congo; Parc Marin de Moheli, Comoros, Kakadu National Park, Australia; Bastimentos Island National Park, Panama; Kiunga Biosphere Reserve, Kenya; Everglades National Park, United States of America; Sirinat National Park, Thailand; Subterranean National Park, Philippines; among others. Despite these efforts, Giri et al. (2011) report that only 6.9 per cent of the world’s mangroves fall within existing protected areas networks (IUCN I- Category IV in the IUCN Protected areas management categories).

5.2 *Conservation through legislation*

In some countries, states, or regions, mangroves are protected through legislation limiting or prohibiting mangrove clearing. Legislation may be national, such as Brazil’s Federal Forestry Code (Brazil, 2012), which has been interpreted to prohibit the use of any components of mangrove trees or plants. Other legislation exists at more localized scales, , such as The Mangrove Trimming and Preservation Act enacted in 1996 in the

¹ United Nations, *Treaty Series*, vol. 996, No. 14583.

state of Florida, (United States of America), to regulate trimming, disturbance or removal of mangroves in the state.

5.3 Conservation through management, education and restoration projects

The decline in global mangrove cover, combined with the highly recognized ecological and ecosystem services values of mangroves, have given rise to a number of non-governmental organizations engaged in education about and conservation and restoration of mangroves. These include organizations with projects around the world, such as the Mangrove Action Project, Western Indian Ocean (WIO) Mangrove Network, the Mangrove Alliance, and Mangrove Watch, as well as domestic organizations, including Honko, a mangrove conservation and education organization in Madagascar, and the Mangrove Forest Conservation Society of Nigeria, among others. Some countries such as Cuba and Ecuador have invested significant resources and are testing new approaches to mangrove conservation through engagement of local communities in natural resource governance (Gravez et al. 2013; Lugo et al. 2014).

Restoration projects have met with mixed and limited success with many documented efforts resulting in large failure rates in achieving successful mangrove restoration. These failures highlight the importance of considering factors that can doom mangrove restoration including poor site and species selection and failure to utilize advances in the recent science of mangrove restoration (Lewis 2005, Lewis and Brown 2014). For example, the use of biotechnological interventions to produce improved mangrove plantlets (e.g., faster growing plants) could improve the success rate of restoration. It would be useful to have better training at all levels on the concepts and application of mangrove restoration (Lewis and Brown 2014).

5.4 Emerging conservation strategies

The movement to implement “Blue Carbon Solutions” (the carbon sequestered by coastal vegetation, namely mangroves, sea-grasses and salt marsh grasses- McLeod et al., 2011) to reduce atmospheric CO₂ has led to the consideration of tools such as payment for ecosystem services (PES) and REDD+ schemes to improve conservation outcomes for mangroves (Alongi, 2011; Locatelli et al., 2014). Such approaches may provide novel strategies for mangrove conservation in countries that lack sufficient resources for conservation and management.

Although raising financial resources for whole ecosystem conservation has historically been beneficial, new risks arise from this approach in the emerging paradigm of conservation through commodification of ecosystem functions, such as those related to carbon storage (McAfee, 1999; Igoe and Brockington, 2007; Kosoy and Corbera, 2010; Corbera, 2012). The emerging commodification paradigm, challenges an old ethical and inter-generational argument that nature needs to be managed and protected for the survival of ecosystems and species; it would be useful for mangrove conservation and

restoration efforts to consider the risks of trading preservation of ecosystems for their intrinsic value and the emerging paradigm of prioritizing some elements of nature that are economically useful, at the potential cost of other values that are less economically valuable or are useful only to certain groups. In this process of assigning a monetary value to an ecosystem service, cultural and social values, such as those held by communities that live near and depend directly on the forests and that possess a deep cultural connection with the system, may be strongly devalued. In this way, power asymmetries in the valuation process may further fuel socio-environmental conflicts involving those interested in carbon and the communities interested in the maintenance of the diversity of functions and services, including cultural values, as recently described by Beymer-Farris and Bassett (2012) for the mangrove forests in Tanzania. However, Ecuador's Mangrove Ecosystem Concessions program provides an example of how government agencies can engage local stakeholders by simultaneously providing resource rights and bestowing management responsibilities on those users (Gravez et al. 2013).

As indicated above, although threatened by sea level rise, mangroves have the potential to keep pace with rising sea level if conditions allow them to modify their surface elevation or to adapt through landward migration (Cahoon and Hensel, 2006; Alongi, 2008; Gilman et al., 2008; Soares, 2009, McKee, 2011). It would be useful for mangrove conservation and management efforts to take into account external sediment supply, benthic mats, tree density and root structure, storm impacts, and hydrological factors such as river levels, groundwater inputs and rainfall (McIvor et al., 2012), as well as consider the maintenance and restoration of system resilience (e.g., its capacity to adapt and migrate landward).

6. Capacity building gaps

Capacity building is the process by which individuals, organizations, institutions and societies develop abilities (individually and collectively) to perform functions, solve problems and set and achieve objectives (UNDP, 1997). Capacity building is therefore facilitated through the provision of technical support activities, including coaching, training, specific technical assistance, and resource networking.

Local, regional, national and international initiatives for capacity building in mangrove conservation and sustainable use as a management tool to protect mangrove habitat are widespread around the world, including those led by the United Nations University (UNU), UNESCO's Man and the Biosphere Programme (MAB), Mangrove Action Project (MAP), Mangrove Alliance, Mangroves for the Future (MFF), Mangrove Watch, WIO Mangrove Network and The International Society for Mangrove Ecosystems (ISME). Examples of initiatives specific to different regions include, International Union for the Conservation of Nature - IUCN's Pacific mangrove initiative (PMI), the United Nations Environment Programme's Integrated Coastal Management, with special emphasis on

the sustainable management of mangrove forests in Guatemala, Honduras and Nicaragua, the Satoyama Initiative in Benin, and Mangrove Action Project (MPA)-Asia in Thailand, among others.

Although several initiatives are concerned with capacity building, capacity building will be more effective if it is integrated and follows a set of basic assumptions about training and knowledge base. Increased effectiveness can be achieved through: (i) training related to conservation and sustainable use of mangrove forests and their resources; (ii) raising awareness among as many stakeholders as possible (especially policy-makers); (iii) political empowerment of stakeholders; (iv) cooperation within and between governments, institutions, organizations and agencies that are engaged in these activities; (v) identification and development of innovative proposals; (vi) maintaining systems for the reduction and resolution of conflicts; (viii) ensuring that programmes include measures to address threats from climate change and human activities.

Specific ideas for capacity building include: use of standardized methods for mangrove species distribution and area surveys (Manson et al., 2012) and development of capacity in the use of base-maps on digital terrain models. These would display areas where mangroves are mostly at risk from submersion due to sea level rise. Capacity to conduct surveys and geographical information systems (GIS) mapping in all regions would be useful, along with the development of capacity for “climate-smart conservation” (Hansen et al., 2010), which would involve strategies for promoting mangrove adaptation to sea level rise. It would be useful for nations to develop the capacity to better identify and evaluate potential barriers for landward migration in response to sea level rise and have more accurate information regarding the location of landward migration corridors as well as improved strategies for ensuring that these migration corridors are present in the future. It would also be useful to know specifically how other drivers of change (e.g., urbanization, other coastal land uses) may affect the potential for landward migration of mangroves in response to sea level rise.

7. Gaps in scientific knowledge

Comprehensive and comparable data on mangrove species and area distribution from all countries with mangroves would be useful. Lack of information on the current status of mangrove species for the documentation of the various types of mangrove losses in each region has been identified as an important knowledge gap. This could improve a range of conservation and management strategies, along with predictions of habitat loss and species extinctions (Polidoro et al., 2010; Spalding et al., 2010). Other areas of considerations in filling the gaps are: determination of the average changes in the emission or sequestration of greenhouse gases from mangrove forests as a result of human activity; accurate and consistent valuation of mangrove goods and services, and vulnerability mapping.

Chapter 49. Salt Marshes

Contributors: J. S. Weis, K. E. A. Segarra, Patricio Bernal (Lead member)

1. Inventory

Salt marshes are intertidal, coastal ecosystems that are regularly flooded with salt or brackish water and dominated by salt-tolerant grasses, herbs, and low shrubs. They occur in middle and high latitudes worldwide and are largely replaced by mangroves in the subtropics and tropics (see Chapter 48). They are found on every continent except Antarctica (Figure 1). In areas of relatively little sediment delivery, salt marshes are highly organic and often peat-based. In contrast, salt marshes in areas of high sediment delivery, such as sheltered estuaries (see Chapter 44), are often well-developed with inorganic substrates.

2. Features of trends in extent

Salt marshes are among the most productive temperate ecosystems in the world. Contemporary salt marshes developed within the last 8,000 years in low-energy, coastal locations in response to rising sea levels (Milliman and Emery, 1968; Redfield 1967). Their ecology and global importance has been described in classic literature such as Chapman (1960), Ranwell (1972), Doody (2008) and Adam (1990). The physical stresses of salinity and flooding generate zones of salt-tolerant emergent vegetation, including such genera as *Carex*, *Spartina*, *Juncus*, *Salicornia*, *Halimone*, *Puccinellia*, and *Phragmites*. Marsh grasses contribute to the accumulation of organic matter and trapping of inorganic sediment. Salt marsh sustainability is mainly controlled by the relationship between marsh vertical accretion (due to sediment accretion, peat accumulation, belowground decomposition, subsidence) and sea level rise (frequency and duration of tidal flooding - Gagliano et al., 1981; Cahoon and Reed, 1995; Hatton et al., 1983; DeLaune et al., 1983). Other facts that impact their development and structure are tidal, wave and current action, erosion, freshwater influx, nutrient supply, and topography (Mitsch and Gosselink, 1993). Less than 50 per cent of the world's original wetlands remain (Mitsch and Gosselink, 1993) and current loss is estimated at 1-2 per cent per year (Bridgham et al., 2006) making wetlands one of the fastest disappearing ecosystems worldwide. Salt marsh loss coincides with a general historical degradation of estuarine ecosystems (Lotze et al., 2006). Just upstream from salt marshes are brackish marshes with lower salinity regimes, which are also highly productive, subject to the same stresses, and of equally great conservation concern.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

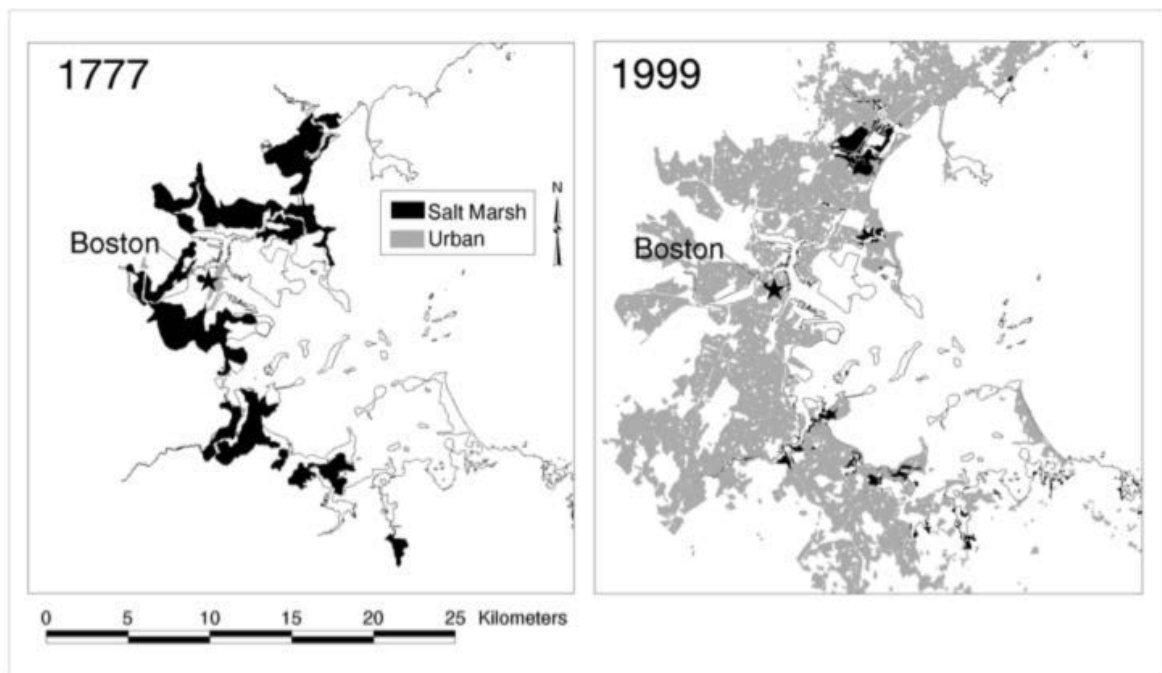

Figure 1. Salt Marshes (in orange). Source: UNEP-WCMC, 2015.

3. Major pressures linked to the trends

Over 60 per cent of the globe's population lives on or near the coast, and coastal populations are increasing at twice the average rate (UNEP, 2006a; Nicholls et al., 1999), making coastlines highly vulnerable to human activities. Salt and brackish marshes, formerly viewed as useless wastelands, were filled in for urban or agricultural development. Reclamation of land for agriculture by converting marshland to upland was historically a common practice. Coastal cities worldwide have expanded onto former salt marshes and used marshes for waste disposal sites. Airoidi and Beck (2007) estimate that countries in Europe have lost over 50 per cent of their salt marsh and seagrass areas to coastal development. Estuarine pollution from organic, inorganic, and toxic substances is a worldwide problem. Marshes have been drained, diked, ditched, grazed and harvested. They have been sprayed for mosquito control, and have been invaded by a range of non-native species that have altered their ecology. As one example, Massachusetts, United States of America, has lost 41 per cent of its salt marshes since the 1770s, with a loss of 81 per cent in Boston (Bromberg and Bertness, 2005; Figure 2).

Key threats to salt marshes are land reclamation, coastal development, dredging, sea-level rise (SLR), hydromodification, alteration of processes (e.g. sediment delivery, freshwater input) and eutrophication. Accelerated SLR is the largest climate-related threat to salt marshes. The Intergovernmental Panel on Climate Change predicts with

medium confidence a SLR of 0.26-0.98 m by 2100 (Church et al., 2013). Nicholls et al. (1999) predict that 1 m SLR will eliminate 46 per cent of the world's coastal wetlands. Some salt marshes can keep pace with SLR, but others, especially those cut off from their sediment delivery via levees and seawalls cannot (Day et al., 1995). Nutrient pollution, which destabilizes below-ground biomass and increase decomposition, is likely to exacerbate salt marsh loss due to SLR (Turner et al., 2009; Deegan et al., 2012). Subsidence, which contributes to relative SLR in some regions, is an additional stressor. The impact of SLR will depend upon accretion and subsidence rates and other processes that influence the marshes ability to grow vertically and/or to migrate inland. "Coastal squeeze" describes the limitation of marshes to extend landward due to boundaries (Pethick, 2001) such as paved areas, seawalls, and bulkheads from coastal development.

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 2. Salt marsh loss in Boston, Massachusetts, United States, between 1777 and 1999 (Bromberg and Bertness, 2005).

4. Implications for services to ecosystems and humanity

Salt marshes play a large role in the aquatic food web and the cycling of nutrients in coastal waters. They serve as critical habitat for various life stages of coastal fisheries that account for a large percentage of the world's fish catch (UNEP, 2006b). Over half of the commercial fish species of the East coast of the United States utilize salt marshes at some time of their lives (Beck et al., 2001). In addition to providing habitat for juvenile fishes, crabs, and shrimps, marshes support populations of some small forage fishes,

which come up on the marsh surface at high tide to feed on invertebrates (Shenker and Dean, 1979; Zimmerman et al., 2000). Many migratory shore birds and ducks use salt marshes as stopovers during migrations and some birds winter in the marsh. Wading birds, such as egrets and herons, feed in salt marshes during the summer. Continued marsh loss could therefore dramatically alter estuarine food webs.

SLR is increasing the vulnerability of coastal populations to coastal erosion, flooding, and storms (IPCC, 2007). Salt marshes serve as natural barriers to these coastal hazards. They serve as shoreline stabilizers because they attenuate wave energy and help prevent erosion (Costanza et al., 2008, Gedan et al., 2011, Moller et al., 2014; see Chapter 26). They also slow and store floodwaters, reducing storm impacts on coastal communities (Cobell et al., 2013). While wetlands do not provide complete protection against coastal hazards, even small salt marshes can provide significant shoreline protection (Gedan et al., 2011). Their preservation and restoration may significantly decrease the economic impact and human losses of extreme events such as hurricanes and tsunamis (Gedan et al., 2011).

Salt marshes remove sediment, nutrients, microbes, and contaminants from runoff and riverine discharge (Gedan et al., 2009), acting as sponges absorbing much of the runoff after major storms and reducing flooding. They sequester pollutants from the water that drains down from the land, protecting nearby estuarine areas and coastal waters from harmful effects. They play a major role in the global carbon cycle and represent a major portion of the terrestrial biological carbon pool. They store excess carbon in their sediments, preventing it from re-entering the Earth's atmosphere and contributing to global warming. Salt marshes are thus an important component of the world's "blue carbon" (McLeod et al., 2011) and currently are being incorporated into global carbon markets. Chmura et al. (2003) estimated that tidal wetlands sequester 10 times the amount of carbon sequestered by peatlands. Salt marshes also provide excellent tourism, education, and recreation services, as well as research opportunities.

It is clear that salt marshes provide enormous benefits to society in the form of "ecosystem services". In this regard, coastal wetlands (which include salt marshes) are among the highest valued coastal ecosystems (Costanza et al., 2014). The serious reduction in salt marsh area reduces their capacity to provide these critical ecosystem services (Gedan et al., 2009; Craft et al., 2009).

5. Conservation Responses and Conclusions

As society has become aware of the environmental and economic values of salt marshes, efforts have commenced to slow their loss and even to restore degraded marshes. These are mostly local initiatives. Concerned individuals and dedicated groups both within and outside government are mobilizing to stop and even reverse the trends. Restoration may involve reconnecting areas to the estuary by excavating channels that had filled in, relying on the tidal flow to allow the marsh to restore itself. Other

restoration projects involve removing unwanted invasive vegetation, changing the marsh elevation, and planting the desired species. Monitoring of such projects would need to be done for years after restoration to see if methods are successful or need modification, and to learn how much time it takes before the restored marsh acquires the biodiversity and ecosystem function of a natural marsh (Craft et al., 1999; Zedler and Lindig-Cisneros, 2000; Rozas et al., 2005). Restoration of coastal marshes is now also included among strategies for climate adaptation planning (Arkema et al., 2013, Barbier, 2014) and mitigating greenhouse gas emissions (Olander et al., 2012), highlighting the multiple benefits that may be derived from salt marsh conservation.

Some international legal instruments and policy frameworks, such as the Convention on Wetlands of International Importance, especially as Waterfowl Habitat¹ (Ramsar Convention), the Convention on Biological Diversity², and Agenda 21 adopted by the 1992 United Nations Conference on Environment and Development, promote the conservation and wise use of wetlands and support economic valuation to support conservation. Economic valuation can be used to evaluate and compare development uses vis-à-vis conservation uses. Although some estimates have been made (Costanza et al., 1997, Minello et al., 2012), placing a monetary amount on these services is difficult and controversial. Many benefits are non-monetary, which makes comparisons difficult in decision-making (Barbier et al., 2011). Improving the assessment and valuation of salt marsh services could assist current conservation methods.

These important vegetated, intertidal habitats and the ecosystem services they provide, such as fisheries, sequestration of pollutants, and protection from flooding and storm surge, are under threat due to natural and anthropogenic forces. Efforts would be needed worldwide to preserve the remaining salt marshes and restore some of those that have been destroyed or impaired.

Chapter 50. Sargasso Sea

Contributors: D. Freestone (convenor), H.S.J. Roe, (principal author), Lorna Inniss (Co-Lead Member), D. d'A. Laffoley, K. Morrison, Jake Rice (Lead Member and Editor of Part VI), and T. Trott

1. Inventory

The Sargasso Sea is a fundamentally important area of the open ocean within the North Atlantic Sub-Tropical Gyre, bounded on all sides by clockwise rotating currents (Laffoley et al., 2011).

The boundaries and names shown and the designations used on this map do not imply official endorsement or acceptance by the United Nations.

Figure 1. Source: <https://chm.cbd.int/database/record?documentID=200098>.

Named after its iconic *Sargassum* seaweed, the Sargasso Sea's importance derives from the interdependent mix of its physical oceanography, its ecosystems, and its role in global-scale ocean and earth system processes. It is a place of legend, with a distinct pelagic ecosystem based upon two species of floating *Sargassum*, the world's only macroalgae that spend their whole life-cycle in the water column (holopelagic), which hosts a rich and diverse community, including ten endemic species. *Sargassum* mats are home to >145 invertebrate species and >127 species of fish; the mats act as important spawning, nursery and feeding areas for fish, turtles and seabirds. In deeper water, the Sargasso Sea is the only known spawning area for both the European and American Eels (*Anguilla anguilla*, *A. rostrata*). Porbeagle Sharks (*Lamna nasus*) migrate from Canada to the Sargasso Sea, where they are suspected of pupping in deep water; several other shark species undertake similar migrations and may be using the area as nursery areas. Thirty species of whales

occur in the Sargasso Sea and Humpback Whales (*Megaptera novaeangliae*) make regular migrations through the area en route from the Caribbean to the northern North Atlantic. Many other species, including several tuna spp., turtles, rays and swordfish, migrate through the Sargasso Sea: it is truly an ecological crossroads in the Atlantic Ocean, linking its own distinct ecosystem with Africa, the Americas, the Caribbean and Europe. Seamounts and volcanic banks rise up from the sea floor and host diverse and fragile communities of invertebrates and fish, including endemic species and others that are currently undescribed. Many of the species that occur in the Sargasso Sea are endangered or threatened and are listed on the IUCN Red List, and/or in the appendices of the Convention on International Trade in Endangered Species of Wild Fauna and Flora¹ (CITES) or in the annexes of the 1990 Caribbean Protocol Concerning Specially Protected Areas and Wildlife² to the Convention for the Protection and Development of the Marine Environment in the Wider Caribbean Region³ (SPAW) (see Laffoley et al., 2011). Laffoley et al. (2011) present a summary of the scientific case for the protection and management of the Sargasso Sea which maps the area and describes its status, its importance and the threats to its continued existence.

2. Trends

The Sargasso Sea is a globally important area for ocean research and monitoring, hosting the world's longest continuous open-ocean time series of ocean measurements (i.e., Hydrostation S and the associated Bermuda Atlantic Time-series Study (BATS) arrays) which make it possible to observe trends and changes over time (Figure 1). These include significant warming of the surface ocean, an increase in salinity in the upper 300 m, and a decrease in surface pH (Figure 2). These data are critical for our understanding of global processes and the role of the Sargasso Sea in these processes. The annual net primary production in the Sargasso Sea is surprisingly high, due largely to picoplankton, and as such the area plays a key role in the sequestration of carbon in the global ocean. Changes are occurring in both phytoplankton biomass and primary production in the northern Sargasso Sea, and the possible connections between such changes and any resulting effects in the ecosystem with global climate change is an active area of research (Laffoley et al., 2011).

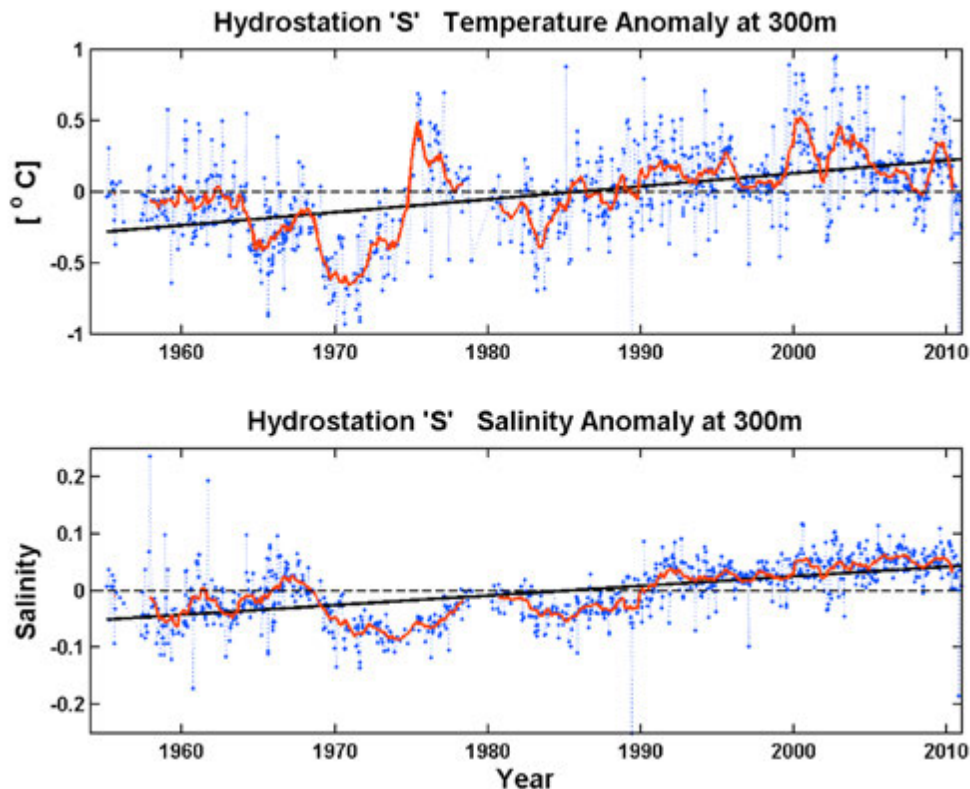

Figure 2. Time-series plots of temperature and salinity anomaly at 300 m (STMW) for Hydrostation ‘S’ 1955-2011. Anomaly computed by subtracting the long-term mean for this depth. Red line shows a one-year central running mean and the observed data are shown as blue dots. Long-term trends for temperature and salinity are determined as $0.009 \text{ }^{\circ}\text{C year}^{-1}$ ($p > 0.01$) and 0.002 year^{-1} ($p < 0.01$), respectively. Source: Lomas, et al (2011).

3. Pressures

In addition to climate change, the Sargasso Sea is threatened by other human activities. Overfishing and the side effects of fishing (e.g., by-catch, lost gear) affect pelagic species e.g., blue marlin and western bluefin tuna are estimated to be overexploited; benthic trawling on seamounts has severely reduced stocks of alfonso and destroyed benthic communities. Ship-related impacts may include pollution from discharges, introduction of alien species through ballast water, underwater noise, collisions with whales, and physical damage to *Sargassum* mats (Laffoley et al., 2011, 2015 in prep). Surface pollutants, including plastics, accumulate in the central Sargasso Sea, because the encircling currents trap water for periods of 50 years or more. Plastics and debris concentrate in *Sargassum* mats and in frontal zones where animals also concentrate to feed. Other potential pressures include the continuing commercial interest in harvesting *Sargassum*, the impact of submarine cables, and seabed mining (see Laffoley et al., 2011).

4. Ecosystem Services

The economic importance of the Sargasso Sea is derived from direct exploitation, via fisheries and tourism, and indirect benefits from ecosystem services. Pendleton et al. (2015), Sumaila et al. (2013), and Laffoley et al. (2011) provide varying estimates of the values of pelagic fisheries, eel fisheries in Canada, Europe and the United States of America that depend upon eels that spawn in the Sargasso Sea, recreational fishing, reef-associated tourism, and whale and turtle watching. Sumaila et al. (2013) also provide estimates of the indirect-use values for the Sargasso Sea associated with the open ocean, coral reefs, coastal systems and coastal wetlands. The accuracy of many of these estimates is questionable, but all values are large and emphasize the economic importance of the Sargasso Sea and the need to conserve and restore the ecosystem.

Although *Sargassum* generally is considered a unique feature of the Sargasso Sea, in reality mats of *Sargassum* have occasionally been seen in many places in the mid-North Atlantic and even to wash up on island beaches from time to time. However, in 2011 large mats of *Sargassum* appeared on beaches in many Caribbean areas, the coast of Brazil and even the coast of West Africa. Similar mass strandings occurred in 2014 and are continuing in 2015. The source of the *Sargassum* is not the Sargasso Sea but the north equatorial recirculation region (NERR) south of the Sargasso Sea between the north equatorial current and the equator. The causes of these mass blooms and strandings are uncertain but may include nutrient availability from the Amazon and Orinoco Rivers, warmer surface temperatures and changes in circulation associated with climate change (Franks et al 2011-2015 in <http://www.usm.edu/gcrl/sargassum/index.php>, Johnson et al 2012, Smetacek and Zingone 2013). The impact of these mass strandings on local economies is severe, affecting tourism and recreation, as the mats are difficult to dispose of and are unsightly and smelly as they decompose (see chapter 27).

5. Conservation Responses

The importance of the Sargasso Sea is now recognised internationally. In October 2012, the Sargasso Sea was accepted by the Conference of Parties to the Convention on Biological Diversity as meeting the criteria for an ecologically and biologically significant area (EBSA) (see <https://chm.cbd.int/database/record?documentID=200098>). Also in 2012, the Bermuda Government declared the Bermuda exclusive economic zone (EEZ) to be a marine mammal sanctuary and signed a Sister Sanctuary Agreement with the United States' Stellwagen Bank National Marine Sanctuary (Bermuda/United States MOA, 2012). The overall importance of *Sargassum* as a habitat for pelagic fish has been recognised by the United States (National Marine Fisheries Service 2003) and by the International Commission for the Conservation of Atlantic Tunas (ICCAT) (see Laffoley et al., 2011), and in 2012 ICCAT agreed to examine the ecological importance of the Sargasso Sea for tuna and tuna-like species (ICCAT Resolution 12-

12). The Northwest Atlantic Fisheries Organization (NAFO) is also considering proposals to protect further the seamounts in the Sargasso Sea section of their regulatory area. On 11 March 2014, five Governments (the Azores, Bermuda, Monaco, the United Kingdom of Great Britain and Northern Ireland and the United States) signed the Hamilton Declaration on Collaboration for the Conservation of the Sargasso Sea, committing themselves to collaborate on conservation in this area, and set up a Sargasso Sea Commission to facilitate this work (Freestone and Morrison, 2014). The Sargasso Sea Commission is working with the Convention on the Conservation of Migratory Species of Wild Animals—(CMS 1979) regarding conservation of the European eel (*Anguilla anguilla*) and in November 2014 the CMS Conference of the Parties added it to Appendix II as a “having a conservation status which would significantly benefit from international co-operation ...”. (UNEP/CMS 2014). It is also in discussions with the International Maritime Organization (IMO) and the Bermudian shipping authorities concerning ways of mitigating shipping risks and it has recently opened a dialogue with the cable-laying industry to develop best environmental practices (SSC Newsletter, 2015). The United Nations General Assembly has taken note of the efforts of the Sargasso Sea Alliance, led by the Government of Bermuda, to raise awareness of the ecological significance of the Sargasso Sea (Resolutions 67/78, 68/70 and 69/245).

Chapter 51. Biological Communities on Seamounts and Other Submarine Features Potentially Threatened by Disturbance

Contributors: J. Anthony Koslow, Peter Auster, Odd Aksel Bergstad, J. Murray Roberts, Alex Rogers, Michael Vecchione, Peter Harris, Jake Rice, Patricio Bernal (Co-Lead members)

1. Physical, chemical, and ecological characteristics

1.1 *Seamounts*

Seamounts are predominantly submerged volcanoes, mostly extinct, rising hundreds to thousands of metres above the surrounding seafloor. Some also arise through tectonic uplift. The conventional geological definition includes only features greater than 1000 m in height, with the term “knoll” often used to refer to features 100 – 1000 m in height (Yesson et al., 2011). However, seamounts and knolls do not appear to differ much ecologically, and human activity, such as fishing, focuses on both. We therefore include here all such features with heights > 100 m.

Only 6.5 per cent of the deep seafloor has been mapped, so the global number of seamounts must be estimated, usually from a combination of satellite altimetry and multibeam data as well as extrapolation based on size-frequency relationships of seamounts for smaller features. Estimates have varied widely as a result of differences in methodologies as well as changes in the resolution of data. Yesson et al. (2011) identified 33,452 seamount and guyot features > 1000 m in height and 138,412 knolls (100 – 1000 m), whereas Harris et al. (2014) identified 10,234 seamount and guyot features, based on a stricter definition that restricted seamounts to conical forms. Estimates of total abundance range to >100,000 seamounts and to 25 million for features > 100 m in height (Smith 1991; Wessel et al., 2010). At least half are in the Pacific, with progressively fewer in the Atlantic, Indian, Southern, and Arctic Oceans. Identified seamounts cover approximately 4.7 per cent of the ocean floor, with identified knolls covering an additional 16.3 per cent, in total an area approximately the size of Africa and Asia combined, about three-fold larger than all continental shelf areas in the world’s oceans (Etnoyer et al., 2010; Yesson et al., 2011).

Seamounts can influence local ocean circulation, amplifying and rectifying flows, including tidal currents, particularly near seamount summits, enhancing vertical mixing, and creating retention cells known as Taylor columns or cones over some seamounts. These effects depend on many factors, including the size (height and diameter) of the seamount relative to the water depth, its latitude, and the character of the flow around the seamount (White et al., 2007).

Where flows are sufficiently vigorous, they provide a sufficient flow of organic matter to support suspension feeding organisms, such as corals and sponges. Such currents also winnow away the sediment, providing hard substrate necessary for most suspension feeders to settle and attach. Depending on depth and current regime, the seamount benthos may be dominated by an invertebrate fauna typical of the surrounding sediment-covered slope or abyssal plain or a more specialized fauna adapted to high-energy, hard substrate-dominated deep-water environments.

Seamounts that rise to mesopelagic depths or shallower ($\leq \sim 1000$ m) often have an associated fish fauna adapted to feed on the elevated flux of micronekton and zooplankton, as well as vertical migrators intercepted by the seamounts during their downward diel migrations (Koslow, 1997; Clark et al., 2010b). More than 70 fish taxa have been commercially exploited around seamounts (Rogers 1994), although the number of species that are found only or principally on seamounts is closer to 13 – 16 (Clark et al., 2007, Watson et al., 2007). Some, such as pelagic armorhead, orange roughy, alfonsino, oreos, and others, are found in substantial aggregations around seamounts, making them efficient targets for fisheries.

Many seamounts are rugged, topographically complex environments, difficult to sample with conventional gear, such as nets. Wilson and Kaufmann's (1987) review reported only 596 invertebrate species recorded from seamounts to that date, with 72 per cent of these species from studies of only five seamounts. Seamount studies ramped up in the 1990s, initially based on concerns about the impacts of deep-water trawl fishing for orange roughy and oreos on seamounts. Based on more intensive and comprehensive sampling, Richer de Forges et al. (2000) reported more than 850 species associated with cold-water coral and sponge communities on seamounts in the Tasman and Coral Seas of the Southwest Pacific, with potentially high levels of endemism. Seamount studies have since been carried out worldwide, significantly stimulated by collaborative efforts such as the Census of Marine Life CenSeam project. A recent review found 1,222 fish species recorded from 184 seamounts (Kvile et al., 2013), approximately doubling the number of seamounts investigated and the number of species recorded from this environment since Wilson and Kaufmann's (1987) review. Overall species richness on seamounts cannot yet be estimated, with < 1 per cent of seamounts sampled and only a few percent of those intensively studied. The number of species recorded from seamounts continues to increase roughly in proportion to sampling effort, with no evidence yet of levelling off (Richer de Forges et al., 2000; Stocks and Hart, 2007; Castelin et al., 2011). Due to the limited sampling, the proportion of species endemic to this habitat is controversial. Some seamounts appear to represent biodiversity hotspots (Samadi et al., 2006; McClain et al., 2009), but variability is extensive, and other studies conclude that species richness is comparable on seamounts and nearby slope habitats (Consalvey et al., 2010; Howell et al., 2010; Castelin et al., 2011).

Biogeographically, seamount faunas generally appear related to the faunas of adjacent basins or continental slopes (Wilson et al., 1985; Parin et al., 1997; Mironov et al., 2006). For seamount fishes, which have been the best studied group of organisms, biogeographical patterns appear to follow the distribution of dominant water masses,

such as Antarctic Intermediate Water and North Atlantic Deep Water (Koslow et al., 1994; Clark et al., 2010a and b). Whereas the dominant genera and families of deep-sea demersal and midwater fishes tend to have global distributions, the dominant fish species on seamounts in different ocean basins are often from entirely different genera, families, and even orders. This indicates that seamount-associated fishes in different ocean basins were reproductively isolated and evolved independently. Their similar morphologies and adaptation to the seamount environment is a striking example of convergent evolution (Koslow, 1996).

Seamounts are the source of significant ecosystem services. In addition to their biodiversity, seamounts often host substantial aggregations of fishes, which have been subject to commercial fisheries. These include species for which seamounts are their primary environment as well as a larger number for which seamounts account for a smaller proportion of their global catch. Annual landings of primary seamount species have fluctuated around 100,000 t since the 1990s, dominated by oreosomatids and orange roughy (Clark et al., 2007; Watson et al., 2007).

Seamounts, along with ridges and plateaus, host ferromanganese crusts that contain cobalt, nickel, and rare earth elements used in high-tech industries and which may have commercial potential, although they are not presently exploited (Hein et al., 2010).

1.2 *Ridges and plateaus*

One of the more prominent features of the global ocean is the 75,000 km long network of mid-ocean ridges, defined as “the linked major mid-oceanic mountain systems of global extent” (IHO, 2008), essentially created at plate boundary spreading zones, where new crust is being formed as tectonic plates move apart. The most prominent is the Mid-Atlantic Ridge that runs down the middle of the Atlantic from the Arctic to the Southern Ocean, where it connects to the more complex system of ridges in the Indian Ocean and the Pacific Ocean. Mid-ocean ridges in the South Pacific comprise 1.87 million km², the largest area in a single ocean (Harris et al., 2014). Ridge features may include islands (e.g. the Azores archipelago (Portugal) and Iceland) and seamounts. Harris et al (2014) distinguish mid-ocean ridges from other ridge features that are isolated, elongate, narrow, steep-sided and at least 1000 m in height. These may overlap with plateaus and seamounts. Hydrothermal vents, which are treated in Chapter 45, are often associated with mid-ocean spreading ridges (Baker and German, 2013).

Studies of ridge features have increased significantly in recent years. Notable among them are studies of the Nazca and Sala y Gomez ridges in the Southeast Pacific (e.g. Parin et al., 1997; Pakhorukov, 2005), the MAR-ECO and ECOMAR studies of the Mid-Atlantic Ridge in the North Atlantic (e.g. special issues of Deep-Sea Research II 55 (1). (2008). and 98 Part B (2013), Bergstad et al., 2008; Vecchione et al., 2010; Priede et al., 2013), as well as studies of the Mid-Atlantic Ridge in the South Atlantic (Perez et al., 2012).

Ridges typically contain seamounts and sedimented slopes; not surprisingly, similarities in the abundance, diversity, and species composition of ridge habitats are found with both seamounts and continental margins (Priede et al., 2013). Priede et al. (2013) also noted that a deep ridge system, such as the mid-Atlantic Ridge (mostly deeper than 1000 m), does not appear to significantly enhance oceanic productivity, although it greatly extends the area of available lower bathyal habitat.

Plateaus and banks are geologically not as well defined or as extensive as ridges, but comprise relatively less steep and comparatively shallow features separated from continental shelves by deep channels. In terms of shape and size, plateaus are wider and much larger than seamounts. Harris et al. (2014) mapped 184 plateaus in the world's oceans, comprising 5.1 per cent of the ocean area. They figure most prominently in the Indian and South Pacific Oceans; Challenger, Campbell, and Kerguelen Plateaus and Chatham Rise around New Zealand are the largest such features. Despite being mostly deeper than 200 m, plateaus may be recognised as oceanic shallows or banks because they are disconnected from continental shelves and coastal waters.

Plateaus share many diversity characteristics and faunas with nearby continental shelves and slopes, and ecosystem services from plateaus are also similar to those of shelves. Most plateaus are nearer to land and are considered richer in terms of harvestable resources than oceanic ridges. Both shallow and deep fisheries on plateaus and banks are therefore relatively substantial. Indeed, most of the deep-water fisheries being conducted at present are either on upper continental slopes or on slopes of plateaus (Koslow et al., 2000; Watson et al., 2007). In addition to fishing, mining and hydrocarbon exploration/extraction are emerging activities on plateaus and ridges (Rona 2003, Ramirez-Llodra et al., 2011).

1.3 Submarine canyons

Submarine canyons are defined as “steep-walled sinuous valleys with V-shaped cross sections, axes sloping outward as continuously as river-cut land canyons, and relief comparable to even the largest land canyons” (Shephard, 1963). Recent estimates of their number and extent vary widely, depending on mapping criteria, from 448 to about 9500 canyons in the global ocean with a total extent ranging from 25,000 to 389,505 km (Ramirez-Llodra et al., 2010; De Leo et al., 2010; Harris and Whiteway, 2011; Harris et al., 2014). Because they cut across the continental shelf and slope, canyons are the deep-sea environment closest to human occupancy, making them convenient to study but also rendering them vulnerable to human stressors.

Canyons have been recognized as distinct topographic features for approximately 150 years (Dana 1863 in Ramirez-Llodra et al., 2010). However, their rough topography compared with nearby slope areas has made studying them difficult. Technological developments of the past few decades, along with international programmes like the Census of Marine Life Continental Margins, or Continental Margin Ecosystems (COMARGE) programme (Menot et al., 2010), and the long-term programme of the

Monterey Bay Aquarium Research Institute (MBARI) in Monterey Canyon have led to a renaissance in canyon studies (e.g. Huvenne and Davies, 2013). Whereas most canyons globally have received little or no scientific attention from any discipline, some individual canyons (e.g., Monterey – western North America, “The Gully” – eastern North America, Kaikura – New Zealand, Nazaré – western Europe) have been studied by multidisciplinary teams.

With steep walls and depositional environments along their axes, canyons are geologically complex, including hard substrates and soft sediments, depending on the slope of the walls. Because canyons cut into the ancient sediments of continental margins, many have hydrocarbon seeps and their associated specialized chemosynthetic communities. They also exhibit complex hydrography, intersecting and diverting along-slope and along-shelf currents. The steep bottom topography can intensify these flows by topographic channelling and constriction. Density-driven flows result in episodic cascading down-canyon, transporting shallow waters into the deep sea along with associated material. The intensified currents can result in higher physical disturbance of the benthos relative to nearby slope areas.

Canyons concentrate both biogenic and anthropogenic material along their deep axes and can transport these materials either onto the shelf or into the deep abyssal environment, depending on local flow conditions. Such material includes organic matter produced in the overlying photic zone, as well as pollutants and other anthropogenic material, either inadvertently discharged or deliberately disposed of. The concentration of sinking surface productivity enriches benthic communities along the canyon axes and can result in high biomass. Flow may similarly enhance recruitment of early-life-history stages of both sessile and mobile fauna by local topographic concentration of eggs and/or larvae in particular areas (Vetter et al., 2010).

The hard substrates and particulate transport in canyons can support abundant, diverse sessile suspension-feeding communities (hard and soft corals, sponges) and associated fauna, whereas areas of sediment accumulation support communities of deposit feeders, scavengers and their predators (De Leo et al., 2010). Canyons are also hotspots of pelagic activity, supporting feeding concentrations of air-breathing marine vertebrates (mammals, birds, turtles), including many protected species. Canyons are also targeted by longline, trap and trawl fisheries. Some of these fisheries can damage or destroy both hard- and soft-substrate benthic communities, which may include very long-lived and slow-growing species. As with other bathyal habitats, canyons will be affected by climate change because of changes in circulation, stratification, primary productivity, expansion of oxygen-minimum zones (OMZs), and acidification. Canyons may also serve as conduits to the deep sea for pollution (including trash) or sediment mobilized by mining or bottom trawling (Ramirez-Llodra et al., 2011).

1.4 Trenches

Trenches are defined as “long, narrow, characteristically very deep and asymmetrical depressions(s) of the seafloor, with relatively steep sides” (IHO, 2008). In addition to featuring steep terrain with typically hard substrates, often narrow terraces and the deepest ocean depths, the trenches have flat floors with accumulated fine sediments. Trenches are formed as oceanic plates collide with continental plates; the heavier oceanic plates are subducted, creating a trench. Trenches are generally narrow (<40 km wide), V-shaped in cross-section and are found near and parallel to island-arc systems and continental land masses (Jamieson et al., 2010). High current velocities (10-32 cm/sec) have been recorded near the bottom in trenches, as have collapsed walls with massive sediment slides and inferred turbidity currents (Ramirez-Llodra et al., 2010). These processes are responsible for the accumulation of sediments and organic matter in the axes of the trenches, similar to what occurs in canyons.

Harris et al. (2014) mapped 56 trenches in the world ocean. Trenches comprise a total area of about 2 million km², less than 1 per cent of the total ocean area. About 80 per cent of all trenches, by area, are found in the North and South Pacific Oceans. The seafloor of most trenches is at hadal depths (>6000 m) but some trenches, such as the Hellenic Trench in the Mediterranean, are shallower (Ramirez-Llodra et al., 2010).

Trenches are probably the most poorly-known deep-sea habitat, because of the cost and difficulty of sampling at such depths. The first biological samples from the trench environment were obtained during the 1948 Swedish *Albatross* Expedition, which was soon followed by the Danish *Galathea* and Soviet *Vityaz* Expeditions, which sampled several trench environments. Bruun (1956) first defined the hadal zone (depths > 6000 m) as distinct from the abyss, based on a marked transition in species composition, presumably because of the need to adapt to increased pressure. Hadal depths are also below the carbonate and opal compensation depths. Some animal groups with carbonate or siliceous skeletons are therefore excluded (non-holothurian echinoderms and non-actinarian Cnidaria) or are characterized by decreased skeletal strength compared to their shallower relatives (gastropods and bivalves). As a result of the discontinuities between trenches and apparent difficulties of dispersion, high levels of endemism exist both within the hadal environment as a whole (56 per cent as estimated by Belyaev (1989)) and within individual trench systems at the species level (Vinogradova, 1997; Blankenship-Williams and Levin, 2009). The hadal environment is often considered to have low biodiversity, but Blankenship-Williams and Levin (2009) note that trenches contain diverse habitats (e.g. cold seeps and hydrothermal vents, steep walls) that have been particularly poorly sampled.

A few broad generalities can summarize what little is known about trench fauna. Foraminifera are common even at the very deepest extremes. Patterns of metazoan diversity vary among communities based on substrate and food sources: fine sediments on ledges and the trench axis support infauna, such as macrofaunal polychaetes and meiofaunal nematodes, as well as deposit feeding epifauna dominated by holothurians; hard substrates of the walls are characterized by non-calcified sessile fauna like

anemones and their mobile benthic associates (e.g., amphipods); communities near hydrothermal vents and cold seeps are dominated by metazoans dependent on symbiotic chemosynthetic microbes. An assemblage of mobile scavengers is dominated by amphipods, some remarkably large (Jamieson et al., 2013), and fishes such as liparids and macrourids (Jamieson et al., 2009; Fujii et al., 2010).

Because of their extreme depth, trenches have not been subject to commercial activity, such as fishing, mining, or energy extraction. However, they have been subject to dumping, such as of pharmaceuticals in the Puerto Rico trench (Ramirez-Llodra et al., 2011).

2. Documented anthropogenic impacts on the deep ocean including their history (as appropriate) on a regional basis.

2.1 Fishing

A few deep-water artisanal hook and line fisheries around islands and seamounts maintained steady landings with few environmental impacts for decades to centuries (e.g. oilfish in the South Pacific and black scabbardfish around Madeira (Koslow 2007; Silva and Pinho, 2007). Modern large-scale fisheries on seamounts, ridges, and other features with abrupt topographies were initiated after World War II, fostered by technological developments and distant-water industrial fishing. Gillnets, longlines, and both pelagic and bottom trawls are the primary gears (Gianni, 2004; Clark et al., 2007; Bensch et al., 2009). Bottom trawls have had greatest impact, affecting both targeted and non-targeted species including associated benthic communities (Koslow et al., 2001; Clark and Koslow, 2007; Clark and Rowden, 2009). These fisheries have occurred in all oceans except the Arctic.

The first Pacific seamount-associated fisheries were for pelagic species, such as albacore, that aggregated over seamounts in the North Pacific. From 1967 to 1989, a demersal seamount trawl fishery targeting aggregations of pelagic armorhead on the Emperor Seamount chain landed about 800,000 tons of armorhead along with about 80,000 t of alfonsino (Clark et al., 2007). These stocks were depleted and have still not recovered (NPFC, 2014).

Two species of red coral (*Corallium* spp.) were also depleted sequentially from the Emperor seamounts by a tangle-net fishery between 1965 and 1990 (Clark and Koslow 2007; Koslow, 2007).

Since the mid-1970s, trawl fisheries expanded to seamounts and plateaus in the South Pacific, predominantly for orange roughy and oreos, but also for alfonsino, black cardinalfish, and other species (Clark et al., 2007). A series of these stocks underwent boom-and-bust cycles, mostly in the space of 5 – 10 years and many have not recovered (Clark et al., 2007). Both pelagic and demersal fisheries also occurred on seamounts and ridges in the southeast Pacific, the East Pacific Rise, the Nazca and Sala-y-Gomez Ridges,

and the Chilean Rise. Catches were not large nor were they sustainable (Clark et al., 2007).

In the Southern Ocean, seamounts were fished for nototheniids between 1974 and 1991. In the 1990s, the ridges, plateaus, and seamounts around remote sub-Antarctic islands came to be heavily fished for Patagonian toothfish with trawls and longlines. Initially much illegal, unreported and unregulated (IUU) fishing occurred but has declined significantly since 1996 (Agnew et al., 2009).

Large-scale industrial deep-water fisheries in the North Atlantic date to the development of redfish fisheries in the 1950s using both midwater and demersal trawls over the mid-Atlantic Ridge and on some plateaus. Redfish catches peaked at almost 400,000 tons in the 1950s and have declined considerably but several continue to support some harvest (Koslow et al., 2000; ICES, 2013). Fisheries for roundnose grenadier and Greenland halibut first developed on the upper continental slopes of the Northwest Atlantic in the late 1960s, peaking at over 80,000 tons in 1971 and then rapidly declined and moved to the mid-Atlantic Ridge and Rockall-Hatton Bank in 1973 (Troyanovsky and Lisovsky, 1995; Clark et al., 2007). Several other species have been exploited from the seamounts and ridges of the North Atlantic, including alfonsino, orange roughy, deep-water sharks, ling, blue ling, black cardinalfish, tusk, deep-water crabs and shrimp, and others (Clark et al., 2007; Bensch et al., 2009). From the latter half of the 1990s onwards, declines in catch per unit effort (CPUE) indicated that most targeted North Atlantic deep-water fisheries were overfished and some severely depleted (Koslow et al., 2000; Large et al., 2003; Large and Bergstad, 2005; Devine et al., 2006; Bensch et al., 2009; Rogers and Gianni, 2010).

In 2003, the International Council for the Exploration of the Sea (ICES) deemed that most deep-water stocks “were probably outside safe biological limits.” In the last decade fisheries on seamounts and ridges in the Atlantic have declined significantly due to a combination of declining fish populations, significantly altered socioeconomic conditions, and increased regulation by national governments and Regional Fisheries Management Organizations (RFMOs).

Retrospective analyses based on research vessel surveys also indicated that several target and non-target species in the Northwest Atlantic had declined by >90 per cent between 1978 and 1994 (Devine et al., 2006). Many fishery restrictions were implemented and recent survey data indicate biomass levels have stabilized in most surveyed areas (Neat and Burns, 2010). However, recovery for deep-water species with low productive capacity will probably take decades or longer (Baker et al. 2009; Neat and Burns, 2010).

Seamount fisheries in the South Atlantic have been undertaken at a smaller scale than in the North Atlantic. However, there have been seamount fisheries targeting orange roughy, alfonsino, cardinal fish, armorhead, Patagonian toothfish and deep-sea red crab, and some continue to the present day (Rogers and Gianni, 2010; www.seafo.org).

Exploratory trawl fishing on seamounts in the Indian Ocean began in the 1970s targeting shallow-water redbait and rubyfish on the Southwest Indian Ocean Ridge, the Mozambique Ridge and the Madagascar Ridge (Romanov, 2003; Clark et al., 2007) and continued into the mid-1980s. In the late 1990s, trawlers working on the Southwest Indian Ocean Ridge targeted deep-water species, such as orange roughy, black cardinalfish, pelagic armorhead, oreosomatids and alfonsino (Clark et al., 2007), but the fishery rapidly collapsed (Gianni, 2004). Fishing has shifted to the many ridges, seamounts and plateaus targeting a variety of species of deep-sea fish and crustaceans (Clark et al., 2007; Bensch et al., 2009; SWIOFC, 2009).

Overall, deep-water demersal fisheries over the continental slope, ridges, seamounts, and plateaus have landed between 800,000 and 1,000,000 t per annum from the mid-1960s to 1990s (Koslow et al., 2000) and annual landings on the order of 100,000 t since about 1990 (Clark et al., 2007; Watson et al., 2007). The vast majority of seamount-associated demersal fisheries have proven unsustainable, undergoing a boom-and-bust cycle that has usually lasted less than 10 years. Many of the stocks have vulnerable life histories and are small, remote, and difficult to monitor and manage effectively (Koslow, 2007). However, during the last 10-15 years many States and intergovernmental organizations have recognized the need for enhanced management action to protect vulnerable marine species and habitats to facilitate the recovery of depleted stocks.

2.2 *Fishing impacts on seamount benthic habitats*

Energetic seamount habitats that support substantial fish aggregations also often host diverse, productive benthic habitats dominated by corals, sponges, and associated fauna (Rogers et al., 2007; Samadi et al., 2007). Demersal trawling on seamounts generally removes benthic habitat as by-catch along with the target species or destroys it converting reefs and other structure-forming species to rubble. See chapter 11 for more details on the nature of these impacts. The United Nations General Assembly has been looking into the impact of bottom trawling (e.g. resolutions 61/105, 64/72 and 66/68),¹ although no global assessment has been carried out on the extent of benthic impacts. The documented widespread extent of deep-water trawl fisheries has led to pervasive concern for the conservation of fragile benthic habitats. Moreover, on seamounts where trawling has been discontinued, little regeneration is observed even after five to 10 years (Althaus et al., 2009; Williams et al., 2010) and recovery may require centuries to millennia. Because of the close correspondence between the productivity and diversity of seamount benthic habitats, there are likely few diverse seamount habitats within the vertical range of bottom-trawl fishing that remain pristine, and many have been denuded, their coral and sponge habitats reduced to rubble.

Examples of measures taken by regional fisheries management organizations and arrangements (RFMO/As) to avoid or mitigate fishing impacts on benthic habitats include:

¹ Reports of the Secretary-General on this issue have been issued as A/61/154, A/64/305 and A/66/307.

- Both the North Atlantic Fisheries Organization (NAFO) and North East Atlantic Fisheries Commission (NEAFC) in the North Atlantic set quotas for deep-sea stocks based on scientific assessments, and have identified and closed to fishing areas that meet the Food and Agricultural Organization of the United Nations (FAO) criteria for vulnerable marine ecosystems.
- The Southeast Atlantic Fisheries Organization (SEAFO) has closed selected ridge sections and seamounts to fishing, restricted fisheries to certain subareas, and introduced catch quotas (TACs) for the fishes and deep-water crab targeted on seamounts.
- States which participated in the negotiations for the establishment of the North Pacific Fisheries Commission have established interim measures for fisheries management and are working towards stock assessments to modify fishing effort to sustainable levels (Rogers & Gianni, 2010; NPFC, 2014).
- The South Pacific Regional Fisheries Management Organization has called for interim conservation measures, including freezing of the fishing footprint and catch based on historical patterns of fishing which have been implemented by some States (SPRFMO, 2014). Efforts are underway by some member States to map vulnerable marine ecosystems and to assess fisheries data in order to estimate stock biomass and sustainable levels of exploitation (SPRFMO, 2014).
- The Commission for the Conservation of Antarctic Marine Living Resources banned bottom trawl fishing; has restricted remaining fishing opportunities to previously licensed fishing areas or exploratory areas and species specific catch quotas (or total allowable catches (TACs)); and is implementing spatial measures to prevent adverse impacts on bottom-associated vulnerable marine communities.
- The Southern Indian Ocean Deep-sea Fishers Association declared a number of seamounts in the Southern Indian Ocean as voluntary closed areas to fishing although levels of compliance amongst non-members are unknown. With the ratification in 2012 of the Southern Indian Ocean Fisheries Agreement (SIOFA), a new regional fisheries management arrangement for the region is expected to lead to better data collection and regulation of seamount fisheries.

While these actions are progressive, their effectiveness in ensuring the sustainability of exploitation of populations or recovery of vulnerable species and communities is not yet clear (see sections 4-6 below). Indeed whether full closures will result in recovery of vulnerable communities to a former state or a shift to some less desirable community state remains uncertain given current knowledge.

2.3 *Pollution*

The deep sea was once considered as being too remote from the point sources of industrial pollution for pollution to be a significant issue. However, key contaminants of

concern, including mercury and many halogenated hydrocarbons (e.g., DDT, PCBs, and many other pesticides, herbicides, and industrial chemicals) are volatile and enter the ocean predominantly through the atmosphere. These are discussed in Chapter 20. As noted there, concentrations of persistent organic pollutants in deep-sea-dwelling fish may be an order of magnitude higher than in surface-dwelling fish, and the deep sea has been described as one of the ultimate global sinks for such contaminants. Butyl tin, an antifoulant that causes imposex in mollusks, is reported in elevated concentrations in deep-sea organisms, particularly in the vicinity of shipping lanes (Takahashi et al., 1997), and microplastics are now widely reported in deep-sea sediments (van Cauwenberghe et al., 2013).

2.4 *Climate change, including acidification and deoxygenation*

Predicted shoaling in the depth of calcium carbonate saturation horizons will expose large areas of seamount, ridge, plateau and slope habitat to undersaturated waters (Guinotte et al., 2006). Recent reviews and meta-analyses of the impacts of ocean acidification summarize the present understanding of its effects on cold-water corals (e.g. Wicks and Roberts, 2012), although to date no experimental studies have focused on seamount species. Studies have highlighted the ability of live cold-water corals to maintain calcification at reduced pH (Maier et al., 2009; Form and Riebesell 2012) but synergistic effects with increasing temperature and longer-term effects on resource allocation and reproduction remain unknown. It is becoming clear that deep-water ecosystems may experience more natural variability in carbonate chemistry than was previously supposed (Findlay et al., 2013; Findlay et al., 2014) and that calcareous species can persist even in under-saturated conditions on Tasmanian seamounts (Thresher et al., 2011). However, undersaturated waters will be corrosive to dead coral skeletons that provide structural habitat for many other species, a factor potentially explaining the limited scleractinian coral reef framework on the Hebrides Terrace Seamount (Henry et al., 2014). Increased carbon dioxide and reduced pH may also directly affect marine organisms' physiology, growth, and behaviour (Wicks and Roberts, 2012). It is thus necessary to understand their ecosystem-level impacts, such as the effects of acidification on bioerosion of deep-water corals (Wisshak et al., 2012).

Global climate models predict that oxygen concentrations will decline in the deep ocean due to decreased ventilation (a warmer ocean will be a more stratified ocean) and decreased oxygen solubility at warmer temperatures (Sarmiento et al., 1998; Matear and Hirst, 2003; Shaffer et al., 2009). Over the past 20 years, oxygen concentrations have declined in regions around the North Pacific Ocean and the tropical Indian, Atlantic and Pacific Oceans which have pronounced OMZs, with concomitant horizontal and vertical expansion of these OMZs (Whitney et al. 2007, Bograd et al., 2008; Stramma et al., 2008; Keeling et al., 2010). Benthic communities are dramatically affected where OMZs impinge on seamounts, ridges or continental margins, with greatly reduced biomass and biodiversity (Wishner et al., 1990; Levin 2003; Stramma et al., 2010). Deoxygenation may also affect deepwater benthic organisms indirectly through habitat

loss and declining food availability. Midwater fishes, the primary food of many deepwater squid and fish species, including orange roughy, declined ~60 per cent during recent periods of low-oxygen availability in the California Current (Koslow et al., 2011). Palaeoceanographic studies have pointed to the significance of perturbations in oxygen concentration in controlling deep coral occurrence in the Eastern Mediterranean (Fink et al. 2012) and on seamounts (Thiagarajan et al., 2013). Most major marine mass extinction events in the geological past are associated with anoxia and acidification (Harnik et al., 2012).

2.5 *Mining*

There is the possibility of future mining of cobalt-rich ferromanganese crusts on the bare volcanic rock of seamounts, ridges and plateaus found particularly on seamounts within the exclusive economic zones of island States in the western equatorial Pacific (Rona, 2003; see Chapter 23). Significant differences have been found in the communities inhabiting cobalt-crust-hosting seamounts in the northern Pacific and seamounts outside of the cobalt-rich zone (Schlacher et al., 2013). These differences are not related to species richness but more to the relative abundance of species and community composition in the cobalt-crust rich areas versus non-cobalt rich areas. A high level of heterogeneity amongst the seamounts in terms of their biological communities within the region was also found. Thus, although it is suggested that mining operations will severely affect a small percentage of available seamount area (Hein et al., 2010), predicting the impacts of such activities will be complicated and precautionary spatial management of mining activities based on scientific information will be required.

2.6 *Dumping*

Although in the past dumping has been a significant issue in the deep sea (Thiel, 2003), it has not been a major issue for most of the habitats treated here, except trenches. Pharmaceutical dumping was permitted in the Puerto Rico Trench from 1973-78, with some 378,000 tons dumped. Impact was noted on the microbial community and invertebrates, and the dumping was halted in early 1980s (reviewed in Ramirez-Llodra et al., 2010). Dumping of radioactive waste in trenches was banned in the 1990s (see Chapter 24).

3. Social and economic considerations, including capacity-building needs.

To date, deep-water fisheries comprise the primary documented direct contribution of seamounts, ridges, canyons, and plateaus to human social and economic wellbeing. Estimating this contribution is challenging, and it is certain that other ecosystem

services are provided by these ecosystems that have not been specifically identified or in any way valued.

Deep-water fisheries exploiting resources associated with seamounts, ridges, and plateaus are a relatively minor component of global fisheries, comprising about 1 per cent of total annual landings (Koslow et al., 2000; Gianni, 2004; Clark et al., 2007; Watson et al., 2007; Bensch et al., 2009; Sumaila et al., 2010). High-seas bottom-trawl fisheries are carried out predominantly by a few developed countries of Asia, Oceania and Europe: Australia, Denmark (Faroe Islands), Estonia, France, Iceland, Japan, Latvia, Lithuania, New Zealand, Republic of Korea, Russian Federation, Spain and Ukraine (Gianni 2004; Sumaila et al., 2010). These fisheries account for about 2 per cent of the total landings and about 3 per cent of the landed value for these countries' fisheries. Total subsidies (fuel and non-fuel) for the high-seas bottom-trawl fisheries are estimated to be about 25 per cent of their value and substantially more than their net profit (Sumaila et al., 2010). Gianni (2004) estimated that high-seas bottom trawling occupied the equivalent of 100-200 vessels full time out of a total of 3.1 million fishing vessels worldwide.

Deep-water trawling affects the sedentary species on the continental shelf of countries, which can extend beyond 200 nautical miles. Many of these are developing countries which may need capacity-building in this regard (Gianni 2004). Fisheries associated with seamounts and other submarine topographic features are exceptionally difficult to manage sustainably. Capacity-building is desirable in the areas of stock assessment and sustainable management where such fisheries occur around developing States. This may require investment in international infrastructure (e.g. fisheries research vessels) that is often unavailable to developing States as well as investment at a national level (e.g. fisheries research laboratories and scientists, fisheries ministries). An example of the former is the Nansen Programme that has operated around the Africa Coast and in the Indian Ocean for several decades.

If mining of seamounts proceeds, multi-sectoral management will be needed, in particular the need to balance mining and fishery interests with those of conservation. Within areas under national jurisdiction, the agencies that manage mineral resources generally have no authority to manage the exploitation of living marine resources. The same is true of the International Seabed Authority with regard to the "Area".

4. Management and conservation of the habitat and its resources.

Several scientific reviews of deep-water fisheries over seamounts, ridges, and other abrupt topographies in deep waters have called attention to serious deficiencies in their management and conservation (Koslow et al., 2000; Koslow, 2007 (Chapter 10); Clark et al., 2007; Clark 2009; Rogers and Gianni 2010; Norse et al., 2012). Key contributing factors include the life-history characteristics of many exploited and bycatch species: extreme longevity, late maturity, slow growth, and infrequent recruitment events.

These characteristics lead to low productivity and high vulnerability to over-exploitation. Low productivity in itself promotes unsustainable harvest practices based on economic incentives to liquidate a relatively unprofitable resource (Clark, 1973). In addition, many of the stocks are small and aggregated predominantly over isolated features, such as seamounts, making the populations highly vulnerable to serial depletion. The fisheries are carried out predominantly with bottom trawls, which are severely destructive to the fishes' associated benthic habitats, which are often dominated by structure-forming taxa such as corals and sponges.

Deep-sea fisheries within the EEZs of coastal States are in a varied state including depleted, overfished and sustainably fished at the present time (e.g. ICES, 2014). Low-productivity deep-sea species have tended to fall into the former two categories. Management of deep-water fisheries on the high seas, where many of the stocks occur, is more complicated and difficult. To address this situation, the United Nations General Assembly adopted resolutions 61/105, 64/72 and 66/68 in 2006, 2009 and 2011, respectively, calling on RFMOs and States to manage high-seas deep-water fisheries sustainably through the application of the precautionary approach to fisheries management, and in 2008 the FAO Guidelines for the management of deep-sea fisheries on the high seas were adopted (FAO, 2009; Norse et al., 2012). These resolutions of the General Assembly recommended that impact assessments be carried out prior to the development of new fisheries and steps taken, such as setting aside reserves, or eliminating damaging forms of fishing from sensitive areas, to ensure the conservation of vulnerable habitat. This approach should be adopted prior to mining development as well.

Because of deep-water fishing impacts on sensitive benthic habitats, many States and RFMOs have set aside portions of such habitats as marine reserves or bottom-fishing closures in the Atlantic and North and South Pacific Oceans (e.g. NAFO, NEAFC and SEAFO; Clark and Dunn, 2012). In general, many of the areas that were protected or are planned to be protected through area-based management tools by States and by RFMOs are located in areas remote from where commercial activities occur or are expected to fail to protect those species, communities and habitats most threatened (Devillers et al., 2014). Given the difficulties of surveying deep-water habitats, predictive habitat models may prove useful to identify areas that might be designated for protective measures to meet conservation goals (Taranto et al., 2012; Yesson et al., 2012) as recently put forward in SPRFMO (SPRFMO, 2014).

However, Rogers and Gianni (2010) have provided examples of inadequate implementation of the FAO Guidelines. The need to review the efficacy of conservation measures has been underlined (e.g., the details of move-on rules: Auster et al., 2011). In 2013 and 2014 several RFMOs revised their relevant management measures. Reports on actions taken by States and RFMOs in response to United Nations General Assembly resolutions 64/72 and 66/68 are due to be reviewed by the General Assembly in 2016. We believe this is likely to be the case for many deep-water marine reserves, although this issue has not been specifically addressed for the deep sea.

5. Integrated assessment of the status of the habitat. Cross-cutting and emergent conclusions.

The development of deep-water fisheries, particularly those carried out across wide areas with bottom trawls over seamounts, ridges, canyons and plateaus at upper bathyal depths, have been one of the most transformative human impacts affecting such areas of the global ocean in the latter half of the twentieth century (Ramirez-Llodra et al., 2011). Impacts appear to have been greatest on shallow seamounts, because the depth, biological and physical conditions (e.g. accelerated current flows) support fish resources that can easily be targeted. However, a continuum of physical conditions and biological communities is found on these types of features. All of these communities have been subject to deep-water fisheries and their impacts.

The vast majority of deep-water fisheries have been carried out unsustainably, or at least without satisfactory assessments of impacts and sustainability. This has led to the serial depletion of dozens of stocks from about a dozen species commercially harvested from these habitats. Severe impacts have been reported for by-catch species, including other fishes and benthic invertebrates from the diverse coral and sponge communities found on these communities. The extent of benthic impacts has been described for local fishing grounds but has not been assessed globally; however, if the impacts of these regional studies are generalized, we can extrapolate that fishing, and in particular deep-water trawling, has caused severe, widespread, long-term destruction of these environments globally. The time scale for recovery of deep-water reef habitats is unknown but has been estimated to be on the order of centuries to millennia. Although progress has been made toward sustainable management and conservation of fish stocks and associated diverse, vulnerable benthic communities, numerous studies show that progress to date has not been adequate, with fisheries often closed or limited only after severe depletion has already occurred.

Extractive industries, such as mining and oil and gas development, are generally required to carry out baseline monitoring and assess their environmental impacts prior to development. The General Assembly has called upon States to strengthen the procedures for carrying out assessments on the impacts of bottom fishing activities on vulnerable marine ecosystems and to make the assessments publicly available; not all are currently available. Deep-water fishing has until recently been permitted to proceed in areas of highly diverse and vulnerable ecosystems without consideration of environmental impacts (despite the known, highly destructive impacts of these activities). There is an urgent need, even at this late date, for baseline monitoring of seamount habitats in regions of ongoing and potential fishing activity, and in areas set aside for protection. It is critical that relevant scientific expertise is engaged to develop representative networks of marine protected areas, which may then require the development of conservation measures, such as banning of destructive fishing methods. Reviews of existing conservation measures could address whether conservation and

management objectives are met. Devillers et al. (2014) consider that high-seas MPAs must address conservation needs and not be merely designated in areas remote from commercial interests.

The impacts of pollution and climate change, including deoxygenation and acidification, remain poorly understood but are potentially severe. There is an urgent need for research to examine how these factors may potentially influence deep-water benthic communities.

Mining of cobalt-rich ferromanganese crusts from these habitats has been mooted but remains uncertain. Mining would remove all benthic organisms where crust is removed and potentially affect a larger area through sediment mobilization. The environmental impact of mining operations would need to be considered carefully, considering the impacts on regional fisheries and benthic communities, and consideration given to setting aside areas for conservation.

6. Gaps in scientific knowledge.

Since 2000, scientific interest in the ecology of seamounts, ridges, and other sensitive submarine benthic habitats has burgeoned. The development of deep-water fisheries and the need to understand and manage these fisheries and their environmental impacts stimulated this interest, with support from international programmes like the Census of Marine Life. However, these habitats are vast, as well as difficult and expensive to study and the research to date has been largely exploratory. Even after more than a decade of scientific activity, it is apparent that these habitats still remain relatively poorly known. Only a few hundred of the $10^5 - 10^7$ seamounts have been sampled, and the rate of discovery of new species still has not levelled off.

Predictive habitat models have recently been developed to indicate where such habitats are likely to occur, but no one has attempted to assess their present status or the global impact of deep-water trawling, and it is doubtful that the data exist to do so. These models remain largely untested; it is urgently necessary to ground-truth them. Furthermore, knowledge of deep pelagic ecosystems is especially poor (Webb et al., 2010) and the ecological interactions between the geological features considered here and the overlying water column comprise a substantial gap.

Deep-sea ecosystems associated with seamounts, ridges, and other topographic features are now and will increasingly be subjected to multiple stressors from habitat disturbance, pollutants, climate change, acidification and deoxygenation. Studies to date on these impacts have been limited and considered in isolation. The scientific understanding of how these stressors may interact to affect marine ecosystems remains particularly poorly developed. For example, the widespread destruction of deep-water benthic communities due to trawling has presumably reduced their ecological and evolutionary resilience as a result of reduced reproductive potential and loss of genetic

diversity and ecological connectivity. The synergistic influence of these factors is unknown at present.

Although it is heartening that some seamounts, ridges and other sensitive marine habitats are being protected by fishing closures, Marine Protected Areas and other actions, little scientific understanding of the efficacy of actions implemented to date and few studies to assess this exist. The connectivity between these habitats remains largely unknown, as are the factors that influence colonization, species succession, resilience and variability. Comparative studies of seamount, canyon, and continental margin habitats seem to indicate that many species are shared (but see Richer de Forges et al., 2000); however, community structure differs markedly and the factors influencing such differences remain unknown (McClain et al., 2009). Our starting point in attempting to understand and manage these habitats is, to paraphrase Socrates, that we know almost nothing.

Chapter 52. Synthesis of Part VI: Marine Biological Diversity and Habitats

Group of Experts: Jake Rice

1. Biodiversity itself

Biodiversity has natural patterns globally, at all levels from phytoplankton to top predators, including fish, marine reptiles, seabirds, and marine mammals. Main factors that underlie these patterns include depth and proximity to coastline, latitude, habitat complexity and primary productivity, temperature and substrate (Chapter 34). These patterns occur on many scales from meters to full ocean basins; the mosaic structure of seafloor benthic biodiversity is often particularly strong. Some types of species are particularly widespread and/or have specialized life history characteristics, making them even more vulnerable to threats and pressures than most other species. They receive special attention in both characterizing the factors that determine their patterns of distribution and in assessing their trends and the associated pressures.

Chapter 35 highlights that although many such patterns are well documented, the ocean's diversity of species, communities and habitats is far from completely sampled. As research continues, new species, new patterns of distribution, and new relationships between components of biodiversity and natural and anthropogenic drivers are being discovered. The incompleteness of our knowledge of biodiversity and the factors that affect it means that decision-making about potential impacts will be subject to high uncertainty, and the application of precaution is appropriate. Nevertheless, as documented below, a central message from Part VI is that detrimental trends in biodiversity on many scales can be at least mitigated, and sometimes eliminated, even when knowledge is incomplete, if the available knowledge is enough to use in choosing appropriate measures and the capacity for implementation of the measures is available.

1.1 *Biodiversity hotspots*

Although nearly all parts of the ocean support marine life, biodiversity hotspots exist where the number of species and the abundance and/or concentration of biota are consistently high relative to adjacent areas. Some are sub-regional, like the coral triangle in the Pacific (Chapter 36D.2.3) and coral reefs in the Caribbean (Chapter 43), cold-water corals in the Mediterranean Sea (Chapter 36A) the deep seas (Chapter 36F) and the Sargasso Sea (Chapter 51). Some are more local and associated with specific physical conditions, such as biodiversity-rich habitat types. This Assessment has several chapters on these types of special habitats, such as hydrothermal vents (Chapter 45), cold-water (Chapter 42) and warm-water (chapter 43) corals, seamounts and related

deep-sea habitats (chapter 51), and the sea-ice zone (Chapter 46), that highlight some of the main factors making an area richer in biodiversity than adjacent areas. Key drivers of biodiversity are complex three-dimensional physical structures that create a diversity of physical habitats (e.g., Chapters 42, 43 on corals, 44 on hydrothermal vents, 51 on seamounts), dynamic oceanographic conditions causing higher bottom-up productivity (e.g., the North Pacific Transition Zone discussed in Chapter 36C, the eastern boundary currents discussed in Chapter 36B.1 [Benguela Current] and 36D.1 [Humboldt Current], and the ice front of the Southern Ocean (Chapter 36H.2.1), as well as the special seasonality of production in the Southern Ocean benthic communities (Chapter 36H2.4)), effects of land-based inputs extending far out to sea (36B1 [Congo, Plata and Amazon Rivers]) and special vegetation features creating unique and productive habitats nearshore (e.g., kelp forests, Chapter 47; mangroves, Chapter 48; salt marshes, Chapter 49; and offshore (Sargasso Sea, Chapter 50).

2. Bridge to trends and impacts

These habitat-based hotspots are of double concern for the following reasons. As hotspots they support high absolute and relative levels of biodiversity, unique species adapted to their special features, and often serve as centres for essential life history processes of species with wider distributions (e.g., lagoons and spawning beaches for sea turtles, Chapter 39.4.1; upwelling and similar high-productivity centres for foraging seabirds, Chapter 38.3; haul-out sites for pinnipeds, Chapter 37.3.3.2); mangroves (Chapter 48); seagrasses (Chapter 47); estuaries (Chapter 44); and cold-water corals (Chapter 42): all harbour juvenile fish which are important for fisheries in adjacent areas.

Sometimes because of the special physical features that contribute to high biodiversity, and sometimes because of the concentration of biodiversity itself, these hotspots are often magnets for human activities; therefore, many societies and industries are most active in the areas that are also biodiversity hotspots. As on land, humanity has found the greatest social and economic benefits in the places in the ocean that are highly productive and structurally complex. For example, of the 32 largest cities in the world, 22 are located in estuaries (Chapter 44), mangroves and coral reefs support small-scale (artisanal) fisheries in developing countries (Chapter 36.D.2.3, Chapters 43, 48), and commercial fishing targets fish aggregations over seamounts (Chapter 51).

These hotspots are also recognized in the scientific and technical information on classes of special habitats, such as Ecologically or Biologically Significant Areas [EBSAs] (CBD) and Vulnerable Marine Ecosystems [VMEs] (FAO), and similar classes of special habitats. These are available to policy-makers and managers in shipping, seabed mining and other sectors. The tendency for biodiversity hotspots to attract human uses and become socio-economic hotspots, with a disproportionate representation of ports and coastal infrastructure (Chapter 18), other coastal land used (Chapter 20), fishing (Chapter 11)

and aquaculture (Chapter 12) is one of the major challenges to conservation and sustainable use of marine biodiversity.

3. Trends in biodiversity for species and groups of species

Superimposed on these patterns at all scales are temporal trends. Biodiversity is not static, hence both random variation and multi-year trends would occur without anthropogenic pressures (for example, Chapter 36C, Figures 8,9,10, which show substantial variation in chlorophyll and zooplankton well offshore of the main influences of land-based inputs, and Chapter 36F, Table 1A; Chapter 36D.2.1, 36G.2, 36H.2.1, 36H.2.2, showing substantial variation in bottom-up productivity in the open ocean and high-latitude seas where anthropogenic nutrient inputs are not large enough to be major drivers of basin-scale trends).

Human uses of the ocean have imposed much greater temporal trends on all biodiversity components. This Assessment found evidence of these temporal trends due to human drivers in every regional assessment and for all components of biodiversity, with some emergent patterns. They are summarized below.

3.1 Phytoplankton and zooplankton

Natural regime shifts have changed baseline bottom-up productivity to some extent, and the species composition of the phytoplankton and zooplankton to a greater extent (e.g., Chapter 36C, Figures 1, 3, 4) on the change in plankton community composition. Changes in species composition of lower trophic levels have broader ecological consequences, because such changes have been found to affect pathways of energy flow to higher levels, affecting species of fish, reptiles, birds, and mammals (e.g., Chapter 36A.7 [Gulf of St. Lawrence], Chapter 36G, Figure 1, both showing changes in food-web structure; Chapter 36A.3, 36D.2.1, 36D.2.2, and 36H.2.2, all showing changes in animal community composition in response to productivity drivers).

In coastal areas, human pressures on bottom-up processes were documented in all the divisions of the ocean described in chapter 36. Scales can be local to, occasionally, that of full semi-enclosed seas; the largest effects are documented where human populations are most dense (Chapter 36A.7 [Mediterranean, Baltic and North Seas], Chapter 36C, Figure 36C-6), but local effects are even seen in high-latitude seas (Chapter 36G [Trends]; 36H.1).

Many documented cases were found where high levels of contaminants or land-based nutrient runoff dramatically reduced diversity of species (Chapter 36C, Figure 36C-1; Chapter 36E.2; see also Chapter 20) or diminished or sometimes eliminated diversity due to hypoxia (see Chapter 36C.2(c) on hypoxia; Chapters 20, 44).

Many documented cases were also found where adoption of appropriate policies to address sources, along with funding for monitoring, correcting problems at source, and when necessary clean-up of affected areas, has reversed these trends and achieved good environmental quality (examples in Chapter 36A.7 [North Sea, Baltic Sea, Chesapeake Bay]).

Further out on shelves and in the open ocean, anthropogenically driven trends in lower trophic levels were less conclusively documented *except for climate change* (examples in Chapter 36C, Figures 36C-8, 9; 36D.2.1, 36G). Documentation of effects seems to emerge more strongly as monitoring continues. When direct impacts of pressures were found, causes generally were due to changes in temperature, water masses (currents, upwelling) and seasonality (examples in Chapters 36A.2, 36B.2, Table 36B1; 36C.1, 36D.2.1, 36E.2) and acidification (Chapter 6.5.3).

A second pervasive pressure on phytoplankton and zooplankton in all parts of the ocean, from coastal embayments to open-ocean areas, are alien invasive species. Ocean physical transport processes and incidental transfer by highly migratory species have always resulted in the possibility that new species would be introduced into an area, become established, and alter energy flows and community structure. As climate change affects temperature and salinity conditions in the ocean, species also may respond with changes in range; the relatively cold-adapted species in a community withdraws towards the poles and species relatively more adapted to warmer conditions expand their range towards the poles. Both types of range changes again can affect the patterns of productivity and community relationships in the areas experiencing changes in species composition of lower trophic levels (e.g., Chapter 36D.2.2). Active, albeit unintentional, transport of species with shipping (Chapter 17) and occasionally tourism can lead to invasions of species across basins and sometimes even greater distances. It is a largely academic argument whether changes associated with natural transport processes and climate-related changes in physical ocean conditions are “invasions”, but the impacts on system structure and dynamics can range from negligible to dramatic.

Cases are documented in all regions of alien species becoming established in new areas, and a portion of such invasions have caused almost complete restructuring of the plankton communities at scales from bays to semi-enclosed seas, with consequences for the biodiversity of all higher trophic levels (Chapter 36A.7 [Black Sea]; 36C, Figure 7).

3.2 *Benthos*

Temporal trends have been less widely documented because of the more local scale of patterns in seafloor biota. Quantifying trends requires expensive and local sampling, which has been undertaken for the most part only in rich countries, in restricted sites close to coasts, and often where problems are already thought to exist, usually due to human pressures.

In cases where appropriate monitoring has occurred, trends in benthos are commonly associated with human pressures. Causes include direct removals for harvesting

(Chapter 11), indirect impacts due to fishing gear and aggregate extraction (Chapter 36A.7 [North Sea]; 36D.2.3; Chapters 11, 42, 43 [corals], 44 [estuaries], 51 [seamounts]), and indirect effects due to pollution, sedimentation, etc. For example, loss of coral cover has been linked to catchment disturbance (Chapter 36D.3; Chapter 43), and species loss due to pollution is widespread in many estuaries (Chapter 44). Salt marshes have been drained, diked, ditched, grazed, sprayed for mosquito control, and invaded by a range of non-native species that have altered their ecology (Chapter 50). Many examples were found of high pollution, etc., altering benthic communities extensively and changing both species composition and biomass/productivity (Chapter 36A.7, 36B.4 [hydrocarbons]; 36C.2b; Chapters 20, 44). Trends in benthic populations or communities are often used as indicators for effects monitoring, because some benthos are sensitive to specific pressures and have high local patchiness of occurrence in specific response to those particular pressures.

This Assessment also contains many documented cases where adoption of appropriate policies to address sources, along with funding for monitoring, reducing the threat at source, and when necessary taking actions to remediate or restore damaged populations, communities or habitats, have reversed these trends and achieved good environmental quality (Chapter 36A.4.b, 36B.4.3, 36D). For example, coral-reef fish populations have been shown to recover within MPAs after they have been declared (Chapter 43) and management of shrimp aquaculture that prohibits clearing of mangroves and replanting of new forest has resulted in an improved condition of that habitat (Chapters 12, 48). Climate change also affects benthic biodiversity, but documentation and understanding of pathways and consequences are at an early stage (Chapter 36A.3, 36G.3).

For offshore benthos, the overwhelming pressure is the impacts of fishing gears. Trends were documented in all regions, and the commonality of these trends has led to the occasional characterization of all mobile bottom gear as a destructive fishing practice. Many types of seafloor habitats and benthic communities, particularly those comprised of soft bodied and leathery species, do show recovery from bottom trawling when the pressure is released, although just as with the fishery communities that are being exploited, full recovery may require years to decades. During periods of disturbance and recovery the *relative* species composition is changed, as long-lived species are reduced in abundance and dominance. However, as long as recovery can commence rapidly and is secure, such perturbations are sustainable and the habitats are considered to have resilience (Chapter 36A.3, 36B.4, 36C.3.b; Chapter 11). However, some special types of habitats and benthic communities are not resilient. Pressures, causing changes to seabed structure or increased mortality of species that are more hard-bodied and that create habitat diversity through burrowing or creating three-dimensional structures, may cause large and lasting trends in the benthic community. Productivity can be reduced and recovery, if feasible at all, could take many decades to centuries (e.g., cold-water coral communities, especially on seamounts; Chapters 42, 43, 51). In such cases, spatial management to prevent impacts is the only effective option to mitigate these trends and allow recovery to commence. Some policies that protect

these highly vulnerable to sensitive benthic habitats are in place for the high seas and many national jurisdictions. For example, some States and intergovernmental entities have adopted measures for the protection of seamounts and other deep water habitats within EBSAs, VMEs and MPAs, as discussed in Chapters 42 and 51. But this has not been done in most parts of the ocean, since the task of identifying such areas of particular importance to biodiversity is incomplete in some parts of the ocean. In addition, the necessary scientific and technical information is sometimes not available to the relevant States and intergovernmental organizations.

As with the plankton in the water column, invasions of alien species pose a risk of altering benthic biodiversity on scales from local and coastal to seas or large stretches of coastlines. The same processes of natural transport of reproductive propagules, range changes in response to climate-related changes in ocean conditions, and accidental transport with shipping or tourism have all been documented, with resultant major changes in benthic and occasionally pelagic community structure at scales at least of bays of hundreds of kilometres of coastline documented in all regions where sampling is adequate to detect such effects (Chapter 36A.3, 36B.4, 36C.3.b). In addition, a few cases are recorded of intentional introduction of larger invertebrates to develop new harvesting opportunities, with subsequent expansion of the species well beyond the area of introduction (such as Kamchatka crab in the Barents Sea Chapter 36A).

The shipping industry is actively seeking to improve practices and reduce risk of transferring species to new areas, and cost-effective risk-management practices are available (Chapters 17, 27). Detection of new benthic species requires intensive and often costly monitoring, for which capacity is limited in many areas. Once alien species are established, their elimination and remediation of the impacts have proven to be very difficult, costly, and rarely feasible.

3.3 *Fish and pelagic macro-invertebrates*

As with the other species groups, fish communities have always varied in abundance over time, sometimes by orders of magnitude, especially for small pelagic species in areas with variable oceanographic conditions (examples in Chapter 11, Chapter 36A.4, 36B, 36C, Figure 36C-4; 36D [salmon]; 36D.2.4). In several ocean basins changes in major portions of fish and invertebrate communities are well documented, and these are often related to corresponding changes in the physical ocean (Chapter 36A.4, 36C.3.a.iv, 36G.4).

Range changes of fish and macro-invertebrates in response to naturally changing ocean conditions are also documented in all regions (examples in Chapter 36A.4.4, 36C.3, 36G.4, 36H.2.3). The responses of fish populations and communities to climate change have been a particular priority for mid- and high-latitude parts of the ocean, with documented effects on productivity, timing of life history processes (e.g., Chapter 36H.5), and community structure in essentially all regions, with magnitudes of effects varying both with the life history of the species and the magnitudes and patterns of

change in the oceanographic conditions (examples in Chapter 36.A.4, 36C, Figure 36C-4; 36D.2.4).

Another type of documented trends in ranges of fish and invertebrate species are invasions of non-native species (example in Chapter 36C, Figure 36C-7) almost certainly associated with shipping. Some of the invasions by large pelagic invertebrates, such as comb-jellies, have completely changed the fish community on the scale of bays, and of the entire Black Sea (Chapter 36A.7, 36C.2). Although the magnitude of the disruptions from such invasions may diminish over time due to both natural ecosystem processes and management interventions, it has not been possible to eliminate or reverse such changes quickly, if at all, and costs have been high both in terms of costs to try to control the invading species, and in foregone benefits from the disrupted fish community (e.g., Black Sea). Prevention of introductions is by far the most logical and cost-effective option, and is receiving attention from the shipping industry. Again, however, resources are needed to implement and ensure adherence to best practices.

Trends in fish populations are linked to contaminants, pollution, and particularly habitat degradation due to land-based sources. However, population-scale effects have been restricted to nearshore areas or semi-enclosed seas where contaminant, pollution and/or sediment levels are high and water quality is degraded, with many fish populations and communities particularly susceptible to reduced oxygen levels in the water due to both climate change and increased nutrient enrichment (Chapter 36A.7 [Gulf of St. Lawrence, Chesapeake Bay, Gulf of Mexico]; 36B.2, 36C and F). However, the concern exists that long before population-scale impacts of contaminants may be apparent, fish may accumulate levels of contaminants in their flesh that pose health risks for consumers (Chapters 10, 15). In addition, it was noted earlier that some specialized habitats that are hotspots for fish and invertebrate biodiversity are also particularly attractive for other human uses. Downward trends in fish populations associated with such habitat losses are documented in many coastal areas (Chapter 36A.7 [all cases]; 36F).

Regardless of the cause of habitat loss or degradation, fish populations and communities have been documented as recovering when effective remediation measures have been taken (Chapter 36.A.4, 36C, Figure 36C-11; Chapter 41). Again, however, costs of remediation have often been high, time lags long, and prevention of loss or degradation is usually the more cost-effective option, with less uncertain outcomes than remediation initiatives.

Exceeding all of these other causes of trends in fish populations and communities are the effects of fishing. Fishing necessarily changes the total abundance and size/age composition of the exploited populations, with effects increasing as bycatch rates increase and as fishing becomes more intense and more selective of only particular species and sizes. The search for levels and methods of fishing that have sustainable impacts has gone on for over a century (Chapters 10, 11). Nevertheless, overfishing has not been eliminated, and downward trends in exploited populations, sometimes to depleted levels, can be found in all regions (Chapter 36A.4, 36B.4, 36D.2.4). Estimates

of the economic cost of such depletions are available (Chapters 11, 15), but ecosystem costs from the biodiversity impacts of overfishing exist as well. If genetic diversity of populations is depleted, resilience to naturally varying environmental conditions is reduced (Chapter 34; Chapter 36A.4). Also as the abundance of large fish in a community is reduced through fishing at levels that allow few fish to live long enough to reach their full potential size, any top-down structuring of community dynamics through predation is weakened, again weakening the resilience of the community to any other perturbation (Chapter 11 [ecosystem effects]; Chapter 36D.2.4). The properties of harvesting strategies that would keep effects of fishing sustainable for the exploited species and communities are generally known, and many examples show that when fisheries are managed with sustainable practices, populations can rebuild to and subsequently remain at healthy levels, although varying in response to natural perturbations (Chapter 11; Chapter 36A.4, 36D.2.4, although recovery may take decades; e.g., 36H.4). However, management authorities must adopt sustainable policies and practices that take biodiversity considerations into account, implement them consistently, monitor population status and fishery performance effectively, and ensure compliance through a combination of stewardship, surveillance, and enforcement that is appropriate to the fishery and community of human users (e.g., Chapter 36A.6, 36H.4).

3.4 *Marine Reptiles, Seabirds, and Marine Mammals*

Many of the species with the greatest declines in abundance are in these groups of top predators (marine mammals, marine reptiles and seabirds); some species of all three higher taxa are assessed as at risk of extinction by IUCN (Chapters 37, 38, 39). In cases where overharvesting was a contributing factor, some of these declines have lasted for over a century (Chapters 37, 39; Chapter 36H.4). All the factors considered for the above groupings of biodiversity are also implicated in the trends in marine reptiles, seabirds and mammals.

Seabirds and marine reptiles have been particularly affected by habitat degradation, e.g., where terrestrial breeding sites were converted to intensive use by coastal industries or tourism (Chapter 39), or, particularly for seabirds, where new predators were introduced on previously isolated breeding sites (Chapter 38). Body burdens of contaminants have been implicated in reduced breeding success of several populations of pinnipeds and smaller cetaceans (Chapter 37; Chapter 20), and in a few cases this pressure alone may be sufficient to pose a risk of extinction to small populations (Chapter 36A.5; Chapter 37).

Bycatches in fishing gear are well-documented threats to populations and species in all three groups of top predators. Most types of fishing gear have been documented to pose potential threats to specific populations or species, including: mobile trawl gear for turtles and sea snakes; longlines for seabirds and turtles; suspended nets for seabirds, small cetaceans, and pinnipeds; and entanglements of whales with lines connected to traps and pots used in fishing (Chapters 37, 38, 39). Practices which mitigate these risks

have been proven to be effective for many types of gear, through changes in gear design (e.g., excluder devices), fishing practices (e.g., surface deployment of longlines), and other methods. However, implementation of mitigation techniques often requires training in their use and is specific to the species, fisheries, and areas where the fishing occurs. Hence additional measures, such as periodic and area closures in areas of high bycatches, or closures of fisheries when allowable bycatch numbers are exceeded, are often applied, with or without gear-based measures (Chapters 38, 39). Downward trends in marine reptile, seabird, or marine mammal populations due to bycatch impacts can be stopped and population increases facilitated by the appropriate combination of these mitigation measures, but require expert study of the nature of the bycatch problem and evaluation of the potential effectiveness of alternative mixes of measures, monitoring of the fishery and the populations suffering the bycatch mortality, often requiring expenditures of capital, time and training in acquiring, adapting, and learning to use the tools, and appropriate surveillance and enforcement.

Not all harvesting-related mortality of marine mammals, seabirds, and marine reptiles is due to bycatches in fisheries. Directed take of marine mammals reduced many whale populations to one or a few per cent of historical populations, and recovery of these species has often been extremely slow, even after harvests were largely eliminated (Chapter 37). Directed harvests of seabirds were historically common in many areas, and are still a practice in some places that still depend on subsistence hunting and fishing (Chapters 36A.5, 36B.8, 36G.6; Chapter 38). Directed harvest of sea turtles was intensive until the early 20th century and depleted many populations, but is now prohibited in most jurisdictions, although again recovery has been slow, usually due to other pressures (Chapter 39).

Aside from directed take and bycatches, fisheries can also affect marine reptiles, seabirds and marine mammals through trophodynamic pathways (examples in Chapter 36B.8). Fisheries on small pelagic stocks have been implicated in depleting the food supply of seabirds, particularly when feeding chicks in breeding colonies (Chapter 38), and cases are documented where the discarding of fishing waste at sea has promoted large increases in populations of scavenging seabirds that in turn displace other seabirds from breeding colonies (Chapter 38). Spatial management measures and adjustments to overall harvesting levels have been successful in dealing with the first type of impact (Chapter 38), and the increasing policy dialogue about managing discard practices in fisheries (Chapter 11; Chapter 36A.5) is at least considering the implications for seabird communities.

Climate change has the potential to affect trends in all three of the types of top marine predators. Studies are being conducted on how changing ocean conditions may affect breeding and resting sites (e.g., sea-level rise and turtle and mammal breeding beaches), loss of ice cover affecting high-latitude seabirds, polar bears, cetaceans and pinnipeds, range changes of species from all groups as temperature and salinity patterns change, and indirect food web effects (Chapter 36.G.5.5, 36H and 38) . Given the long life expectancies of most of these types of species, population impacts of climate drivers

may only show up gradually, but may be hard to reverse. Moreover the impacts may be non-linear once they start to be manifest, with possibly steep “tipping points”, further increasing the policy and management challenges. Some interest exists in spatial management tools as a way to partially mitigate impacts of climate on these populations, but work to test and, as appropriate, implement such measures is in the early stages (Chapters 38, 39).

For all of these species groups, measures to mitigate any of the anthropogenic and climate drivers of decreasing trends in populations have opportunity costs from displacing or refraining from conducting an activity providing social and economic benefits and direct costs of deploying more expensive fishing gear, patrolling of breeding sites of turtles and mammals, etc. (Chapters 37, 39). However, the high regard in which many societies hold these types of species (Chapter 8) also provides opportunities for increasing public awareness of all marine biodiversity concerns, and building public and industry support for taking appropriate actions to address trends and ensure practices are sustainable.

4. Trends in biodiversity for habitats

In cases where habitat features make an area a hotspot for marine biodiversity, the potential for negative trends in biodiversity is greater for several different types of reasons:

- Special habitat types can host uncommon or rare species requiring the special features of these habitats for some aspects of their life histories. Their inherent rarity and high ecological specialization can make such species particularly vulnerable to impacts from human activities and changes in environmental conditions. This Assessment found examples of such vulnerable species in most habitat types examined: for example, the general importance of seagrasses for juvenile fish as well as dugongs and human activities that affect seagrass and/or water quality (Chapter 47), and salmon sensitivity to human impacts on coastal areas (Chapter 36C.5).
- Just by being rich in biodiversity, particularly high interdependencies can exist among the species in these specialized habitats. Perturbations of even a few key species in these ecosystems can affect many other species with which they have ecological relationships, spreading and sometimes amplifying the initial perturbations to produce much greater consequences for the biodiversity as a whole. Again, such vulnerabilities of the biotic community to perturbations of even a few components were found in many of the special habitats assessed in the WOA. For example, overfishing of herbivorous reef fish has resulted in decline of coral cover because of overgrowth of algae (Chapter 43).
- Areas that are biodiversity hotspots often are associated with specialized structural features of the seafloor and/or the water column for which many

- species use those particular areas for some or all life history processes. If those specialized structural features are disturbed intentionally or collaterally by human activities, their ability to serve those functions for all the species depending or attracted to them is reduced, again with the potential for widespread detrimental effects on biodiversity. Some of the specialized habitats examined showed many examples of declines in biodiversity due to such alterations or elimination of the physical attributes of the habitats. For example, bottom trawling in many areas and cases of oil and gas development in some places have removed large areas of cold water corals and its associated biodiversity (Chapters 42, 51).
- By having specialized physical characteristics and by supporting many different kinds of marine life, the specialized habitats can be particularly vulnerable to some kinds of human uses (e.g., Chapter 36D.2.3). Some are activities that focus on the special physical features, such as use of high local productivity for aquaculture (for example, conversion of mangrove or other estuarine habitats; Chapters 44, 48) and/or on the high concentration of biodiversity, such as fishing or tourism (for example, coral reefs; Chapter 43). Others are activities that may not intentionally focus on the hotspot, but on the physical features and processes that result in the areas supporting high levels of biodiversity; these also result in the areas being especially exposed to collateral impacts from other human activities, such as the types of biodiversity hotspots that are areas of high land-based inputs or that support higher concentrations of coastal residents than other areas. Examples include estuaries (Chapter 44), mangroves (Chapter 48) and salt marshes (Chapter 49).

This Assessment not only found widespread evidence that specialized habitats commonly show particularly strong negative trends in components of biodiversity, it also found global spatial patterns in the types of vulnerabilities of various different types of specialized habitats.

A few of the specialized habitats were either offshore and/or deep-sea habitats (seamounts, hydrothermal vents and seeps, cold-water corals, the Sargasso Sea, high-latitude ice), where human populations and industrial activities have historically not concentrated. These are highly specialized habitats requiring particularly high adaptation by the biological community to their specialized conditions. However, in providing unique features, such as the enhanced biological productivity of seamounts and the ice edge, high three-dimensional structure of the corals, etc., the areas become biodiversity hotspots relative to adjacent areas that are not as productive. In these habitats, recovery from physical damage to the specialized habitat features and/or depletion of the biological populations is often extremely slow and uncertain, just because of the harshness of the background conditions in adjacent areas, and/or the particularly high specialization of the species to these special environments, and/or the complexity of the specialized habitat itself. Climate change poses particular threats to some of these types of special habitats, because ice melting and thermal stress are altering the special habitat features themselves (e.g., reduction in the area of Arctic sea-

ice habitat (Chapter 46) caused by global warming). Also coral bleaching is widespread and has affected the quality of coral reef habitat in all areas of the oceans (Chapter 36D2.3; Chapter 43).

Fishing is the primary activity likely to be attracted to the biota at these special habitats, particularly in the deep sea. Both the complex structure of the habitats and the highly specialized fish populations may be highly vulnerable to physical damage and/or exploitation, and the slow recovery potential of much of the associated biodiversity is a particular risk (for example, cold-water coral communities on, e.g., seamounts; Chapters 42, 43). Many human activities, such as shipping lanes, undersea cables, etc., can be designed to avoid these special areas. However, as the capacity to exploit the physical resources of the deep sea increases, extractive uses may be attracted to exactly these specialized habitats (for example, species found associated with deep-sea hydrothermal vents and cold seeps; Chapter 45). The potential for increased shipping and tourism in the high latitudes is also an increasing threat to biodiversity.

The other specialized habitats are generally associated with nearshore and coastal areas (kelps and seagrasses, mangroves, salt marshes, estuaries and deltas), although low-latitude/warm-water corals may extend out onto continental shelves for many kilometres. A much wider range of human activities poses potential threats to these habitats. Many have the high vulnerability to land-based run-off discussed above (e.g., estuarine habitats), high attractiveness of their biota to directed uses, such as fishing and tourism (e.g., coral reefs) and adjacent coastal development, and of their physical features to extractive uses (for example, carbonate mining of reef rock; Chapter 43) or intentional alteration (e.g., conversion of mangrove habitat for aquaculture; Chapter 48).

The productivity of these more coastal areas is often higher, such that recovery from some types of perturbations of the biodiversity may be more rapid and secure than in off-shore, deep-water habitats (Chapter 36H). On the other hand, these specialized habitats and their biodiversity are likely to be exposed to a myriad of pressures from multiple human activities. That diversity of pressures means that the cumulative impacts on these habitats and communities can be high, even when individual pressures may be managed, and the effectiveness of management measures applied to one pressure may be affected by the nature and intensity of other pressures, e.g., salt marshes (Chapter 49). As a result, protection of these specialized habitats and their biodiversity may require complex and coordinated planning and implementation, and it may be hard to motivate single industries to bear the costs of mitigation measures if the pressures from other uses are likely to continue (illustrations from all of Parts V and VI).

In summary, this Assessment finds that specialized habitats that are also biodiversity hotspots face a potential triple threat from higher vulnerability to perturbations, higher attractiveness to many human uses, and higher challenges to recovery from perturbations if they occur. Correspondingly, evidence of degradation of habitats and communities from one, two, or all three of these factors is widespread for all habitat types and in all regions where they are found. Nevertheless, many cases exist where

the threats have been adequately managed, the habitats and their biodiversity protected, and at least some recovery from past perturbations has been recorded. For example, 24 estuarine case studies reported that management has resulted in improving estuarine health (Chapter 44) and declaration of MPAs has prompted the recovery of ecosystem and fish populations in coral reefs (Chapter 43). Although the benefits of coordinated planning and management of pressures cannot be overemphasized, targeted and proactive measures can have high payoffs if even one pressure is reduced effectively (e.g., seasonal closures of fisheries to protect spawning aggregations (Chapter 11); stopping mangrove habitat conversion for aquaculture (Chapter 48)). It is important, however, to match the management tool to the particular needs of the specialized habitat; for example, limits on catches or effort in a fishery may keep a fishery sustainable at the population level, but spatial tools may need to be added if the fishery can concentrate on biodiversity hotspots causing local depletions of species serving key functions in the biotic community (illustrations from Part IV, Chapters 36, 42-51]. However, progress and even success is possible with the proper suite of measures, and the capacity to implement them.

Methods used in the assessment of the status and condition of species and habitats have undergone a rapid transformation in recent years with the advent of predictive habitat modelling (PHM). This approach has revolutionized the study of many habitats and their associated biota. For example, cold-water coral communities were virtually unknown prior to the discovery of extensive bioherms off Norway in the early 1980s, but the application of PHM enabled the discovery of a completely new habitat for scleractinians on steep submarine cliffs in 2011 and was confirmed almost immediately through field observation in the Mediterranean and Bay of Biscay (Chapter 42).

In summary, the diversity of the world's oceans is rich and dynamic, but it has been incompletely quantified, and even descriptions and inventories of marine biodiversity are incomplete for the open ocean, the deep sea and many shelf and coastal areas. Despite our incomplete knowledge, however, trends in measures of biodiversity at the scales of populations, species, communities and habitats are found almost everywhere, demonstrating that our information is sufficient to look for trends, and often to inform development of policies and management measures to address drivers of the trends. Natural processes play some role in these trends, and occasionally can be a prominent driver. However, in the majority of cases, anthropogenic drivers are the major influence on changes in biodiversity.

The nature of the human activity generating the pressure will strongly influence the scale of impacts in space and time. Some pressures, such as climate change, inherently operate at large (global) scales, others, such as fisheries, may operate at the scale of individual fisheries, but fisheries are widespread and have adversely affected biodiversity in most parts of the ocean. Other pressures are inherently more local in both operation and occurrence, such as hydrocarbon extraction and seabed mining, but they can be intensive pressures where they do occur. Moreover, it is common for

biodiversity on local to basin-wide scales to be exposed to cumulative effects of multiple pressures interacting in ways that are usually poorly understood.

Certain types of species, such as marine mammals, seabirds, marine turtles, large sharks and fragile benthic taxa, such as corals and sponges, and certain types of habitats, including coral reefs, hydrothermal vents, estuaries, mangroves, and others, are both particularly sensitive to pressures from many types of human activities and attract human uses in large part because of their biodiversity characteristics. These are often the components of biodiversity showing the strongest declines over time, and thus pose particularly great conservation concern.

Notwithstanding the widespread negative trends in biodiversity and the number and ubiquity of anthropogenic pressures associated with those trends for all components of biodiversity and all types of pressures, positive examples of eliminating or mitigating pressures and reversing the unsustainable trends exist. The likelihood of success in managing threats and protecting and recovering biodiversity that has been affected increases with better knowledge of biodiversity and the pressures in the area, adoption of policies appropriate to the context, and the improvement of capacity to implement the policies effectively.

Chapter 53. Capacity-Building Needs in Relation to the Status of Species and Habitats

Contributors: Renison Ruwa (Convenor and Lead Member), Amanuel Ajawin, Sean Green, Osman Keh Kamara, Jake Rice, Lorna Innis and Alan Simcock (Co-Lead Members)

1. Introduction

Knowledge of the status of species and habitats forms a fundamental basis for understanding biodiversity at all scales (Chapter 34) and ecosystem functions and services (Part III and Millennium Ecosystem Assessment, 2005). This facilitates identifying the capacity-building needs for appropriate interventions that will enhance and promote sustainability. This creates a need for knowledge of marine biological diversity and habitats from a marine ecosystem approach, and of how biodiversity varies in relation to various levels of anthropogenic perturbations. Gaps in scientific knowledge, technological advances, human skills and infrastructure for the conservation of marine biodiversity and habitats are crucial. Part VI addresses these issues focusing on the major oceans in relation to marine ecosystems, habitats and major species groups that are emerging from our assessments as potentially threatened, declining or needing special attention. All these categories need a variety of capacity building, technical skills, technology and infrastructure to address their trends. To facilitate this capacity building, we undertook the identification of knowledge gaps mainly from the Part VI Chapters, and the capacity building needed to address socio-economic issues for human well-being. Chapter 32 and this Chapter both address capacity-building needs. However, whereas the identification of needs in Chapter 32 was based on outcomes of regional workshops and the Chapters of Part V, this chapter is based on all the authored chapters, which also include identification of gaps from literature reviews on the oceans.

To address the objective of the Regular Process to ensure that capacity building and technology transfer are done through promoting cooperation, not only North to South but also South to South cooperation (UNGA, 2010; UNGA/AHWGW, 2009; UNGA/AHWGW, 2010), the synthesis is done in geographical areas following the oceans and the major regional seas addressed in Chapter 36. Further capacity needs were identified in relation to the knowledge gaps from the chapters focused on the overall status of the major groups of species and habitats, including the socio-economic aspects of their conservation.

The marine species groups that were given special attention or protection are: marine mammals, seabirds, marine reptiles, sharks, tuna and billfish. These were dealt with globally without specifically linking them to particular oceans. The same general analysis was followed for specific marine ecosystems and habitats addressed in Chapters 42-51, including cold-water corals, warm-water corals, estuaries and deltas, open-ocean

deep-sea biomass, hydrothermal vents and cold seeps, high-latitude ice, kelp forests and seagrass, mangroves, salt marshes, Sargasso Sea, seamounts and other submarine geological features potentially threatened by disturbances.

There are already many international initiatives to build capacities (both in terms of skills and of equipment) to meet many of the capacity-building gaps identified in this Assessment. One example among many is the programme of the Food and Agriculture Organization of the United Nations, supported by Norway, using the Research Vessel Dr. Fridtjof Nansen. However, on the information available, it is impossible to say what gaps currently exist in arrangements to build these capacities: conclusions on where the capacity-building gaps exist could only be reached on the basis of a survey, country by country, of the capacity-building arrangements that currently exist and how suitable they are for each country's needs. This applies more generally, but is particularly important in relation to capacity-building in relation to marine biodiversity. The initial inventory of capacity-building arrangements¹ compiled by the Division for Ocean Affairs and Law of the Sea as part of the Regular Process would provide some initial information on which to base such a review, but it would take much more detailed study than has been possible in the first cycle of the Regular Process to match this with the needs of each country.

2. Outcomes based on regional workshops on capacity-building needs

The following regional workshops were held: South-West Pacific region (UNGA, 2013a), Wider Caribbean region (UNGA, 2013b), Eastern and South-Eastern Asian Seas (UNGA, 2012a), South-East Pacific region (UNGA, 2011), the joint North Atlantic, Baltic Sea, Mediterranean and Black Sea region (UNGA, 2012b), the Western Indian Ocean (UNGA, 2013c) South Atlantic Ocean (UNGA, 2013d) and Northern Indian Ocean (UNGA, 2014). From the regional synthesis based on the outcomes of the regional workshops, it appeared that some needs were regionally cross-cutting and some were directly relevant to Chapter 53. The following were more specific to species and habitat relationships across the regions:

- (1) Taxonomy and genetics
- (2) Bio-physical/chemical research on the ocean environment
- (3) Socio-economics of oceanic natural resources focusing on biodiversity and habitats
- (4) Skills in integrated assessments, including modelling
- (5) Infrastructure with relevant supportive technology, especially in research vessels and laboratories to support multidisciplinary research
- (6) Geographical Information System mapping skills.

¹ See A/67/87, Annex V.

3. Outcomes based on chapters focusing on knowledge gaps to inform capacity-building needs

3.1 Overview of marine biological biodiversity

The global biological diversity patterns are described in relation to key taxa and habitats and to the identification of key environmental and anthropogenic drivers. The gradients in marine biodiversity are assessed using a taxonomic framework of well-known key groups of organisms (for example, marine mammals; turtles; finfish; plankton (phytoplankton and zooplankton), and seabirds in Chapters 34-36. In addition, a habitat framework was used when the taxonomic identity of the species was of secondary importance to the type of community or conditions in which they occurred, the species and habitat framework focusing on marine ecosystems, species and habitats (Chapters 37-51, Section B).

3.2 Overall status of marine biological diversity in the oceans and knowledge gaps

The Atlantic and Pacific Oceans are relatively more studied than the Indian Ocean, which is the third-largest ocean and almost entirely surrounded by developing countries. By contrast, both the Atlantic and Pacific Oceans are mostly surrounded by developed countries or economies in rapid transition. However the North Atlantic and the North Pacific Oceans are comparatively better studied than the South Atlantic and South Pacific Oceans.

In terms of identifying the global diversity patterns, the gradients in marine biodiversity of the North Atlantic and the North Pacific are assessed primarily in terms of taxonomic frameworks, whereas for the South Atlantic and South Pacific the taxonomic framework is used when possible, but is often augmented by the habitat frameworks in areas surrounded by developed countries and developing countries, respectively. For areas surrounding the Indian Ocean, where many knowledge gaps are found, the gradients in marine biodiversity are assessed primarily in terms of habitat frameworks. As regards the Polar waters, the Antarctic has been more studied than the Arctic, but it is necessary to increase scientific efforts for the Arctic and Antarctic due to their uniqueness.

3.3 Deep-sea environment

Shallow coastal waters are comparatively better researched than the deep sea because of their greater accessibility. It is necessary to build the essential capacity, including deep-sea platforms to provide relevant research and technical skills at regional and global levels to address the following problems:

- Despite technological advances and a sharp increase in deep-sea exploration in the past few decades, a remarkably small portion of the deep sea has been investigated in detail. There are therefore large gaps in what we know about the deep sea.
- Although the species which are specifically considered in this Assessment are vertebrates, it is important to improve the knowledge base about invertebrates, microbes and viruses.
- Deep-sea biodiversity is very poorly characterized compared to the shallow-water and terrestrial realms. Without better characterization of deep-sea biodiversity, its protection will be hampered.
- The deep ocean has many species, with genetic, enzymatic, metabolic and biogeochemical properties which may hold potential for major new pharmaceutical and industrial applications. Without better knowledge of these species and their properties, important opportunities may be missed.
- The deep oceans are estimated to have up to millions of species. Because conservation and sustainable use of biodiversity is improved when the species are known and their biological characteristics inventoried, much effort and time will be required to describe them.
- The deep seas are threatened by ongoing global climatic changes due to increasing anthropogenic emissions and resulting biogeochemical changes. The impacts of climate drivers on the deep sea biota and the magnitude of the drivers in the deep sea need to be better documented.
- The deep oceans may be threatened by, e.g., oil and gas exploitation, mining for metals, fishing practices (both destructive fishing techniques and an excessive scale of fishing) and pollution. More measurement is needed of the scale of these pressures and their potential impacts.
- Perhaps the most important knowledge gap is the knowledge of the effectiveness of alternative management options when applied in such a vast, dynamic space, much of which is beyond national jurisdiction, to reduce the impact of man-made stressors.
- The design of protected areas based on geographic definitions must necessarily account for the fluxes through the system as well as the movement of the inhabitants.
- Deep-sea observatories are becoming increasingly important in monitoring deep-sea ecosystems and the environmental changes that will affect them. These observatories aim at addressing important societal issues, such as climate change adaptation, ecosystem conservation and sustainable resource management. Tackling these issues, along with efficient and clear stakeholder communication, is particularly important for the deep sea, which remains largely unexplored, yet affects the lives and livelihoods of the global population directly or indirectly. Technological advances in recent years offer the ability to continuously monitor the ocean in time and space; in particular, the development of *in-situ* sensors, autonomous vehicles, and cyber-infrastructure,

including telecommunications and networking. If these technologies are applied more widely in the world's oceans they would add to the capacity to monitor the deep sea and feed the obtained information into science-policy interfaces and marine management and policy.

4. Specific data or knowledge gaps identified in the Assessments by key marine species or habitats

4.1 Marine species

4.1.1 Marine mammals

Data are obtained mostly from ship-board observations and use of satellite telemetry. The latter has improved offshore data acquisition, because most of the data are taken within the Exclusive Economic Zones (EEZs). USA, European and Antarctic waters are the best assessed waters. The largest knowledge gaps occur in Indian Ocean waters. Only by continuing to monitor and assess the marine mammals in EEZs and putting more research effort into the Areas Beyond National Jurisdiction (ABNJ) can sufficient data be obtained to document trends and inform decision-making.

4.1.2 Seabirds

Birdlife International, the IUCN Red List authority for birds, has the most authoritative global database on seabirds. At regional levels, Europe and North America are most thoroughly assessed; many knowledge gaps remain in the developing world.

- Important knowledge gaps exist in studies of seabird migrations, some of which cross continents, or are inter-continental, because these routes are not well known. Other gaps that cannot be filled without additional capacity include improving understanding and increasing data available on seabird coastal habitats; seabird bycatch; vulnerability to pollution (especially oil, garbage in dumpsites, marine litter and plastics); disturbances of coastal and deep-sea habitats; adequacy of habitat protection; whether and what kind of marine protected areas (MPAs) may address this gap globally; their role in ecosystem, socio-economic and livelihood services; the effectiveness of alternative conservation elements for taking the migratory habits of seabirds into account, and other factors for sustainability in protected areas.

4.1.3 Sea turtles

With respect to sea turtles, the issues where gaps in knowledge and capacity-building are involved include:

- Assessments spearheaded by IUCN's Red List of threatened species and the global listing for vulnerable species exist. However, marine turtle population traits and trajectories can vary geographically and the listing criteria could only

be applied effectively if there were a better characterization of the status and trends of individual populations and if the information was used to establish categories for regional sub-populations in addition to the single overall global listings.

- Gaps in knowledge of risks due to effects of climate change still remain a challenge because of insufficient data for analysis of long-term trends. Improved conservation of sea turtles could result from an increase in regional assessments for sea turtles due to their migratory nature. Monitoring and reporting criteria would also perform for effectively if they were augmented by information on the status and trends of population sizes, as well as global threats to the sea turtles.
- Data needs are critical for data-poor regions, especially Africa, the Indian Ocean and South East Asia.

Increased capacity to address these gaps at regional and global levels would allow more effective conservation of marine reptiles. Such efforts would benefit from cooperative regional and global partnerships, because sea turtles are migratory and transboundary.

4.1.4 Sharks and other elasmobranchs

In relation to sharks and other elasmobranchs, there is inadequate capacity in many countries and most regions to address the following issues:

- Lack of or deficient monitoring data make it difficult to assess the status of many sharks. The most data-deficient areas are: Western Central Atlantic Ocean, Eastern Central Atlantic Ocean, the Wider Caribbean Sea, South West Indian Ocean and the eastern and southeastern Asian Seas.
- In addition to obtaining data from fisheries, surveys and catch landings increasing the capacity to use emerging technologies, such as satellite tags, acoustic tracking, digital underwater photography, and sophisticated photo identification systems would facilitate population and distribution estimates in defined geographic locations.
- Although the recent decline in reported landings is consistent with declining abundance due to overfishing, any interpretation should consider that reported landings are almost certainly a gross underestimation of actual catches. To ascertain actual trends in shark catch and landings, which are likely to be even worse than expected, would require increasing the management priority of sharks by regional fisheries management organizations (RFMOs) and national management bodies. Better independent catch and bycatch monitoring data are needed to know the effectiveness of conservation measures taken by RFMOs, noting that destructive fishing is still increasing in regions such as the Indian, central Pacific and south and central Atlantic Oceans.
- Mortality due to fishing, both directly and as bycatch, is almost entirely responsible for the worldwide declines in shark and ray abundance. However, knowledge of survival of living sharks released at sea is limited.
- Persistent bioaccumulation of toxins and heavy metals has been documented in sharks feeding at high trophic levels. Levels which can be toxic to human consumers

have been reached in some areas, but their effect on the host shark remains unknown. The global extent and specificity in occurrence of various contaminant burdens are unknown. These knowledge gaps would have to be filled before the population-level threat of toxins and heavy metals could be evaluated effectively.

- Elasmobranchs (sharks and rays) play an important role in the marine ecosystem food chains as top predators; they contribute to maintaining balances in species numbers and biomass abundances. This function is, however, not very clear at local and sometimes regional scales; its overall global manifestation is not well known either as the role of temporal variability is poorly understood. These knowledge gaps would have to be filled in order to place shark conservation in the context of ecosystem functioning.
- A key challenge is to secure ongoing assessment activities, particularly the continuance of research surveys, and to expand assessment activity to encompass not only the largest, most charismatic species, but also the lesser-known species which are often more threatened, particularly the rays and shark-like rays, and the 90 obligate and euryhaline freshwater species. Geographically, greater attention needs to be paid to Central and South America, Africa, and Southeast Asia.

4.1.5 *Tuna and Billfishes*

These fish are an important part of the global capture fisheries sector. Billfishes are heavily fished and have therefore attracted the attention of IUCN; some species are listed as vulnerable. Capacity-building gaps exist in addressing the following gaps:

- Assessments are done by RFMOs using fisheries stock assessment methodology and capacity is inadequate in many parts of the world to employ this methodology and to establish research infrastructure with the necessary technology, including satellite tracking facilities, to facilitate the required studies. Lack of this capacity hinders conservation and management of these species. A global paucity of data exists on the population status of these species. Only with additional stock assessments would it be possible to identify and protect early enough many species possibly threatened by overfishing for effective conservation measures to be taken. This can only be done effectively if it is approached at both regional and global levels.
- Although the current exploitation status for the principal market tunas is relatively well known globally, knowledge on the exploitation status for the non-tuna billfish stocks and species is fragmentary and uncertain. Furthermore, tuna RFMOs have not yet conducted formal fisheries stock assessment evaluations or adopted management and conservation measures for any of the eight non-principal market tuna species. Therefore their current exploitation status is unknown or highly uncertain throughout their distribution range, and can only be filled by additional capacity to assess their status.
- It is generally agreed that catch estimates for non-principal market tunas and billfishes have been and still are underestimated, as the majority of these species are caught by small-scale fisheries or as a bycatch of principal market tuna

fisheries. Therefore effective assessments of these species requires improved catch reporting from small-scale coastal fisheries targeting both principal market tunas and the smaller non-principal market tunas. Similarly, billfish catches, which generally come from industrial tuna fisheries as bycatch, have also been commonly poorly reported and monitored.

- Climate change is another potential pressure that needs to be taken into account in the assessment of the biology, economics and management of tuna and billfish species. Climate change might have an effect on tuna and billfish species by changing their physiology, temporal and spatial distribution and abundance, but these possible relationships can only be known with much more study.
- To what extent the widespread declines in tuna and billfish populations have altered the capacity of the ocean to support vital ecosystem processes, functions and services by reducing their abundances and altering species interactions and food web dynamics is poorly known.
- Incorporating ecosystem considerations into the management of tunas and billfish fisheries would help to move their assessments into an ecosystem context.
- The main challenges to conservation responses and factors for sustainability are: (1) reduction in the existing overcapacity of fishing fleets; and (2) adoption of protocols that ensure implementation of effective Monitoring, Control and Surveillance (MSC) techniques.
- A further challenge is the paucity of knowledge of the impacts of tuna and billfish fisheries on other less productive species such as sharks, on species interactions and food web dynamics, and on the greater marine ecosystems.

4.2 *Marine ecosystems and habitats*

4.2.1 *Cold-water corals*

With respect to cold-water corals, the issues where gaps in knowledge and capacity-building are involved include:

- Information on cold-water corals (CWC) in the Indian Ocean region is scanty, even though the region covers an area between latitudes 70°N - 60°S, a range where seamount CWC are known to occur.
- Technology and skills for discovering CWC are still lacking in some regions, especially the developing world. Additional fine-grained and broad-scale habitat modelling are still needed to discover additional habitats, and to forecast the fate of CWC facing both direct (fisheries) and indirect (environmental) impacts.
- It is necessary to increase knowledge of the characteristic geological structures and environmental factors facilitating CWC settlement and growth. The current list includes provision of hard, current-swept substrate, and often topographically guided hydrodynamic settings. All need to be identified and mapped. The skills needed include knowledge of combined physical, bio-geo-

hydro-chemical analytical techniques (e.g., of ambient seawater characteristics and measurement of current velocities).

- Global knowledge is lacking of CWC distribution in terms of their species occurrences and population abundances; this makes it difficult to set up regional cooperation to consider these species.
- Knowledge of how cold-water corals respond to damage inflicted by pollution is limited. Without better knowledge, it will be difficult to design protective regimes and response mechanisms.

4.2.2 *Warm-water corals*

With respect to warm-water corals, the issues where gaps in knowledge and capacity-building are involved include:

- Damage to warm-water corals may be more serious than currently perceived because submerged reefs below 20m depth cannot be detected using satellite technology. Submerged reefs cover large areas and understanding the extent of submerged reefs is therefore important.
- GIS mapping of coral reefs is necessary to understand their spatial distribution, especially in shallow water areas where the worst affected reefs are found.
- Corals show trends that justify measures to protect them from anthropogenic impacts. Such protection can be enhanced by spatial management tools, including the creation of MPAs. Globally, only six percent of warm-water reefs are contained in marine reserves. Establishment of more spatial management measures including MPAs would address this concern and aid in reducing anthropogenic impacts, and also assist in meeting other challenges.
- Monitoring sites and the flow of information on coral ecosystems (and in some cases other marine habitats such as mangrove and seagrasses beds) have been reduced in some cases. This will not help to improve the little that is known on the status of their ecological interaction with the changing pressures.
- Restoration and enhancement of capacity for monitoring would be required to allow status and trends of these habitats to be assessed effectively.
- Where warm-water corals are damaged by cumulative impacts, measures which address the full range of the pressures will be the most effective response. This includes pressures from tourism (see Chapter 27).
- Corals provide important cultural values. Indigenous people in some developed countries have been granted rights to access and benefit sharing of genetic resources and traditional knowledge. This recognition acknowledges the importance of these cultural aspects that link human populations and reefs. Capacity building for indigenous access and benefit sharing would be beneficial to the well-being of these peoples.

It would be extremely useful to build capacity for studying and managing coral reefs, at national, regional and global levels, to provide the right skills and infrastructure to address the issues identified and continue to enable coral reefs to provide goods and services that contribute to socioeconomic well-being and the health of the planet as a whole.

4.2.3 *Estuaries and Deltas*

With respect to estuaries and deltas, the issues where gaps in knowledge and capacity-building are involved include:

- A paucity of knowledge exists about the threats due to human activities, global climate change and extreme natural events.
- Globally very few integrated assessments encompass multiple aspects of estuarine environments, i.e., that include habitats, species, ecological processes, biophysical and socio-economic aspects.
- It would be extremely useful for the better conservation of estuaries and deltas to develop and apply the capacity to address these issues, including incorporating hydrological modelling into coastal modelling and forecasting efforts, in order to link better with the land-coast interface where these important habitats are located.

4.2.4 *Hydrothermal vents and cold seeps*

With respect to hydrothermal vents and cold seeps, the issues where gaps in knowledge and capacity-building are involved include:

- The survey and research activities have mostly been undertaken in the Pacific (especially in the northeast and northwest Pacific) and Atlantic Oceans (especially the north Atlantic). Very few have been conducted in the Indian Ocean, and those few have mostly been carried out in international waters. Therefore a better global picture of trends would require survey and research efforts to be expanded.
- Increasing knowledge of vents and seeps would only be possible if essential capacity to address all these gaps were built. For developing countries, this would need to be greatly increased, because the capacity is at best low, and usually almost non-existent, in many countries.

4.2.5 *High-Latitude Ice*

With respect to high-latitude ice, the issues where gaps in knowledge and capacity-building are involved include:

- The ecology of the Arctic and Antarctic regions is still little known due to the challenges their unique environments pose to human beings. This has necessitated the use of special skills and technology to undertake the essential research to understand the effects of the emerging threats of climate change, not only in these regions, but also how these effects would consequently affect

- wider geographical regions. Capacity to apply these skills and technologies would have to be increased to obtain the full benefit of their potential;
- The ability to manage the effects of sea-level rise caused by melting of polar ice is still a challenge. It is causing considerable social and economic losses along continental coasts and is threatening property and life on entire islands. This is due to the loss of habitats and consequently of biodiversity on which humans depend for their well-being. The costs of economic losses and level of human suffering are not fully quantified, and augmenting this knowledge is necessary to perform threat assessments of these factors;
 - Further challenges stem from the inadequate understanding of the polar ecosystems; these are under increasing pressure caused by anthropogenic activities in the form of commercial exploitation of polar natural resources, which include oil and gas. With little ecological understanding of these ecosystems and therefore inadequate mitigation measures, a concern is growing as to how to deal with the looming complex environmental degradation and the need to identify and implement mitigation measures. These possible threats can only be assessed and managed if our ecological understanding is improved through expanded research and monitoring.

4.2.6 *Kelp Forests and Seagrass Meadows*

With respect to kelp forests and seagrass meadows, the issues where gaps in knowledge and capacity-building are involved include:

- The rate of loss of species is very high due to encroachments on these ecosystems and their proximity to coasts and consequently to human activities. The gravity and extent of these losses vary regionally and have yet to be determined in most areas. However, the causes are commonly due to coastal urbanization and industrialization, and conversion of some areas to build recreation facilities and harbours which involve heavy dredging. However, these pressures are rarely well quantified at local scales. Effective conservation and sustainable use of these habitats will require better quantification at local and regional scales.
- The costs of restoring these habitats (in the rare event that restoration is even possible) are high and the requisite restoration technology and skills are yet to be readily available in most regions. Even when restoration efforts are made, it is difficult to attain the original conditions and biodiversity that were present before degradation. Where restoration is desired or necessary for return of ecosystem services, greater study of restoration technologies would be required.
- The multitude and variety of uses of seagrass and kelp habitats (examples: aquaculture, harvesting, recreational and commercial fishing, tourism, etc.) have created conflicts over best management practices within these ecosystems. If these conflicts are going to be managed and best practices applied, improved capacity in integrated management would be necessary to address these conflicts in their early stages.

4.2.7 Mangroves

With respect to mangroves, the issues where gaps in knowledge and capacity-building are involved include:

- Despite considerable regional and global awareness campaigns on the value of mangrove ecosystems, and therefore the need to sustain their integrity so that they can provide their ecosystem services sustainably for the benefit of human well-being and the environment, estimates of increased destruction and loss in mangrove coverage continue to be reported regionally and globally at different levels of exploitation, although the actual data underpinning these estimates are unclear. If these trends are to be reversed, it is essential to document quantitatively, using the best available technological advances in skills, the various types of losses characteristic of each region and the consequences for biodiversity loss or extinction at the relevant taxonomic levels, as well as the ecosystem services that will be lost regionally and globally. This will enable assessment and quantification of the real risks and development of means to mitigate them.
- The ecosystem services provided by salt marshes are largely unknown.
- At regional and global levels, it is still not clear how to distinguish the characteristic biodiversity index of mangrove species taxonomically in a given area because of the ambiguous definition of a mangrove tree or vegetation. With existing technological advances, species identification should be based not only on morphological descriptions but also on their molecular attributes to avoid ambiguous descriptive terms like mangrove associates or hybrids. Use of these technologies in conservation and management will require building capacity for their application.
- Mangrove restoration is still at its early stages of development. It either uses seeds planted directly in the soil of mangrove habitat or seeds that are first nurtured and grown in a nursery before being planted in the mangrove habitats along the shores. These seeds are not improved in any way. If mangrove restoration is to accelerate it would be necessary to promote faster growing mangrove trees, including those improved through the use of biotechnology application and to ensure that the physical and chemical properties of the soils are optimal for their growth and that mangrove pests are eliminated or kept away from the plantations. These activities should involve local communities to enhance their education about and awareness of this ecosystem.
- Conservation and sustainable use of mangroves would benefit from promotion of ecotourism in natural and restored mangrove forests, managed by local communities for income generation; this is expected to instil in them the importance of these ecosystems in supporting their livelihoods without destroying them for unsustainable exploitation.
- To enhance carbon sequestration and at the same time increase their economic income as well as supporting mangrove conservation and enhancing mangrove

ecosystem services would require increased carbon credits to local communities that become involved in growing mangrove forests.

- Protection of mangroves will require improved understanding of why naturally occurring bare, salty, and sandy flats occur in mangrove ecosystems, which would also inform the creation of buffer zones in landward areas that will allow mangroves to migrate landward in response to sea-level rise. This is an established practice for integrated coastal zone management.
- Promotion of ecotourism in natural and restored mangrove forests, as well as management by local communities for income generation, will instil in them the importance of these ecosystems for supporting their livelihoods, without destroying the system through unsustainable exploitation.
- Capacity-building needs should be recognized if there is a desire to address acquisition of technological skills to enhance restoration, growth and management of mangrove forests, infrastructure to support development and use of biotechnology techniques to promote faster growing mangroves and to improve soils.

4.2.8 *Salt Marshes*

With respect to salt marshes, issues where gaps in knowledge and capacity-building are involved include:

- Salt marshes, in both tropical and temperate zones, are one of the fastest disappearing ecosystems worldwide. This is mostly due to anthropogenic activities, yet little is known about them in terms of their ecology and socio-economic contribution to human well-being.
- In the tropics and sub-tropics, the nature of the ecological interaction of salt marshes and mangrove ecosystems where they share a location is largely unknown; one result is the classification of salt marsh vegetation as associate mangrove species. In other words, the ecological role of salt marshes is masked by, or confused with, mangrove vegetation and therefore constitutes a large knowledge gap for both ecosystems.
- The ecological significance of the role of migratory fauna between salt marsh and mangrove vegetation is poorly known.

4.2.9 *Sargasso Sea*

With respect to the Sargasso Sea, the issues where gaps in knowledge and capacity-building are involved include:

- If the following issues are to be addressed, it is necessary to build techniques, personnel and infrastructure to address them: The Sargasso Sea is a complex habitat characterized by an interdependent mix of its physical oceanography, its ecosystems and its role in the global scale of ocean and earth processes. It is not fully known how these processes operate to produce this unique habitat.
- The Sargasso Sea ecosystem links to ecosystems in Europe, Africa, the Americas and the Caribbean. This provides a unique ecosystem for study to understand

how the divergent and convergent ecological functions of these widely spread, but interlinked, geographic ecosystem regimes operate. Targeted research could produce new knowledge of impacts caused by climate change.

4.2.10 Seamounts and other submarine geological features

With respect to submarine geological features, the issues where gaps in knowledge and capacity-building are involved include:

- Seamounts are predominantly submerged volcanoes, generally now extinct, that can rise to a few thousand metres above the surrounding seafloor. The most significant human activities around seamounts so far are fishing and, potentially, mining. To increase the knowledge available to manage activities around these features, it would be necessary to build techniques, personnel and infrastructure to address the following issues: Only about 6.5 per cent of the sea floor is mapped, so the global number of seamounts can only be estimated.
- Globally, overall species richness in seamount ecosystems is poorly known and therefore improving our knowledge of species composition would require undertaking comprehensive studies of the ecology of seamounts, ridges and other sensitive submarine benthic habitats. Appropriate conservation of these ecosystems requires scientific research.
- The interaction of the geological features with the overlying water column is poorly known.
- Impacts of acidification and de-oxygenation on these ecosystems are also unknown, and are not monitored sufficiently to detect impacts: many seamounts already experience low oxygen and low calcium carbonate saturation levels.
- Trawl gear disturbs and destroys benthic fauna and in some seamounts little recolonization is observed, even years after the closure of fishing. The destructive effects of trawl gear on benthic communities are generally incompletely known, but it is possible that these have reduced the ecological resilience and consequently also reduced reproductive potential, and contributed to the loss of genetic diversity and ecological connectivity.
- Capacity for stock assessment and sustainable management, including investment in shared infrastructure (for example, fisheries research vessels), is insufficient and capacity building would improve the possibility that such fisheries could be sustainably managed.
- Mining of seamounts would benefit from multisectoral management, especially for balancing mining and fishery interests. A first step in this direction could be to build the capacities of those involved to participate in the international work on this subject.
- Managing the effects of multiple stressors on seamounts would benefit from expanding both monitoring and research and may require building capacity to address this need. This would include capacity building for personnel and infrastructure, including multidisciplinary research teams, research vessels and laboratories.

Chapter 54. Overall Assessment of Human Impact on the Oceans

Group of Experts: Patricio Bernal, Beatrice Ferreira, Lorna Inniss, Enrique Marschoff, Jake Rice, Andy Rosenberg, Alan Simcock

1. Overview of impacts

No part of the ocean has today completely escaped the impact of human pressures, including the most remote areas. One clear example of this is the universal presence of stratospheric fall-out from atmospheric nuclear-weapons testing, but many other pressures on the marine environment are nearly as widespread.

Human pressures impact on the ocean in many and complex ways. They can take effect directly (as when an oil spill kills sea-birds and sessile benthic biota) or indirectly (as when climate change results in changes to the stratification of seawater, with an adverse effect on the nutrient cycle and the production of the plankton on which fish feed). Equally, the effects can be seen both on the natural environment (as when populations of sea turtles are reduced by tourist development on or near their breeding beaches) as well as on human society and economic activities (as when the collapse of a fish stock removes the economic base of coastal communities). Human pressures can also vary widely in their intensity and spread. Sometimes they have a concentrated impact: for example, the annual expansion of a large dead zone in the Gulf of Mexico, resulting from the high level of inputs of nitrogen compounds in the run-off from the Mississippi and other catchments. Sometimes the effects of human pressures have a very widely distributed effect: for example, the diffusion of persistent organic pollutants over the Arctic zone by airborne volatilization (for both examples, see Chapter 20 on land-based inputs) (Halpern, 2008).

1.1 *Summarizing the impacts*

An analysis of the overall impact of all the human pressures examined in this Assessment has to start by looking at the direct impacts and collateral effects of each pressure and to examine where those impacts and effects are found. However (as argued below), although this is an essential first step, it is not enough. In addition, any review of the effects of human pressures on the marine environment has to look both at the effects on the marine environment and at the consequences for human society and economies. A taxonomy of the main sources of human pressures on the marine environment that need to be considered must include the following (though these are not listed in any order of priority):

- (a) Climate change (and ocean acidification, including the resulting changes in salinity, sea-level, ocean heat content and sea-ice coverage, reduction in oxygen content, changes in ultra-violet radiation);

- (b) Human-induced mortality and physical disturbance of marine biota (such as capture fisheries, including by-catch), other forms of harvesting, accidental deaths such as through collisions and entanglement in discarded nets, disturbance of critical habitat, including breeding and nursery areas);
- (c) Inputs to the ocean (these can be broken down according to the nature of their effects: toxic substances and endocrine disruptors, waterborne pathogens, radioactive substances, plastics, explosives, excessive nutrient loads, hydrocarbons). Remobilization of past inputs also needs to be considered;
- (d) Demand for ocean space and alteration, or increase in use, of coasts and seabed (conflicting demands lead to both changes in human use of the ocean and changes to marine habitats);
- (e) Underwater noise (from shipping, sonar and seismic surveys);
- (f) Interference with migration from structures in the sea or other changes in routes along coasts or between parts of the sea and/or inland waters (for example, wind-farms, causeways, barrages, major canals, coast reinforcement, etc.);
- (g) Introduction of non-native species.

It is a matter of debate how any taxonomy should be structured. For example, all inputs might be classed together, since they are all the result of human activities affecting the ocean. However, there are important differences in the ways in which these pressures will affect the littoral, the water column and the benthos. In addition, the way in which these affect the environment and human societies and economies differs significantly. Hazardous substances may have toxic effects (either directly on animals which ingest them or through the food web on animals and humans that eat contaminated fish and seafood), may affect resilience to infections or may affect reproductive success. Waterborne pathogens may affect marine biota, but can be of particular concern when they are likely to affect humans who bathe in the sea or eat seafood. Excessive nutrients may lead to dead zones or cause blooms of algae that generate toxins. Explosives from past wars dumped into the sea may well not affect marine biota, but may kill or maim fishers who bring them up in trawls. Hydrocarbons may kill marine biota directly, but can also be broken down by bacteria and thus enter the food web. The worst effects of some emissions (such as exhaust fumes from ships) may not be the way that they enter the sea, but the way in which they contribute to damage to human health on land through air pollution. No taxonomy of these kinds of pressures, which are operating in very different fields, is likely to be beyond debate. Table 1 (at the end of this chapter) summarizes the varieties of human pressures on the marine environment, indicating the environmental and the social and economic effects. The categories of pressure aim to bring together the pressures resulting from various human activities that have similar effects, but keep separate some categories which have some effects of a very different nature, even though they may overlap with other categories in creating some effects.

1.2 *Environmental effects*

This chapter aims to summarize the overall impact of human activities on the ocean. The elements noted in Table 1 therefore relate very much to the impact of human activities on the marine environment. As the regional biodiversity assessments in chapter 36 of Part VI of this Assessment show, there are well-documented examples of cases where habitats, lower-trophic-level productivity, benthic communities, fish communities, or seabirds or marine mammal populations have been severely altered by pressures from a specific activity (such as over-fishing, pollution, nutrient loading, physical disturbance, or non-native species). However, many biodiversity impacts, particularly at larger scales, are the result of cumulative and interactive effects of multiple pressures from multiple drivers. It has repeatedly proven difficult to disentangle the effects of the individual pressures. This impedes the ability to address the individual causes.

Even in the Arctic Ocean, where human settlements are relatively few and small, the potentially synergistic effects of multiple stressors come together. And this is against a background of pressures from a changing climate and increasing human maritime activity, primarily related to hydrocarbon and mineral development and to the opening of shipping routes. These changes bring risks of direct mortality, displacement from critical habitats, noise disturbance, and increased exposure to hunting, which are superimposed on high levels of contaminants, notably organochlorines and heavy metals, as a result of the presence of these substances in the Arctic food web.

Likewise, in the open ocean (remote from land-based inputs), shifts in bottom-up forcing (that is, primary productivity) and competitive, or top-down forcing (that is, by large predators) will produce complex and indirect effects on ecosystem services. Stress imposed by lower oxygen, lower pH (that is, higher acidity), or elevated temperature can reduce the resilience of individual species and ecosystems through stressing organism tolerances or shifting community interactions. Where this happens, it retards recovery from disturbance caused by human activities such as oil spills and trawling and (potentially in the future) seabed mining. Acidification-slowed growth of carbonate skeletons, delayed development under hypoxic conditions, and declining food availability illustrate how climate change could exacerbate anthropogenic impacts and compromise deep-sea ecosystem structure and function, and ultimately its benefits to human welfare.

These multiple pressures interact in ways that are poorly understood, but that can amplify the effects expected from each pressure separately. The North Atlantic is comparatively rich in scientific resources. It has many long-term ocean-monitoring programmes and a scientific organization (the International Council for the Exploration of the Sea) that have functioned for over a century to promote and coordinate scientific and technical cooperation among the countries around the North Atlantic. Even here, however, experts are commonly unable to disentangle consistently the causation of unsustainable uses of, and impacts on, marine biodiversity. This may seem initially discouraging. Nevertheless many well-documented examples exist of the benefits that can follow from actions to address

past unsustainable practices, even if other perturbations are also occurring in the same area.

Cumulative effects are documented for species groups of the top predators in the ocean, including marine mammals, seabirds, and marine reptiles. Many of these species tend to be highly mobile, and some species migrate across multiple ecosystems and even entire ocean basins, so they can be exposed in their annual cycle to many threats. Direct harvest occurs for some of these species, particularly some pinnipeds (seals and related species), seabirds and sharks, and bycatch in fisheries can cause significant mortality for many species. However, in addition to having to sustain the impacts from these direct deaths, all of these species suffer from varying levels of exposure to land-based pollution sources and increasing levels of noise in the ocean. Land-nesting seabirds, marine turtles and pinnipeds also face habitat disturbance, including invasive predators on isolated breeding islands, disturbance of beaches where eggs are laid, or direct human disturbance from tourism, including ecotourism.

Some global measures have been helpful in addressing specific sources of mortality, such as the global ban on high-seas drift-netting introduced by the United Nations General Assembly in 1994, which was a major step in limiting the bycatch of several marine mammal and seabird species that were especially vulnerable to entanglement. However, for seabirds alone, at least 10 different pressures have been identified that can affect a single population through its annual cycle, with efforts to mitigate one sometimes increasing vulnerability to other pressures. Because of the complexity of these issues, conservation and management must be approached with care and with alertness to the nature of the interactions among the many human interests, the needs of the animals and their role in marine ecosystems.

1.3 Social and economic effects

Many of the human activities that affect the ocean affect not only its environmental condition, but also various social and economic aspects related to the marine environment. Most human activities in and around the ocean are aimed at getting some form of social or economic benefit from the ocean, and Chapter 57 (Overall value of the ocean to humans) attempts to pull together these aspects. Some human activities, in effect, can undermine their own success: capture fisheries and tourism are a good example of this: over-fishing results in keeping harvested species at less than the maximum sustainable yield, while tourism that attracts too many tourists can downgrade the environment that originally attracted them. In addition, many types of human activity may have adverse impacts on the success of other human activities. For example, marine noise from ships may cause the marine mammals to re-locate and thus undermine a previously successful whale-watching activity (see Chapters 27 and 37). The trade-offs among classes of interacting activities need careful consideration – especially as governance arrangements may make it difficult for such trade-offs to be easily considered together. This can happen either because the voices of some of those affected are not easily heard (for example, small-scale fishers) or because the governance arrangements do not

address the same areas (for example, long-range aerial or riverine transport of pollutants may start in areas well away from any ocean). Some effects (such as ocean acidification) may only be capable of being addressed at a global scale, but the ecological effects may be much more localized, because of the uneven distribution of the environmental effects. Likewise, the social and economic impacts of such global pressures may be much more unequally distributed than the ecological effects, because of regional differences in uses of the ocean.

Many of the more serious cases of trade-offs of this kind affect food from the sea. As explained in Part IV, overfishing of certain fish stocks is a very clear example of the way in which an activity can undermine its own success in generating economic and social benefits in terms both of food from the sea and of employments and livelihoods. At the same time, excessive inputs of nutrients (among other things, from sewage discharges or agricultural run-off) can lead to dead zones or hypoxic zones, which can seriously affect the recruitment of fish stocks on which both large-scale and small-scale fisheries depend. To these adverse effects on fish stocks can be added further effects such as those from losses of breeding or nursery areas through land reclamation, the effects of hazardous substances on reproductive success and oil pollution from shipping. Since small-scale fisheries are in general less well studied than the larger, more commercial fisheries, the social and economic consequences of these multiple impacts are not easily quantified. Indeed, as noted above, even for larger, more commercial fisheries the overall way in which multiple pressures work together to produce adverse effects is not well understood. Nevertheless, it is clear that some problems are sufficiently well understood that remedial actions can have some success. For example, reductions in the occurrence of liver tumours in fish in Netherlands waters have been linked to decreases in the levels of organic pollutants (OSPAR 2010). On the other hand, improvements in aquaculture techniques have allowed substantially increased production with lower inputs of fishmeal (FAO, 2012).

The changes in marine biodiversity can have knock-on effects on other ecosystem services that humans obtain from the ocean. An illustration of this is the important link between the health of warm-water corals and tourism. Warm-water corals represent a major component of the attractiveness of many tourist resorts in the Caribbean, the Red Sea, the Indian Ocean, south-east Asia and the South Pacific. The competitive position of their resorts would be seriously undermined if the tourists could no longer enjoy the corals. The same applies to other resorts (even in cold-water areas) where one of the attractions is scuba diving to enjoy the marine ecosystems.

The disappearance (or, more commonly, the reduction in numbers) of iconic species can similarly adversely affect traditional practices. For example, native people on the north-east Pacific coast have seen their traditional whale-hunting halted, because of past over-harvesting by others of grey whales (see Chapter 8, Cultural ecosystem services from the ocean). This hunting was an integral part of their cultural heritage, and the affected tribes consider the cultural loss to be very serious. Pollution can have similar effects: for example, the Faeroese authorities are taking measures to control the traditional food obtained in the islands from pilot whales, because of the high levels of pollutants they contain (see Chapter 20, Land-Based

inputs to the ocean). Demand for ocean space and alteration of coasts and seabed will lead to destruction of underwater cultural heritage (see Chapter 26 on land/sea physical interaction; and Chapter 27 on tourism and recreation).

2. Information gaps and capacity building gaps

2.1 Information gaps

Taking an overall view of the state of the world's marine environment presents many challenges, because it requires a large number of different sets of data to be brought together. Techniques for doing this are in their infancy, and many difficult problems need to be resolved.

In the first place, as the chapters in Parts III, IV, V and VI of this Assessment demonstrate, there are many gaps in the basic information necessary to build a reliable, world-wide, comprehensive, quantified survey of the state of the ocean. This Assessment shows that a qualitative view can generally be achieved of most aspects of the oceans and that some aspects can, at least in places, be quantified. More quantified information is needed to achieve a robust quantified assessment. The various chapters of Parts III, IV, V and VI of this Assessment identify major information gaps. Most of these will need to be filled before detailed methods of quantification can be developed that will achieve general acceptance.

In pursuing the aim of a more quantified integrated assessment of the ocean, it will therefore be important to try to improve the detailed information available.

2.2 Capacity gaps

At the same time, there is a more general gap in techniques for bringing information on the different aspects of the ocean together to give an overall picture. Various attempts have been made to do this at various levels, both as to the area to be covered and as to the degree of integration sought.

2.3 Ocean Health Index

One of these is the Ocean Health Index (OHI) (OHI, 2014; OHI, 2013; OHI, 2014). This index is mentioned as an illustration of the challenges in preparing even a semi-quantitative, but comprehensive, assessment of the ocean. There is a wide range of expert views of the robustness of this index – and, indeed, of other such indices. At the same time, it should be noted that many of the most important messages drawn from the OHI do correspond to conclusions drawn in this Assessment. Those conclusions have been drawn by other assessments as well.

The OHI is an attempt to produce a comprehensive assessment of the ocean in numerical terms at the highest possible level. Originally covering only coastal waters, it now covers all aspects of the marine environment and all parts of the ocean (220 areas within national jurisdictions and 16 much larger areas beyond

national jurisdictions). Its aim is to convert all the information into numerical scores for the status of each of the goals and sub-goals (shown in Table 2). Some of these goals have clear gaps: for example, the “Clean Water” goal does not cover point source discharges. The exercise also derives figures for trends, pressures and resilience to allow forecasting of future status. Given the limitations of the data that are available, various statistical techniques have had to be applied to that data in order to achieve coherent, comprehensive outputs. A detailed study of the efforts involved in developing the Ocean Health Index quickly shows how difficult it is to gather full information.

Having derived numerical scores for the goals and sub-goals, the next step in the OHI process is then to aggregate the indices developed for each goal into a single index figure for the status of each area of sea covered by the exercise, and then into a single figure for the ocean as a whole. It is possible to allow for different weightings between the results for the different goals, based on expert judgement, in order to allow for different views on the balance between preservation and exploitation (OHI, 2013).

Table 2. Summary of the goals and sub-goals used for the Ocean Health Index

GOAL	SUB-GOAL	REFERENCE POINT TYPE AND BRIEF DESCRIPTION OF BASIS
Food Provision	Fisheries	Functional relationship (difference of total landed biomass from estimated maximum sustainable yield)
	Mariculture	Spatial comparison (sustainably harvested yield of mariculture normalised for the area of inshore waters)
Small-scale Fishing Opportunities		Functional relationship (level of demand for small-scale fisheries (estimated from poverty level and degree of regulation of such fisheries))
Natural Products		Temporal comparison (historical benchmark) (level of exports for the area of coral, ornamental fish, fish oil, seaweeds and marine plants, shells, and sponges compared with the highest level achieved, as a substitute for the maximum possible level)
Carbon Storage		Temporal comparison (historical benchmark) (Current area of mangroves, seagrass beds and salt-marshes compared with historical benchmark)
Coastal Protection		Temporal comparison (historical benchmark) (Current area of mangroves, coral reefs, seagrasses, salt marshes, and sea ice compared with historical benchmark and adjusted for the differing protective effects of each)

GOAL	SUB-GOAL	REFERENCE POINT TYPE AND BRIEF DESCRIPTION OF BASIS
Coastal Livelihoods & Economies	Livelihoods: jobs and wages	Temporal and spatial comparisons (moving target) (Number of jobs directly and indirectly supported by tourism, commercial fishing, marine mammal watching, aquarium fishing, wave and tidal energy, mariculture, transportation & shipping, ports and harbours, shipbuilding and boatbuilding, compared with average of last five years, and adjusted by the average wage in each sector)
	Economies	Temporal comparison (moving target) (contribution to Gross Domestic Product generated directly or indirectly by the sectors mentioned in the entry of the previous sub-goal, compared with historical benchmark)
Tourism & Recreation		Spatial comparison (Originally based on international tourist arrivals, but since 2013 based on employment in tourism, adjusted by for sustainability in line with the World Economic Forum's Travel and Tourism Competitiveness Index)
Sense of Place	Iconic Species	Known target (Percentage of species in the World-Wide Fund for Nature's lists of Priority Species and Flagship Species for the area that are classed by the International Union for the Conservation of Nature (IUCN) as threatened, weighted by the threat category)
	Lasting Special Places	Established target (The mean of (a) area of coastal marine protected areas as a percentage of an assumed target that 30% of the area within 3 nautical miles of the coast should be protected, and (b) the length of coastline within 1 kilometre of the shore that is protected as a proportion of an assumed target that 30% of such coast should be protected)
Clean Waters		Known target (Geometric mean of (a) number of people in the coastal area without access to enhanced sanitation, rescaled to the global maximum, (b) modelled index of land-based inorganic pollution from urban runoff from impervious surfaces, (c) modelled index of land-based organic pollution from pesticides and (d) modelled index of pollution from shipping and ports)
Biodiversity	Habitats	Temporal comparison (historical benchmark) (average of the assessed conditions of such of the range of mangroves, coral reefs, seagrass beds, salt marshes, sea-ice edge, and sub-tidal soft-bottom habitats as are present in the area; the assessments of conditions are drawn from a variety of wide-ranging assessments of these habitats)
	Species	Known target (Temporal comparison (historical benchmark) (IUCN Global Marine Species Assessment of the extinction risk status of 2,377 species for which distribution maps exist, calculated as the area- and threat-status-weighted average of the number of threatened species within each 0.5° grid cell)

Source: adapted from Halpern et al., 2012 and OHI, 2013.

The OHI depends crucially on the availability of satisfactory data across many fields, and on the expert judgements made about the weighting to be given to the different fields covered. Much of the necessary data is not available, and estimates of various

kinds have to be used instead. The scale of the expert judgements needed means that there is a substantial subjective component in any results.

2.4 Water-quality indexes

At a much less aggregated level, as described in Chapter 20 (Land-based inputs to the ocean), some regional seas organizations and some States have tried to produce a single index of water quality in the parts of the ocean with which they are concerned. Such efforts, too, require judgements on the relative importance of the effects of hazardous substances and of eutrophication problems, and therefore rely to a substantial degree on expert judgement.

2.5 Ecological quality objectives

An alternative approach accepts that there will inevitably be an element of expert judgement involved, and legitimate differences in views on the appropriate weights given to various types of impacts and benefits, and therefore develops measures along a number of axes. There is no attempt to convert these various measures into a single quantified measure. Rather, users are left to apply their varying expert judgements on how much importance to attach to each axis, and on how to interpret what the different measures show. One version of this approach, developed by the regional seas organization for the North-East Atlantic, has been to try to find a suitable set of ecological quality objectives (EcoQOs) for an ocean area (OSPAR, 2007). These EcoQOs are derived by considering successively:

- (a) What are the important ecosystem components that collectively reflect a high ecological quality?
- (b) What are the human impacts on this component and how can they be monitored?
- (c) What are the objectives to be achieved, taking into account existing policies?

These EcoQOs may be quite numerous, and no attempt has yet been made to specify what the relation among them should be: the aim is to develop a set of measures that can be used for diagnosing whether there are problems. So far, a pilot project has looked at 11 such EcoQOs for the North Sea (OSPAR, 2007).

2.6 European Union's Marine Strategy Framework Directive

A related approach is being developed for the implementation of the European Union's (EU) Marine Strategy Framework Directive (MSFD) (EU, 2008). As a starting point, this involves each EU coastal Member State assessing the state of its waters against a list of eleven descriptors, shown in Table 3. The European Commission has produced a set of criteria and indicators to assist in developing common approaches to making these assessments. An initial assessment should then be made whether assessments show that the waters of the Member States have "good environmental status". Environmental targets, associated indicators and a programme of measures

to maintain that state, or to achieve it by 2020, should then be established by 2015. A preliminary report by the European Commission suggests that much work remains to be done to deliver this programme, and agreement on the relative or absolute benchmarks for good environmental status on many of the descriptors has not been reached (EU, 2014).

Table 3. Descriptors of Good Environmental Quality for the European Union Marine Strategy Framework Directive

DESCRIPTOR	TITLE	DETAIL
1	Biodiversity	Biological diversity is maintained. The quality and occurrence of habitats and the distribution and abundance of species are in line with prevailing physiographic, geographic and climatic conditions.
2	Non-indigenous species	Non-indigenous species (NIS) introduced by human activities are at levels that do not adversely alter the ecosystems.
3	Fish and Shellfish stocks	Populations of all commercially exploited fish and shellfish are within safe biological limits, exhibiting a population age and size distribution that is indicative of a healthy stock.
4	Food webs	All elements of the marine food webs, to the extent that they are known, occur at normal abundance and diversity and levels capable of ensuring the long-term abundance of the species and the retention of their full reproductive capacity.
5	Eutrophication	Human-induced eutrophication is minimised, especially adverse effects thereof, such as losses in biodiversity, ecosystem degradation, harmful algae blooms and oxygen deficiency in bottom waters.
6	Benthos	Sea floor integrity is at a level that ensures that the structure and functions of the ecosystems are safeguarded and benthic ecosystems, in particular, are not adversely affected.
7	Hydrography	Permanent alteration of hydrographical conditions does not adversely affect marine ecosystems.
8	Contaminants	Concentrations of contaminants are at levels not giving rise to pollution effects.
9	Fish and seafood quality	Contaminants in fish and other seafood for human consumption do not exceed levels established by Community legislation or other relevant standards.
10	Marine litter	Properties and quantities of marine litter do not cause harm to the coastal and marine environment.
11	Energy introduction	Introduction of energy, including underwater noise, is at levels that do not adversely affect the marine environment.

Source: EU, 2008, Annex I

Unlike the Ocean Health Index, however, these EcoQO and MSFD approaches do not specifically integrate social and economic aspects, although the effects of sustainable uses are taken into account in setting their benchmarks for good environmental status.

2.7 Conclusion on capacity-building gaps

Some attempts have been made to develop ecosystem-based approaches to managing human activities that affect the ocean. Even here, however, much work remains to be done to develop systems for assessing the overall impacts of human activities on the ocean. There thus remains a general need to develop methods for integrated assessments of the marine environment that can deliver an assessment of the marine environment that is not only (1) integrated across environmental, social and economic aspects, (2) integrated across sectors of human activities, and (3) integrated across all the components of the marine environment, but also gives reliable, quantified information about all parts of the world. There is therefore a general need for capacities to develop and implement such assessment methods.

Table 1. Pressures and Impacts of Human Activities on Environmental and Socioeconomic Aspects of the Marine Environment

No	PRESSURES FROM HUMAN ACTIVITIES ¹	SEE	IMPACTS ON ENVIRONMENTAL ASPECTS OF THE MARINE ENVIRONMENT	IMPACTS ON SOCIOECONOMIC ASPECTS OF THE MARINE ENVIRONMENT	MGT ²
1	Acidification of the ocean (arising from increased CO ₂ emissions)	Ch 5 Ch 7 Ch 36 A-H Ch 42 Ch 43 Ch 46	Reduction of reproductive success, recruitment, growth and survival of some species, especially those with (calcareous) exoskeletons (shells etc). Reduced resilience of coral reefs to other stresses. Second-order loss of habitat for other species if coral reefs degrade.	Losses in livelihoods in some small-scale fisheries. Lower production of some commercial fisheries. Loss of competitiveness for tourism dependent on corals. Potential loss of coastal protection services where coral reefs are degraded. Potential costs of reducing CO ₂ emissions.	Not yet

¹ In alphabetical order, not in any order of importance.

² MGT = Management possibilities: "Yes": examples are known of successful management strategies to reduce this pressure generally; "Some": examples are known of successful management strategies to reduce some aspects of this pressure; "Not yet": no such examples are yet known. NOTE – this marking does not allow for measures that ADAPT to changes: for example, the way in which some aquaculture facilities are mitigating some impacts of acidification.

No	PRESSURES FROM HUMAN ACTIVITIES ¹	SEE	IMPACTS ON ENVIRONMENTAL ASPECTS OF THE MARINE ENVIRONMENT	IMPACTS ON SOCIOECONOMIC ASPECTS OF THE MARINE ENVIRONMENT	MGT ²
2	Changes in sea temperature	Ch 4 Ch 5 Ch 7 Ch 34 Ch 36 A-H Ch 42-50 Ch 43 Ch 15	Increased sea-surface temperature will probably increase stratification and thus affect nutrient cycling, with effects on productivity. Changes in species distribution and productivities, bottom up ecosystem productivity and community structure. Coral bleaching. Reduction of sea-ice cover in Arctic and Antarctic will impair species dependent on that habitat.	Adverse changes in weather patterns, including increased storms in higher latitudes. Fisheries and aquaculture potential may have to relocate or change preferred species. Changes in high latitude temperature regimes increase access for many industries with the potential for major impacts on Arctic communities.	Not yet
3	Changes in the salinity of seawater (arising from climate change)	Ch 4 Ch 6 Ch15 Ch 34 Ch 36 A-G	Changes to the thermohaline circulation of the ocean, in some places leading to increased up-welling of nutrients (see also Item 14). Increased likelihood of stratification of seawater, with consequent adverse effects on primary production that supports fish and seabirds.	Potential fundamental changes in availability of fishery resources with implications for food security and other important ecosystem services. Changes in currents may alter the way that ocean moves heat around the planet, with widespread consequences	Not yet
4	Creation of underwater noise (arising from shipping, offshore prospecting, offshore renewable energy installations and tourism and recreation)	Ch 17 Ch 21 Ch 22 Ch 23 Ch 27 Ch 36 Ch 37	Disturbance of fish, macro-invertebrates, and marine mammals. Mortality due to noise rare but disruption of behaviour may have consequences for life history activities including feeding, migration, recruitment and social behaviour.	Potential costs of reducing noise emissions, including potential closure of sensitive areas to certain activities seasonally or permanently, thus limiting economic activity.	Yes

No	PRESSURES FROM HUMAN ACTIVITIES ¹	SEE	IMPACTS ON ENVIRONMENTAL ASPECTS OF THE MARINE ENVIRONMENT	IMPACTS ON SOCIOECONOMIC ASPECTS OF THE MARINE ENVIRONMENT	MGT ²
5	Increased demands for marine space for potentially conflicting uses (arising from fisheries, aquaculture, shipping routes, submarine cables and pipelines, offshore hydrocarbon and mining operations, solid waste disposal, tourism)	Ch 11 Ch 12 Ch 14 Ch 18 Ch 19 Ch 21 Ch 22 Ch 23 Ch 24 Ch 26 Ch 27 Ch 48	Depending on the human activity, the ecological functions of natural habitats in the marine space allocated for human use may be altered, degraded, or destroyed (including by removing or smothering marine plants and benthos). Consequent reductions of habitat available for nature. Changes in habitat productivity can alter ecosystems. Disposal of disused offshore installations can create new habitats.	Conflicts among potential uses of a place may arise, causing problems in finding most suitable allocation of space among potential uses, and increases in costs to manage conflicts. Development pressures may favour higher impact uses such as ports or energy production, with negative implications for lower impact uses such as small-scale subsistence fishing, impacting food security. Secondary impacts on harvesting and tourism are possible, if the permitted uses decrease biological productivity or make the area unavailable.	Yes
6	Increased direct mortality of marine animal populations , including those not directly targeted (arising particularly from fisheries, including recreational fisheries)	Ch 11 Ch 15 Ch 17 Ch 27 Ch 36 Ch 37 Ch 38 Ch 39 Ch 40	Decline in populations if the mortality is unsustainable. Alterations in population structures towards ones composed of smaller and younger individuals, with broader impacts on productivity. Potential alterations to ecosystem balance through differential effects on species.	Unsustainable mortality rates imply declines of living marine resources, with implications of decreasing food security, reduced livelihoods in coastal areas, and reduction in recreational enjoyment. The costs of restoring over-exploited resources are generally very high compared to those of preventing overexploitation from occurring.	Yes
7	Increased disturbance of fauna and flora , arising from increased numbers of people in the coastal zone, and increased amounts of shipping	Ch 17 Ch 18 Ch 21 Ch 23 Ch 26 Ch 27 Chs 37 – 44	High levels of the presence of people affect animal behaviour, including breeding, rearing, feeding, and migration. May reduce the carrying capacity of the coastal zone for marine biota.	Need to manage access of people to ecologically significant places can impose costs on development, and limit scale of industries such as eco-tourism	Yes

No	PRESSURES FROM HUMAN ACTIVITIES ¹	SEE	IMPACTS ON ENVIRONMENTAL ASPECTS OF THE MARINE ENVIRONMENT	IMPACTS ON SOCIOECONOMIC ASPECTS OF THE MARINE ENVIRONMENT	MGT ²
8	Increased ultra-violet radiation (arising from reductions in ozone layer)	Ch 6	Possible adverse effects on primary production and on fish larvae. Effects on titanium dioxide nanoparticles, creating biocides affecting phytoplankton, and thus potentially the food web.	Potential effects on harvesting if fish stocks are affected.	Yes ³
9	Input of explosives and hazardous gases in containers (from dumping)	Ch 24	Additional source of hazardous substances and seabed smothering: see Items 12 and 17.	Harm to fishers who catch such dumped material in their nets, and to pipeline- and cable-laying in affected areas.	Yes
10	Input of hydrocarbons (from land-based sources, offshore installations, pipelines and shipping)	Ch 12 Ch 17 Ch 19 Ch 20 Ch 21 Ch 23 Ch 27 Ch 37 Ch 38 Ch 39	Killing of benthic biota, fish, marine mammals and reptiles and sea birds. Adverse effects on their later reproductive success.	Consequent damage to aquaculture and fisheries. Fouling of beaches and consequent adverse impact on tourism	Yes
11	Input of nutrients, both airborne and water-borne (arising from land-based activities, shipping, solid waste disposal).	Ch 6 Ch 12 Ch 17 Ch 20 Ch 24 Ch 25 Ch 27 Ch 36 A-H Ch 43 Ch 44 Ch 48	Coastal eutrophication, leading to dead zones, hypoxic zones and algal blooms (including toxic algal blooms). Shifts of ecosystem regimes. Consequent loss of benthic diversity and adverse effects on fish and shellfish stocks and on seabirds and marine mammals and reptiles. Algal smothering of coral reefs	Adverse effects on human health, especially through shell-fish poisoning and waterborne pathogens. Adverse effects on fisheries and shellfisheries from dead zones and hypoxic areas. Adverse effects on tourism from beaches covered in algae, and loss of competitiveness from reduced marine wildlife (especially where coral reefs are affected) Increased costs of treatment of inputs.	Some

³ There has been some success in reducing the ozone-depleting effects of certain chemicals, with consequent improvements in the UV-filtering effects of the ozone layer.

No	PRESSURES FROM HUMAN ACTIVITIES ¹	SEE	IMPACTS ON ENVIRONMENTAL ASPECTS OF THE MARINE ENVIRONMENT	IMPACTS ON SOCIOECONOMIC ASPECTS OF THE MARINE ENVIRONMENT	MGT ²
12	Input of plastics (from shipping, fishing, offshore installations, poor control of land-based waste disposal, dumping).	Ch 6 Ch 11 Ch 17 Ch 24 Ch 25 Ch 37 Ch 38 Ch 39	Potential effects from breakdown into nanoparticles on food web, through effects on plankton and on filter-feeding species, resulting in changes in productivity. Mortality from ingestion by, and physical entanglement of, fish, marine mammals, reptiles and seabirds. Loss of habitat contaminated with durable debris.	Potential effects on fish and shellfish stocks through changes in the food web. Loss of vulnerable species may impact tourism or cultural needs. Loss of amenity and fouling of beaches. Consequent adverse impacts on tourism. Costs for cleanup of plastics, lost fishing gear etc., are very high.	Yes
13	Input and transfer of waterborne pathogens (arising from land-based activities, open-pen aquaculture, shipping and offshore installations).	Ch12 Ch 17 Ch 20 Ch 25 Ch 37 Ch 43	Possible adverse effects on marine fish, bird, turtle and mammal populations due to introduction of diseases. Coral diseases leading to death and impacts in coralline communities.	Damage to human health from the spread of diseases and from contaminated food from the sea.	Yes
14	Input, or remobilization, of hazardous substances, by both airborne and waterborne routes (arising from land-based activities, dumping, offshore installations and shipping).	Ch 17 Ch 20 Ch 21 Ch 23 Ch 24 Ch 15	Reduction in reproductive success and in ability to resist disease of marine biota. In extreme cases, killing of marine biota. Bio-accumulation of toxins in organisms that are subsequently harvested.	Damage to human health from contaminated food from the sea. Adverse effects on fisheries and shellfisheries from effects on stocks.	Yes
15	Interference with aerial migration routes (from wind-farms)	Ch 22 Ch 38	Potential damage to seabird population from deaths and injuries from collisions with rotors of wind-farms during migration.	Benefits of increasing non-carbon-intense energy sources involve trade-off with risk of increases from a new source of direct mortality.	Yes
16	Introductions of non-native species or genetic strains (arising from aquaculture, shipping and recreational boats)	Ch 12 Ch 17 Ch 27 Ch 36 A-H Ch 43	Degrading genetic pools, Reduction in biodiversity. Destruction of existing wild stocks. Potential for disruptions of natural populations and biotic communities.	Interference with fisheries and shellfisheries. Interference with operation of plant. Aquaculture benefits greatly from the use of strains of fish adapted for culture, which are often different genetically from natural populations.	Yes ⁴

⁴ Transfers of foreign species in ships' ballast water can be managed. It is difficult to impose regimes to protect against transfer of species through attachments to the hull, especially on recreational boats.

No	PRESSURES FROM HUMAN ACTIVITIES ¹	SEE	IMPACTS ON ENVIRONMENTAL ASPECTS OF THE MARINE ENVIRONMENT	IMPACTS ON SOCIOECONOMIC ASPECTS OF THE MARINE ENVIRONMENT	MGT ²
17	Physical alteration of sea-bed habitats (arising from bottom-fishing, aquaculture, dredging for shipping, ports, submarine cables and pipelines, offshore hydrocarbon industries and mining, coastal defences, land reclamation, solid waste disposal and tourism and recreation).	Ch 11 Ch 12 Ch 18 Ch 19 Ch 21 Ch 22 Ch 23 Ch 24 Ch 27 Ch 36 A-H Chs 42-50	Direct mortality by physical impacts or smothering. Reduction in three-dimensional habitat structure can reduce biodiversity and productivity. Disturbance of sediments can reduce water quality and/or release contaminants, also impacting biotic communities and populations.	Costs of reducing impacts: some activities necessarily require habitat impacts as part of the business (mining, aggregate extraction); other activities result in habitat impacts as a collateral, but sometimes unavoidable, consequence (fishing with mobile bottom-contacting gears).	Some
18	Sea-based emission of air-polluting substances (nitrogen oxides etc) (arising from shipping, fishing vessels, offshore hydrocarbon and mining operations).	Ch 17 Ch 20 Ch 21 Ch 23	Additional source of nutrients, and thus of the problems related to them (see Item 14).	Damage to human health from coastal air pollution. Potential costs of controlling emissions.	Yes
19	Sea-level rise (arising from climate change).	Ch 4 Ch 7 Ch 26 Ch 36 Ch 43 Ch 47	Changes in coastal habitats. Contaminants from frequent coastal flooding are likely to add to toxics and nutrient pollution. Loss of coastal ecosystems such as sea grasses due to increase in turbulence.	Inundation of low-lying States. Inundation of low-lying cities and other areas resulting in loss of property and population displacement. Critical infrastructure built in low lying areas is highly vulnerable (airports, sea ports, highways and train routes). Potential costs of protecting the built environment.	Not yet (Env) Yes (S/E)

Chapter 55. Overall Value of the Oceans to Humans

Group of Experts: Patricio Bernal, Beatrice Ferreira, Lorna Inniss, Enrique Marschoff, Jake Rice, Andy Rosenberg, Alan Simcock (Lead Members)

1. Introduction

The ocean provides countless ecosystem services. The Millennium Ecosystem Assessment describes ecosystem services as “the benefits people obtain from ecosystems” (MEA, 2005). Some of the ecosystem services from the ocean are delivered without human intervention – though they can be affected or disrupted by such intervention. Examples of these are the regulating and supporting ecosystem services (as described in Chapter 3), such as distribution of heat around the planet, the functioning of the hydrological cycle and the absorption of carbon dioxide as part of the carbon cycle. Other ecosystem services are obtained as a result of human activity to acquire the benefits. Most of these are provisioning ecosystem services (as also described in Chapter 3). The obvious example of such acquired ecosystem services is the food provided by capture fisheries, where humans take from the ocean significant amounts of the protein required for human diets. As demonstrated in Part IV and Part V and in Chapter 54, if the human activities are not carefully managed to maintain ecosystem structure and function, the acquisition of such ecosystem services can result in damage to the marine environment and reduction or loss of ecosystem services. Important issues arise for the institutions of ocean governance at global, regional, national and local levels in balancing the benefits of acquiring these services against the disbenefits (referred to by some as detriments) caused by over-exploitation and in preventing or mitigating those disbenefits.

Very different aspects of the concept of value are brought into play by these different kinds of ecosystem services. For most of the ecosystem services obtained from the ocean by human effort, there are global or local markets for the products obtained. Market valuations are therefore possible, although in some cases questions arise whether such a market value captures all the facets of the value to humans. For example, the value of fish in the sea in maintaining biodiversity and ecosystem functions may be more than the market value of the fish if they were caught and sold for consumption. Or, on a lesser scale, the value of their activities to recreational sea anglers may well be more than the market value of the fish (if any) that they catch. For ecosystem services that do not involve human effort to benefit from them, there is no market, and it is a question of producing a valuation in other ways. It is also important to remember that any discussion of value has to take into account the question of who is benefiting (or suffering the disbenefits) – even where they are unaware of what they are benefiting (or suffering).

A further category of ecosystem services of importance to humans are the aesthetic, cultural, religious and spiritual ecosystem services (“cultural ecosystem services” for short). Some of these (such as cultural objects and marine plants and animals that

have cultural significance) are on much the same footing as the other material that humans take from the sea, and may well have market value (see Chapter 8). However, even marketed objects of cultural significance have an added dimension that may well not be captured by the market. This is particularly the case where the cultural value lies in communal self-identification through sharing in the activity that wins the cultural objects (such as communal whale-hunting in the North-East Pacific or the Faeroe Islands). Other cultural ecosystem services stand outside any market: for example, the cultural/religious values that are obtained by having access to the sea during rituals, through the existence of special, sacred places, the cultural values that lie in the enjoyment of the seascape or watching the beauty of seabirds, marine mammals or corals and the knowledge that comes from underwater cultural heritage.

2. Quantification

To mention value is almost inevitably to raise the issue of quantification: comparing values and assessing trade-offs require some idea of the relative sizes of what is being compared. There are many ways of measuring the benefit that humans derive from ecosystem services from the marine environment. “Consuming an ecosystem service” can cover all facets of deriving benefit from some aspect or aspects of the marine environment. It can, for example, include the way that, in some countries, houses enjoying a view of the sea can command higher prices than identical houses without such a view. It is not therefore easy to delimit the scope of what are the values that need to be taken into account. This is particularly the case with cultural values.

Looking only at economic valuations of the marine environment, one library among many contains nearly a thousand such valuations, with nearly twice as many valuation estimates (MESP 2014). And economic valuations are not the only forms of valuation that can be made: social and ecological metrics can be equally significant, without necessarily being reduced to a single economic balance-sheet. Among the metrics that can be important for many different groups of stakeholders are:

- (a) The net economic value (for example, the net economic benefits that those who enjoy an ecosystem service derive from it (consumer surplus), or the economic value that those who use some component of the marine environment derive from it (producer surplus). This kind of metric can be valuable when the economic services enter directly into commerce;
- (b) The gross and net revenues in monetary terms that are gained by those who enjoy an ecosystem service, or use some component of the marine environment. Such metrics focus on the cash flows related to the ecosystem service, and can sometimes be more readily derived as a measure of changes in the enjoyment of an ecosystem service. This kind of metric can be valuable in many contexts of ecosystem services,

including those where non-monetary valuation approaches are necessary;

- (c) Measures of the numbers of those employed in a human activity and the rewards (in kind or in cash) that they gain. This kind of metric can be valuable when considering livelihoods outside the monetary economy, as well as when labour is engaged for wages;
- (d) Numbers of people benefiting from specific forms of ecosystem service, such as coast protection, recreational use of beaches, eating food from the sea or enjoyment of watching wildlife. This kind of metric can be useful in considering the extent to which different groups benefit from the ecosystem service, since it will avoid building differences in economic circumstances between the groups into the valuation;
- (e) Direct measurements of the environmental situation (for example, area covered by mangroves, proportion of coral reefs that are in good condition, lengths of beaches with low levels of marine debris, proportion of dead seabirds contaminated with oil). This kind of metric can be useful when considering values where some of the areas are not (or only sparsely) inhabited, and the value lies in the areas' contributions to some other metric of overall global or regional value.

Considering only economic valuations, there are a wide range of techniques that can be used. Table 1 sets out some of the main approaches that can be used.

Table 1. Some economic valuation methods, typical applications, examples, and limitations

VALUATION METHOD	APPROACH	TYPICAL APPLICATIONS	EXAMPLES	LIMITATIONS Some of these may apply to more than one method
<i>Methods using issue-specific data</i>				
Market price	Observe market prices and volumes of trade to analyze the economic activity generated by use of an ecosystem good or service. (Includes economic impact analysis, which examines the impacts of spending related to the good or service, and can also include indirect impacts in related economic sectors, as well as financial analysis, where operating costs	Coastal goods and services that are traded on markets	Fisheries, tourism, mangrove timber	Market prices can be distorted (for example, by subsidies). Additional data is required to estimate net value added. Under conditions of unsustainable use the value in trade may be higher than the value the ecosystem can provide sustainably. Many ecosystem services are not traded in markets.

VALUATION METHOD	APPROACH	TYPICAL APPLICATIONS	EXAMPLES	LIMITATIONS Some of these may apply to more than one method
	are subtracted.)			
Replacement cost	Estimate cost of replacing ecosystem service with man-made service. Requires three conditions be met to be valid: (1) man-made equivalent provides the same level of ecosystem service; (2) man-made equivalent is the least-cost option of providing the service; (3) people would be willing to incur the cost rather than forgo the service.	Ecosystem services that have a man-made equivalent that provides similar benefits	Shoreline protection by reefs and mangroves; water filtration by forests and wetlands	Estimates might not reflect the true value of ecosystem goods and services. The method only seeks equivalence for the subset of services being costed. The co-benefits of other services provided by the ocean feature of concern are not considered. For example, a seawall might effectively protect the shore, but does not provide fish habitat in the way a healthy coral reef does.
Cost of avoided damage	Estimate damage avoided (e.g., from hurricanes or floods) due to ecosystem service	Ecosystem services that provide protection to houses, infrastructure or other assets	Shoreline protection by reefs and mangroves	Difficult to relate damage levels to ecosystem quality.
Production function	Estimate value of ecosystem service as input in production of marketed good	Ecosystem services that provide an input in the production of a marketed good	Commercial fisheries	Technically difficult to determine and model the relationship between ecosystem change and its impact on the provision of the ecosystem service. High data requirements.
Hedonic pricing	Estimate influence of environmental characteristics on	Environmental characteristics that vary across	Tourism, shoreline protection	It is possible to value individual units, but much more difficult to

VALUATION METHOD	APPROACH	TYPICAL APPLICATIONS	EXAMPLES	LIMITATIONS Some of these may apply to more than one method
	price of marketed goods	goods (for example, houses or hotels with a sea view compared with those that do not)		generalize from this to broader coverage.
Travel cost	Travel costs people are prepared to incur to access a resource indicate a minimum value	Recreation sites (for example, some marine protected areas)	Tourism	Technically difficult. High data requirements.
Contingent valuation	Ask survey respondents directly for willingness to pay for ecosystem service	Any ecosystem service (most widely used for non-market ecosystem and services)	Tourism	Expensive to implement because of survey costs. Vulnerable to many sources of bias and requires careful survey design.
Choice modelling	Ask survey respondents to trade off ecosystem services to elicit their willingness to pay	Any ecosystem service (most widely used for non-market ecosystem and services)	Tourism	Expensive to implement because of survey costs. Vulnerable to many sources of bias and requires careful survey design.
<i>Methods using data not specific to the particular issue</i>				
Benefits transfer	Value transfer: Use values estimated at other locations ("study sites") Function transfer: Use a value function estimated at another location to predict values	Any ecosystem service	Any ecosystem service	Relies on judgements of what other locations are sufficiently similar. Possible transfer errors if the "study sites" and "policy site" are different.
Meta-analysis	Synthesize results from multiple existing valuation studies, using mathematical methods to estimate a value function. Meta-analysis can be used for benefits transfer.	Any ecosystem service	Any ecosystem service	Requires compilation of multiple studies and power depends on sample size of value estimates. Adequacy of studies may vary. Can lead to a loss of important valuation information during data aggregation process

Source: adapted from Waite et al, 2014.

Although such economic valuation methods have been used to varying degrees, and several of them widely and with considerable success, in many cases the results do not achieve general acceptance as a significant factor to be taken into account. The reasons for lack of acceptance can include that:

- (a) Decision-makers do not consider that the decision should turn on purely economic factors. They may wish to apply some overriding principle, such as national security or some other long-term goal, which they regard as incommensurable with economic factors;
- (b) The techniques may not manage to give an economic value to some policy or other concerns of the decision-makers or of the society involved that is sufficient to carry conviction that a valid value has been calculated;
- (c) The margins of error in the techniques are such that the meaning of the results is unclear to users;
- (d) The potential users distrust the reliability of the method of valuation. This can sometimes be because the method has not been adequately explained;
- (e) The decision-makers may not have an adequate understanding of the techniques or access to the necessary skills.

Furthermore, most of these techniques require detailed data, which in many cases does not exist for them to be applied. However, where they have been applied at local, national and sometimes regional level, the results are interesting, and can be used for a number of purposes.

3. Value of non-marketed ecosystem services

Looking at the ecosystem services that are delivered without human intervention, there are major problems in trying to place a value on them, especially in monetary terms. Some of these ecosystem services (such as the transfer of heat from the equatorial regions towards the poles) are such fundamental and inherent features of the way in which the whole planet operates that it is not possible to imagine the planet without this type of ecosystem service. It is not possible to conceive of the earth with its present populations of plants and animals (including humans) without the ocean. Without the ocean and therefore without the ecosystem services that it provides, the planet would be totally different. We cannot therefore consider scenarios with and without one of these non-marketed ecosystem services, and use the difference between the two scenarios to isolate an absolute value (whether in monetary terms or in some other form) of the benefits conferred by that ecosystem service.

Nevertheless, changes in the way in which the planetary ecosystem services operate can be measured, since it is possible to compare two different situations. The

consequences of those changes can be seen to be massive. A good example of this is the El Niño Southern Oscillation (ENSO). This name refers to the way in which the ocean system of the tropical and subtropical Pacific can, in some years, produce a significant warming of the sea off the western coast of North and South America, often greatest off Peru, in the middle of the southern hemisphere summer. The coastal water temperature difference between one year and another, measured on the same day at the same hour, can be as much as 10° Celsius (Glantz, 2001). This produces major changes in weather across not only South and North America (with major increases in rainfall or other changes in Brazil, Peru, and the United States of America, for example), but also in Australia, India, Indonesia, the Philippines, and parts of Africa (see Chapter 5). There are only limited economic studies of the global effects of the variations brought about by the ENSO. Nevertheless, one study concluded that, over the period 1963-1997, the ENSO cycle can explain about 10-20 per cent of the variation in the growth in gross domestic product of the world's seven largest economies and about 20 per cent of real commodity-price movements (Brunner, 2002). A more recent modelling exercise, looking at the period 1979-2013, concluded that Australia, Chile, Indonesia, India, Japan, New Zealand and South Africa faced short-lived falls in economic activity following an El Niño shock, but that the United States may have benefitted from such events (Cashin et al., 2014). The conclusion on the situation in the United States is illuminated by an analysis of the severe El Niño event of 1998/1999. This analysis estimated that, compared with an average year, the 1998/1999 El Niño event led to costs of 4,000 million United States dollars for the United States; however, there were offsetting savings of 19,000 million dollars (in lower expenditure on natural gas and heating oil, increased economic activity, lack of spring flood damages and savings in highway-based and airline transportation) (Changon, 1999). Elsewhere, of course, the costs outweighed the savings. Such estimates of the economic implications of changes in the behaviour of the ocean are, of course, capable of generating endless discussion, but they serve to give an idea of the orders of magnitude of the costs and benefits that such changes can cause. In Part III of this assessment, likely and potential changes in the delivery of non-marketed ecosystem services from the ocean are noted. Such changes would be accompanied by massive economic consequences, but the data to develop sound economic valuations have not yet been assembled.

The distribution of those economic consequences around the globe is likely to follow the distribution of the changes, but it is clear that some of that distribution will have very different effects in different situations. Some States are at risk of finding much, if not all, of their territory lost to the sea as a result of sea-level rise. Elsewhere, some island and coastal communities risk suffering a similar fate, but impacts would be more local – although with consequences (such as population movements) possible far beyond the coastal sites potentially inundated. Where it is possible to safeguard against such losses by improved sea defences, the cost implications can be regarded as the cost of such improvements. Where the whole territory is lost, different considerations of value come into play. Where sites of cultural significance are lost, another dimension is added to the problem. In addition, of course, the capacities to address the costs are not distributed equally around the world.

It has not proved possible to come to conclusions on one important aspect of assessing the marine environment: a quantitative picture of the levels of many of the non-marketed ecosystem services provided by the ocean. There is simply insufficient quantitative information to allow an assessment of the way in which different regions of the globe benefit from these. Nor do current data-collection programmes appear to make robust regional assessments of ocean ecosystem services likely in the near future, especially for the less developed parts of the planet. Calculations can be made on the basis of sweeping assumptions, which allow estimates to be produced, but the assessment would then be an assessment of the assumptions, and not of the situation that is actually present. This is not to say that some valuations cannot be made at a local level where adequate data is available. Such local valuations can be valuable in assessing the marginal trade-offs between options for action in relation to the management of human activities.

4. Value of cultural ecosystem services

If it is difficult to approach the physical value of non-marketed ecosystem services, it is even more difficult to do so in respect of the cultural aspects of ecosystem services. We may be able to rank some cultural ecosystem services in terms of their importance for the cultures that they support. For isolated aspects such as a particular view of a seascape, it may even be possible to produce a monetary valuation, using one of the methods described in Table 5.1. But the more an aspect of an ecosystem services is embedded in a culture, and the more fundamental that aspect is to the culture, the less that kind of approach can work. Putting an explicit value of any kind on a whole cultural system is impossible, since it would involve value judgements for which there is no recognized system. However, the world may sometimes make implicit valuations of such cultural ecosystem services when it allows a cultural ecosystem service to be downgraded or lost as a result of pursuing some other objective.

5. Value of market-related ecosystem services

The discussions in Parts III, IV and V of the various ecosystem services from the marine environment that are linked to markets contain estimates of the values that can be linked to them. It is not, however, sensible to try to compile such estimates to give an overall picture. There are several reasons for this conclusion.

First, there are the problems of the quality of the estimates. If one takes the example of capture fisheries, it appears from Part IV that there is probably under-reporting, including of the scale of activities of small-scale fisheries. Such under-reporting is bound to distort any attempt to bring together estimates of the value of the different fisheries. Moreover, the “value” of fisheries must be viewed through multiple lenses. Estimates suggest that small-scale fisheries contribute about half of global fish catches, and large-scale fisheries the other half. When considering

market-price, production-function or even hedonic-pricing valuations, the revenues generated through commerce would indicate large scale fisheries have much higher “value”. However, when considering the provision of livelihoods, nutrition and food security to low income, food-deficit parts of the world, then the value of catches contributed by small-scale fishers increases greatly, on account of the importance of affordable fish and employment to populations in developing countries. Any single method of valuation would fail to communicate crucial information about each type of fishery. Even if a view is taken through a single lens – using a single one of these valuation methods – the uncertainty about the statistics in this field mean that overall estimates of the economic value of fisheries, and of the number of people working in them, are not sufficiently well-founded to compare with the figures for, say, seafarers, where much more comprehensive reporting is available.

Second, there are problems of definition. A good example of this is the tourism industries. Estimates exist of the number of people employed in tourism and of the contributions of tourism to Gross Domestic Product, both directly and indirectly (see Chapter 27). At present, however, there is considerable doubt about how consistently definitions are applied to the tourist industries in deriving the data on which those estimates are based (for example, how far back up supply chains the effects are estimated). There is further difficulty in deciding what parts of the values that can be attributed to “tourism” are related to the ocean and coasts directly. Most reports of tourism revenues do not differentiate revenues from tourism directly related to maritime areas from inland tourism. Even where tourism in the coastal zone can be separated from that inland, it may be generated by the direct attractions of the sea and coast (with tourists engaging in ocean-based activities), it may be indirectly linked, (with tourists visiting coastal cities or sites for cultural or historical features that are present because of the links between the places to the sea), or it may not be linked to the sea at all (for example, if a casino simply happens to be at the seaside). Consequently, the value of ocean-related tourism is a matter of inference. Therefore, there are major issues on how far it is appropriate to analyse or aggregate information within this field, or indeed other fields, and how to bring that information together with information from other fields.

Third, there are problems of the availability of data. Tourism is again an example here. For example, the involvement of international companies in the trade gives rise to uncertainty about the levels of value generated in particular areas (see Chapter 27). Shipping is another field where the lack of information is significant. International shipping is the foundation of most global trade. Without it, much economic activity would cease. Some information can be gathered on the earnings of those employed in the industry, and revenues earned in some parts of the world. However, information is not readily available on the overall earnings of the industry, and therefore its share in the world economy (see Chapter 17), nor on the distribution around the globe of direct revenues, profits, and increases in value of trade goods because ocean-based trade is available.

Nevertheless, some States are making efforts to put values on the benefits created from the ocean areas under their jurisdiction. For example, the United Kingdom published in 2010 a first attempt to put monetary values on a range of activities taking place in its waters. The activities covered were offshore oil and gas, maritime

transport, telecommunications cables, leisure and recreation, military defence, fisheries, aquaculture, water abstraction, mineral extraction, renewable energy, coastal defence, waste disposal, education, power transmission and storage of gases. For most of these, an estimate was made of the gross value added, but for some it was only possible to estimate the money being invested in the process. The detailed workings of this exercise show the amount of effort needed to achieve even approximate values (DEFRA, 2010).

6. Global distribution

Some observations can, nevertheless, be made about the way in which the values of some of the market-related ecosystem services provided by the ocean are distributed around the world.

6.1 Fish and seafood consumption

Annual per capita consumption of fishery products has grown steadily in developing regions (from 5.2 kg in 1961 to 17.0 kg in 2009) and in low-income food-deficit countries (from 4.9 kg in 1961 to 10.1 kg in 2009) (see Chapters 10 and 11). This total consumption is still considerably lower than in more developed regions, although the gap is narrowing. A sizeable share of fish consumed in developed countries consists of imports, and, owing to a steady demand and declining domestic fishery production (down 10 percent in the period 2000–2010) (see Chapters 10 and 11), their dependence on imports, in particular from developing countries, is projected to grow. Studies have shown that the selling or trading of even a portion of their catch represents as much as a third of the total income of subsistence fishers in some low income countries. Thus an increase in imports of fish by more developed countries from less developed countries has the potential simultaneously to increase wealth in low income communities and to increase inequities in food security and nutrition, unless these considerations are taken into account in global trade arrangements (see Part IV).

Over time, there has been a striking shift in the operation and location of capture fisheries. In the 1950s, capture fisheries were largely undertaken by developed fishing States, and their activities were largely in fishing grounds in the North Atlantic and North Pacific. Since then, developing countries have increased their share, and the distant water fleets of developed countries range further in the sea. It is illuminating to compare the Northern and Southern Hemispheres. Although the two hemispheres do not precisely reflect developed as compared with developing fishing States, the figures are, nonetheless, indicative. In the 1950s, the Southern Hemisphere accounted for no more than 8 per cent of the landed market value of fish. By the 2000s, the Southern Hemisphere's share had risen to 20 per cent (see Part IV).

6.2 *Maritime transport*

All sectors of maritime transport (cargo trades, passenger and vehicle ferries and cruise ships) are growing in line with the world economy. According to estimates by the United Nations Conference on Trade and Development (UNCTAD), owners from five countries (Greece, Japan, China, Germany and the Republic of Korea) together accounted for 53 per cent of the world tonnage in 2013. Among the top 35 ship-owning countries and territories, 17 are in Asia, 14 in Europe, and 4 in the Americas. It seems likely that profits and losses are broadly proportional to ownership (see Chapter 17).

6.3 *Offshore energy businesses*

Offshore oil production is predominantly in the Gulf of Mexico (about 60 per cent of the industry is located in the Gulf of Mexico) and the North Sea. The industry accounts for about 1.5 per cent of the United States GDP, 3.5 per cent of the United Kingdom's GDP, 21 per cent of Norway's GDP and 35 per cent of Nigeria's GDP. The large majority of offshore hydrocarbon production is in the hands of international corporations or national companies (often working in partnership with the international companies). This makes the tracking of the distribution of benefits from this sector, other than direct employment in extraction and processing, very difficult (see Chapter 21). Offshore renewable energy production is very much in its infancy, and it will be some time before a clear picture of what will be the long-term future of the industry emerges (see Chapter 22).

6.4 *Developments in offshore mining*

There is limited information about the value of the offshore mining industry or the number of people employed, but it is unlikely to be significant in comparison to terrestrial mining. For example, in the United Kingdom, which is the world's largest producer of marine aggregates, the industry directly employs approximately 400 people. There seems little doubt that there will eventually be substantial expansion of offshore mining as terrestrial mineral deposits are worked out. In some cases (for example, diamond and tin mining), major international undertakings are involved. In the remaining cases, most offshore mining is within exclusive economic zones (and, indeed, generally close to the shore), and undertaken by relatively local enterprises. Mining in the Area (seabed, ocean floor and subsoil thereof) will be subject to a decision of the International Seabed Authority (see Chapter 23).

6.5 *Tourism*

Tourism has generally been increasing fairly steadily for the last 40 years (with occasional set-backs or slowing down in times of global recession). In 2012, estimates of international tourism expenditure exceeded 1 trillion dollars for the first time. Total expenditure on tourism – domestic as well as international – is several times that amount. Globally, the direct turnover of tourism was estimated to contribute 2.9 per cent of Gross Domestic Product (GDP) in 2013, rising to 8.9 per

cent when the multiplier effect on the rest of the economy is taken into account. The Middle East is the region where tourism plays the smallest part in the economy (6.4 per cent of GDP including the multiplier effect), and the Caribbean the region where it plays the largest part (13.9 per cent including the multiplier effect). In small island and coastal States, coastal tourism is inevitably predominant. Particularly noteworthy is the way in which international tourism is increasing in Asia and the Pacific, both in absolute terms and as a proportion of world tourism, with the implication that pressures from tourism are becoming of significantly more concern in those regions (see Chapter 27).

Tourism is also a significant component of employment. Globally, it is estimated that in 2013, tourism provided 3.3 per cent of employment, looking at the numbers directly employed in tourist industries, and 8.9 per cent when the multiplier effect is taken into account. In the different regions, the proportion of employment supported by tourism is approximately the same as the share of GDP contributed by tourism, although again the proportion of that which is based on the attractions of sea and coast is poorly known (see Chapter 27).

6.6 Use of marine genetic material

The commercial exploitation of marine genetic resources had very modest beginnings in the 20th century. The value of the use of marine genetic material is therefore only just beginning to develop and projections of its potential economic value differ greatly among plausible scenarios for its future development. All scenarios assume that increases in commercial exploitation will be driven primarily by more developed countries, making considerations relating to access and benefit sharing of marine genetic resources an important issue (see Chapter 29).

7. Knowledge and capacity-building gaps

As is apparent from what has been said in this chapter, there are major gaps in the knowledge available for considering the overall value of the ocean to humans. These gaps in knowledge have important implications for the governance of the ocean, because many issues turn on weighing advantages and disadvantages, and how they are distributed among the marine ecosystems and the maritime countries of the planet. Informed consideration of these issues is made the more difficult the less that is known about the values to be put upon those advantages and disadvantages.

So far there is still much debate on methods of valuing the provision of non-marketed ecosystem services. The work of the United Nations Statistics Division on valuing such ecosystem services for the purposes of national accounts may assist in informing the debate on these issues (see Chapter 9 for discussion of this programme). Other initiatives, such as the WAVES (Wealth Accounting and the Valuation of Ecosystem Services) partnership, aimed ensuring that natural resources are mainstreamed in development planning and national economic accounts, may also help in this task (WAVES, 2014).

As has been said, there are also many gaps in the basic information needed for valuation of market-related ecosystem services, in whatever manner this is eventually applied. These gaps are identified in the individual chapters dealing with the various human activities that result in the acquisition of these services, and the need for this information for comparative valuation purposes adds to the case for filling these gaps. Equally, there are gaps in our understanding of the biophysical models linking metrics of the basic features of ecosystems to the production of the goods and services to be valued. Resolving such gaps requires interdisciplinary collaboration.

There is likewise a need for capacity building in most developing countries in the use of valuation techniques and in the collection of the necessary data.

Glossary

Abyssal plain

An abyssal plain is an extensive, flat, gently sloping or nearly level region at abyssal depths. *See also* Trenches.

Area

Article 1, paragraph 1, of UNCLOS defines the Area as “the seabed and ocean floor and subsoil thereof, beyond the limits of national jurisdiction.” Article 136 of UNCLOS provides that “[t]he Area and its resources are the common heritage of mankind.”

Atolls

Atolls are coral islands consisting of a ring-shaped reef, nearly or entirely surrounding a central lagoon. They occur in the warm waters of the tropics and subtropics. These low-lying and vulnerable landforms owe their origin to reef-building corals. The origin of atolls was explained by Charles Darwin as the result of subsidence (sinking) of a volcanic island.

Baseline

The baseline is the line from which the outer limit of a State’s territorial sea is measured. The breadth of other maritime zones is also measured from the same line. The United Nations Convention on the Law of the Sea (UNCLOS) sets out several methods for determining the baselines, providing that coastal States may determine baselines by any of these methods (article 15):

- Normal baseline: “[e]xcept where otherwise provided in this Convention, the normal baseline for measuring the breadth of the territorial sea is the low-water line along the coast as marked on large-scale charts officially recognized by the coastal State” (article 5). “
- Straight baseline: “In localities where the coastline is deeply indented and cut into, or if there is a fringe of islands along the coast in its immediate vicinity, the method of straight baselines joining appropriate points may be employed in drawing the baseline from which the breadth of the territorial sea is measured” (article 7, paragraph 1). The remaining paragraphs of article 7 establish the criteria to draw straight baselines as follows: “2. Where because of the presence of a delta and other natural conditions the coastline is highly unstable, the appropriate points may be selected along the furthest seaward extent of the low-water line and, notwithstanding subsequent regression of the low-water line, the straight baselines shall remain effective until changed by the coastal State in accordance with this Convention. 3. The drawing of straight baselines must not depart to any appreciable extent from the general

direction of the coast, and the sea areas lying within the lines must be sufficiently closely linked to the land domain to be subject to the regime of internal waters. 4. Straight baselines shall not be drawn to and from low-tide elevations, unless lighthouses or similar installations which are permanently above sea level have been built on them or except in instances where the drawing of baselines to and from such elevations has received general international recognition. 5. Where the method of straight baselines is applicable under paragraph 1, account may be taken, in determining particular baselines, of economic interests peculiar to the region concerned, the reality and the importance of which are clearly evidenced by long usage. 6. The system of straight baselines may not be applied by a State in such a manner as to cut off the territorial sea of another State from the high seas or an exclusive economic zone.”

- Archipelagic baselines: “[a]n archipelagic State may draw straight archipelagic baselines joining the outermost points of the outermost islands and drying reefs of the archipelago provided that within such baselines are included the main islands and an area in which the ratio of the area of the water to the area of the land, including atolls, is between 1 to 1 and 9 to 1” (article 47). The remaining paragraphs of article 47 establish the criteria to draw archipelagic baselines as follows: “2. The length of such baselines shall not exceed 100 nautical miles, except that up to 3 per cent of the total number of baselines enclosing any archipelago may exceed that length, up to a maximum length of 125 nautical miles. 3. The drawing of such baselines shall not depart to any appreciable extent from the general configuration of the archipelago. 4. Such baselines shall not be drawn to and from low-tide elevations, unless lighthouses or similar installations which are permanently above sea level have been built on them or where a low-tide elevation is situated wholly or partly at a distance not exceeding the breadth of the territorial sea from the nearest island. 5. The system of such baselines shall not be applied by an archipelagic State in such a manner as to cut off from the high seas or the exclusive economic zone the territorial sea of another State. 6. If a part of the archipelagic waters of an archipelagic State lies between two parts of an immediately adjacent neighbouring State, existing rights and all other legitimate interests which the latter State has traditionally exercised in such waters and all rights stipulated by agreement between those States shall continue and be respected. 7. For the purpose of computing the ratio of water to land under paragraph 1, land areas may include waters lying within the fringing reefs of islands and atolls, including that part of a steep-sided oceanic plateau which is enclosed or nearly enclosed by a chain of limestone islands and drying reefs lying on the

perimeter of the plateau. 8. The baselines drawn in accordance with this article shall be shown on charts of a scale or scales adequate for ascertaining their position. Alternatively, lists of geographical coordinates of points, specifying the geodetic datum, may be substituted. 9. The archipelagic State shall give due publicity to such charts or lists of geographical coordinates and shall deposit a copy of each such chart or list with the Secretary-General of the United Nations.”

UNCLOS also establishes the methods to draw the baselines in the presence of reefs (article 6); mouths of rivers (article 9) and bays (article 10), provided that certain conditions are met. In addition, UNCLOS regulates the effect of the outermost permanent harbour works (article 11), roadsteads (article 12) and low-tide elevations (article 13) on baselines.

Beach

A beach is a type of shore and is an area on which the waves break and over which shore debris, such as sand, shingle and pebbles accumulate. A beach includes backshore and foreshore. The foreshore is often defined as the area covered and uncovered by the tides.

Bioerosion

Bioerosion is an important process in reefs, with bioeroders, such as algae, sponges, polychaete worms, crustaceans, sea urchins, and boring molluscs (e.g., *Lithophaga*), reducing the strength of the framework and producing sediment that infiltrates and accumulates in the porous reef limestone

Biological pump

The biological pump is the process of active biological uptake of CO₂ into the biomass and skeletons of plankters (the individuals that collectively form plankton).

Bruun Rule

The Bruun Rule is a simple heuristic that uses the slope of the foreshore and conservation of mass to predict the extent to which sea-level rise will cause erosion and net recession landwards for many beaches.

Canyon

Submarine canyons are defined as “steep-walled sinuous valleys with V-shaped cross sections and axes sloping outward as continuously as river-cut land canyons, with relief comparable to even the largest land canyons”.

Clausius-Clapeyron relationship

The Clausius-Clapeyron relationship is the water-holding capacity of the atmosphere, which increases by 7 per cent for every degree Celsius of warming.

Contiguous Zone

According to article 33 of UNCLOS, “[i]n a zone contiguous to its territorial sea, described as the contiguous zone, the coastal State may exercise the control necessary to: (a) prevent infringement of its customs, fiscal, immigration or sanitary laws and regulations within its territory or territorial sea; (b) punish infringement of the above laws and regulations committed within its territory or territorial sea.” In addition, according to the same provision “[t]he contiguous zone may not extend beyond 24 nautical miles from the baselines from which the breadth of the territorial sea is measured.”

Continental shelf

‘Continental shelf’ in this Assessment refers (unless stated otherwise) to the geomorphic continental shelf (as shown in Figure 1) and not to the continental shelf as defined in Article 76 of UNCLOS. The geomorphic continental shelf is usually defined in terms of the submarine extension of a continent or island as far as the point where there is a marked discontinuity in the slope and the continental slope begins its fall down to the continental rise or the abyssal plain. UNCLOS provides that “The continental shelf of a coastal State comprises the seabed and subsoil of the submarine areas that extend beyond its territorial sea throughout the natural prolongation of its land territory to the outer edge of the continental margin, or to a distance of 200 nautical miles from the baselines from which the breadth of the territorial sea is measured where the outer edge of the continental margin does not extend up to that distance.” This definition is refined in Article 76, paragraphs (4) to (7).

Continental rise

A submarine feature which is that part of the continental margin lying between the continental slope and the deep ocean floor; simply called the rise in the UNCLOS.

Continental slope

The continental slope is that part of the continental margin that lies between the continental shelf and the continental rise floor.

Deep sea

In this Assessment “deep sea” refers to the sea floor of deep-water areas that are beyond (that is, seawards of) the geomorphic continental shelf. It is the benthic zone that lies in deep water (generally >200 metres water depth).

Dead-weight tonnage

Dead weight tonnage is the measure of how much weight a ship can safely carry. It is the aggregate of the weights of cargo, fuel, fresh water, ballast water, provisions, passengers, and crew.

Downwelling and upwelling

Where surface ocean currents move seawater toward coasts, the water is forced to sink, in the process known as coastal downwelling. Coastal upwelling occurs where surface waters are moved away from the coast: that water is replaced by water that wells up from below. Upwelling and downwelling also occur in the open ocean where winds cause surface waters to move away from a region (leading to upwelling) or to converge toward a region (leading to downwelling).

Ecosystem

The Millennium Ecosystem Assessment defines an ecosystem as “a dynamic complex of plant, animal and micro-organism communities and their non-living environment interacting as a functional unit”

Ecosystem services

The Millennium Ecosystem Assessment (2005) classified ecosystem services as: provisioning services (e.g., food – including food traded in formal markets and subsistence trade and barter - pharmaceutical compounds, building material); regulating services (e.g., climate regulation, moderation of extreme events, waste treatment, erosion protection, maintaining populations of species); supporting services (e.g., nutrient cycling, primary production) and cultural services (e.g., spiritual experience, recreation, information for cognitive development, aesthetics).

El Niño/Southern Oscillation

The name “El Niño/Southern Oscillation” (ENSO) refers to the way in which the ocean system of the tropical and subtropical Pacific can, in some years, produce a significant warming of the sea off the western coast of North and South America, often greatest off Peru, in the middle of the southern hemisphere summer.

Enclosed and semi-enclosed seas

Article 122 of UNCLOS defines an enclosed or semi-enclosed sea as a “gulf, basin or sea surrounded by two or more States and connected to another sea or the ocean by a narrow outlet or consisting entirely or primarily of the territorial seas and exclusive economic zones of two or more coastal States.”

Estuary

An estuary is the tidal mouth of a river, where the seawater is measurably diluted by the fresh water from the river.

Euphotic zone

This is the layer below the ocean’s surface that receives enough light for photosynthesis to occur. This is usually taken to be where photosynthetically active radiation [PAR] is more than 1 per cent of the surface intensity.

Exclusive economic zone

UNCLOS provides that “The exclusive economic zone is an area beyond and adjacent to the territorial sea, subject to the specific legal regime established in this Part, under which the rights and jurisdiction of the coastal State and the rights and freedoms of other States are governed by the relevant provisions of this Convention”. UNCLOS further provides that “The exclusive economic zone shall not extend beyond 200 nautical miles from the baselines from which the breadth of the territorial sea is measured.”, and that “In the exclusive economic zone, the coastal State has: (a) sovereign rights for the purpose of exploring and exploiting, conserving and managing the natural resources, whether living or non-living, of the waters superjacent to the seabed and of the seabed and its subsoil, and with regard to other activities for the economic exploitation and exploration of the zone, such as the production of energy from the water, currents and winds; (b) jurisdiction as provided for in the relevant provisions of this Convention with regard to: (i) the establishment and use of artificial islands, installations and structures (ii) marine scientific research; (iii) the protection and preservation of the marine environment; (c) other rights and duties provided for in this Convention.”

Expendable Bathythermograph

An Expendable Bathythermograph (XBT) is a device that, using electronic solid-state transducers, registers and reports temperature and pressure while it free-falls through the water column. Mechanical Bathythermographs (MBTs) are their mechanical predecessors, that were lowered on a wire suspended from a ship, used a metallic thermocouple as transducer.

Fjord and ria areas

Fjord and ria areas are long narrow inlets into the land from the sea (in the case of fjords, between high cliffs), with depth usually diminishing landwards.

Freshwater flux

Freshwater fluxes into the ocean include: direct runoff from continental rivers and lakes; seepage from groundwater; runoff, submarine melting and iceberg calving from ice sheets; melting of sea ice; and direct precipitation, which is mostly rainfall but also includes snowfall.

Gross primary production (GPP)

Gross primary production is the rate at which photosynthetic plants and bacteria use sunlight to convert carbon dioxide (CO₂) and water to the high-energy organic carbon compounds used to fuel growth.

Gyres

Gyres are circular patterns of currents in ocean basins. In the centre of a gyre the seawater moves less than the seawater in the currents around it. There are five

major gyres: in the North and South Atlantic Ocean, in the North and South Pacific Ocean and in the Indian Ocean.

Harvest Control Rule

In the context of fisheries management, this rule has been defined as “An agreed rule (algorithm) that describes how harvest is intended to be controlled by management in relation to the state of some indicator of stock status. For example, a harvest control rule can describe the various values of fishing mortality which will be aimed to be achieved at corresponding values of the stock abundance”.

High Seas

Article 86 of UNCLOS defines the high seas as “all parts of the sea that are not included in the exclusive economic zone, in the territorial sea or in the internal waters of a State, or in the archipelagic waters of an archipelagic State.”

Hydrological cycle

The Earth’s hydrological cycle (or water cycle) is the process by which water evaporates from the Earth’s surface and is then precipitated as rain, hail or snow. It also includes the processes by which water moves from place to place across land and sea.

Indian Dipole

The Indian Ocean Dipole is an irregular oscillation of sea-surface temperatures: the western part of the equatorial Indian Ocean becomes alternately warmer and then colder than its eastern part. These changes affect the climate of the countries that surround the Indian Ocean.

Isobath

An isobath is an imaginary line representing the horizontal contour of the sea-bed at a given depth.

Large marine ecosystems

Large marine ecosystems (LMEs) are regions of the ocean encompassing coastal areas from river basins and estuaries out to the seaward boundaries of continental shelves and the outer margins of the major current systems. These areas are characterized by their distinct bathymetry, hydrography, productivity and food webs. The term often refers to the set of 64 LMEs identified by the United Nations Environment Programme’s Regional Seas Programme for analytical purposes.

Macronutrients and micronutrients

Macronutrients are elements needed in relatively large quantities for photosynthesis. They include calcium, carbon, nitrogen, magnesium, phosphorus, potassium, silicon and sulphur. Micronutrients are elements needed in lesser

quantities and provide the necessary co-factors for metabolism to be carried out. They include iron, copper and zinc.

Mangroves

Mangroves are one of several genera of tropical trees or shrubs which produce prop roots and grow along low-lying coasts into shallow water. The term is also used for the habitats in which mangrove genera grow.

Marine wetlands

Marine wetlands are areas of salt marsh, fen or shallow water, whether natural or artificial, permanent or temporary, with water that is static or flowing. The Convention on wetlands of international importance, especially as waterfowl habitat (Ramsar Convention)¹, includes areas of marine water the depth of which at low tide does not exceed six metres.

Meridional overturning circulation

The meridional overturning circulation is a system of surface and deep currents linking all ocean basins. It transports water (and, with it, heat) salt, nutrients and other substances around the globe, and connects the surface ocean and the atmosphere with the deep sea. *See also* Thermohaline circulation.

Micronutrients *see* macronutrients

Mid-ocean ridges

Mid-ocean ridges are geologically active chains of submarine mountains formed by plate tectonics. In some ocean basins (for example, the Pacific), they are located away from the centre. Most are linked into a 70,000-kilometre long chain encompassing the whole globe.

Natural capital

Natural capital is usually defined as the stocks of natural assets, including rocks, soil, air, water and all living things. Ecosystem services are derived from this natural capital. In the marine context, natural capital contrasts with human-made capital like ports and navigation systems.

Nautical mile

A nautical mile is defined as 1,852 metres (approximately 2,025 yards, or 1.15 miles).

Net primary production (NPP)

Net primary production is Gross Primary Production (GPP) less the respiratory release of CO₂ by photosynthetic organisms, i.e., the net photosynthetic fixation of inorganic carbon into autotrophic biomass.

¹ United Nations Treaty Series, volume 996-I, No.14583.

Ocean acidification:

When CO₂ reacts with water, it forms carbonic acid, which then dissociates and produces hydrogen ions. The extra hydrogen ions link with carbonate ions (CO₃²⁻) to form bicarbonate (HCO₃⁻). In this process, the pH and concentrations of carbonate ions (CO₃²⁻) decrease. As a result, the carbonate mineral saturation states also decrease. The water thus becomes more acid and less basic (alkaline). Due to the increasing acidity, this process in the ocean is commonly referred to as “ocean acidification”. (pH is a numeric scale used to specify the acidity or basicity of a water-based solution, calculated as the negative logarithm to base 10 of the activity of the hydrogen ions).

Ocean acidification hotspots

Although the average oceanic pH can vary on interglacial time scales, the changes are usually on the order of ~0.002 units per 100 years; however, the current observed rate of change is ~0.1 units per 100 years, or roughly 50 times faster. Regional factors, such as coastal upwelling, changes in riverine and glacial discharge rates, and sea-ice loss have created “Ocean acidification hotspots” where changes are occurring at even faster rates.

Ocean currents

Ocean currents are continuous, directional movements of seawater generated by forces such as wind, the Coriolis effect from the rotation of the Earth, differences in temperature and salinity of different parts of the ocean and the effects of mixing bodies of seawater with these different qualities. They are distinct from tides, which are caused by the gravitational effects of the moon and the sun. In the upper ocean, the effects of wind and Coriolis effect predominate. In deeper water, the main driver is the thermohaline circulation.

Oxygen minimum zones

Oxygen minimum zones are the places in the ocean where oxygen saturation in the water column is at its lowest. Such zones typically occur at midwater depths (200-1000 m).

Phenology

Phenology is the study of the timing and duration of cyclic and seasonal natural phenomena (e.g., spring phytoplankton blooms, seasonal cycles of zooplankton reproduction), especially in relation to climate and plant and animal life-cycles.

Precautionary Approach

Principle 15 of the 1992 Rio Declaration on Environment and Development² provides “In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation”. In the context of fisheries management, the Food and Agriculture Organization of the United Nations has defined it as “A set of agreed cost-effective measures and actions, including future courses of action, which ensures prudent foresight, reduces or avoids risk to the resource, the environment, and the people, to the extent possible, taking explicitly into account existing uncertainties and the potential consequences of being wrong”.

Reef

A reef is a solid structure either of rock, or created by accumulations of organisms (often corals) – a “biogenic reef”. Reefs rise from the seabed, or at least clearly form a substantial, discrete community or habitat which is very different from the surrounding seabed. The structure of a biogenic reef may be composed almost entirely of the reef-building organism and its tubes or shells, or it may to some degree be composed of sediments, stones and shells bound together by the organisms. Reefs which either reach close to the sea surface or are exposed at low tide are of particular importance as coastal structures.

Reference Points

In the context of fisheries management, “reference points” are defined as “Benchmarks against which the abundance of the stock, the fishing mortality rate or economic and social indicators can be measured in order to determine its status. These reference points can be used as limits or targets, depending on their intended usage.”

Runoff

Runoff is the sum of all upstream sources of water, including continental precipitation, fluxes from lakes and aquifers, seasonal snow melt, and melting of mountain glaciers and ice caps.

² A/CONF.151/26.

Salinity

Salinity refers to the level of dissolved salts in seawater. It varies significantly from place to place. On average, it is around 35 grams of salts per litre. In the Red Sea and the Persian Gulf, the most saline major sea areas, it reaches an average 40 grams of salts per litre, because of the high rate of evaporation and the low rate of freshwater inflow.

Salt marshes

Salt marshes are intertidal, coastal ecosystems that are regularly flooded with salt or brackish water and dominated by salt-tolerant grasses, herbs, and low shrubs. They occur in middle and high latitudes worldwide.

Seamounts

Seamounts are predominantly submerged volcanoes, mostly extinct, rising hundreds to thousands of metres above the surrounding seafloor.

Sedimentation

Sedimentation is the consolidation of loose sediments that have accumulated in water or in the atmosphere. The sediments may consist of rock fragments or particles of various sizes (conglomerate, sandstone, shale), the remains or products of animals or plants (certain limestones and coal), the product of chemical action or of evaporation (salt, gypsum, etc.) or a mixture of these materials.

Solubility pump

The solubility pump is the process of physical air-sea flux of atmospheric CO₂ at the ocean surface.

Southern Ocean

The Southern Ocean is defined as all the ocean area south of 60°S.

Steric

Steric refers to density changes in seawater due to changes in heat content and salinity.

Stratification

Ocean stratification occurs when water masses with different properties (such as oxygenation, salinity or temperature) form layers that limit mixing between the water masses.

Territorial sea

Article 2 of UNCLOS provides that “[t]he sovereignty of a coastal State extends, beyond its land territory and internal waters and, in the case of an archipelagic State, its archipelagic waters, to an adjacent belt of sea, described as the territorial sea.” Article 3 of UNCLOS provides that “[e]very State has the right to establish the breadth of its territorial sea up to a limit not exceeding 12 nautical miles, measured from baselines determined in accordance with [UNCLOS].

Thermohaline circulation

The thermohaline circulation is a process driven by differences in the density of water water due to temperature (“thermo”) and salinity (“haline”) in the various parts of the ocean. Currents driven by thermohaline circulation move much slower than surface currents.

Tidal flats

Tidal flats are marine wetlands that are in the zone between high and low tides.

Ton

In this Assessment, the metric ton of 1,000 kilograms is used.

Toxic Algal Blooms

Toxin-producing algae are a diverse group of phytoplankton species with two characteristics in common: (1) they produce toxins which harm people and ecosystems; and (2) their initiation, development and dissipation are governed by species-specific population dynamics and oceanographic conditions.

Trenches

Trenches are long, narrow, characteristically very deep and asymmetrical depressions of the seafloor, with relatively steep sides. *See also* abyssal plain.

Upper ocean

In this Assessment, the term “upper ocean” is used to describe both the epipelagic zone (between the surface and 200 metres depth) and the mesopelagic zone (between 200 and 1000 metres depth). The euphotic zone lies within the epipelagic zone (*see* “euphotic zone”).

Water column

The water column is the vertical continuum of water from sea surface to sea-bed.

Water cycle (*see* Hydrological cycle)
